Life-threatening bacterial and fungal infections and high level of morbidity with colitis, growth failure, and respiratory disease have led the effort to continue improving transplantation protocols in CGD. A recent UK study (Soncini et al., 2009) contained data from 20 patients; 16 received myeloablative conditioning (busulfan 16 mg/kg, cyclophosphamide 200 mg/kg) with alemtuzumab (CAMPATH-H1; anti-CD52 MoAb, 1 mg/kg) if a non-sibling donor was used. Those receiving unrelated donor transplants did just as well as those receiving matched sibling transplants. Survival was 90 percent, with two deaths due to preexisting disseminated fungal disease. Complications occurred in patients with preexisting infection or inflammation, as would be expected. For the survivors, growth improvement was good and major infections were absent beyond 3 months posttransplantation. Morbidity related to HSCT or graft-versus-host disease in some of the patients was considerable.

The reduced intensity conditioning (RIC) protocol used in Zürich (busulfan 8 mg/kg, fludarabine 180 mg/m^2, alemtuzumab [antiCD52 MoAb] 0.3 mg/kg) has also shown excellent outcome in 10 CGD patients transplanted with HLA-identical siblings, with tolerance of the procedure in all patients. There were a few days of bone marrow aplasia after day +10 but full engraftment in all patients. Again, 90 percent survived. Minor mismatches still matter, but alemtuzumab has been shown to result in very efficient prophylaxis against graft-versus-host diseases. Graft-versus-host disease more than grade 2 was absent even with matched unrelated donors. Secondary tumors are not an issue in primary immunodeficiency in general and have not been seen in the CGD setting, even with myeloablative regimens. Probably, this holds true for the lack of infertility as well (Güngör et al., 2005, 2009).

Knowing that supportive care and the efficacy of newer antifungal drugs will continue to improve outcome, it will remain difficult to advise whether a given CGD patient should undergo bone marrow transplantation in the absence of serious infections or inflammatory disease in the past. The current 10 percent mortality rates will remain an unacceptable obstacle to preemptive transplantation for many parents of young CGD patients. Prognostic indicators such as superoxide production (Kuhns et al., 2010) and disease-modifying genes possibly associated with outcome in CGD (see Phenotype–Genotype Correlation section) may be helpful in making the choice between conservative management and bone marrow transplantation.

FUTURE DIRECTIONS

The improvement in the prognosis for patients with CGD over the past 10 to 15 years has been remarkable. Patients diagnosed in infancy and treated with prophylactic antibiotics, antifungals, and rIFN-γ before a relentless cycle of serious infections begins have a fairly optimistic future. It is clear, however, that the prophylactic and therapeutic approaches currently employed are still imperfect, as even these very young, optimally treated children can develop disastrous infections and die. Moreover, all of the treatments developed to date (with the exception of bone marrow transplantation) are only supportive, not curative, and demand a lifetime of diligence and compliance. While further refinements in the medical and surgical management of CGD are likely in the years to come, the ultimate goal is the development of curative approaches for this immunodeficiency. Attention has appropriately been directed toward gene replacement therapy (see Chapter 61). The study of patients with variant forms of X-CGD has revealed that levels of oxidase activity as low as 3 to 5 percent in neutrophils may be associated with a mild clinical phenotype. In addition, insights derived from X-CGD carriers indicate that as few as 5 percent fully functioning neutrophils can provide substantial protection against infection. It is thus clear that full correction of 100 percent of the circulating neutrophils in CGD patients is not required to ameliorate disease. Even if corrected cells are only transiently generated, there is the potential for substantial benefits for CGD patients, as this therapeutic approach could be used to help treat stubborn, recalcitrant infections.

Partial correction of the oxidase defect has been achieved in vitro by transduction of CD34-positive peripheral blood or bone marrow progenitor cells from patients with any of the four major types of CGD, using retroviral vectors containing the correct cDNA for the missing NADPH oxidase component (Li et al., 1994; Porter et al., 1996; Sekhsaria et al., 1993; Weil et al., 1997). Substantial reconstitution of oxidase activity was also achieved in granulocyte/monocyte bone marrow progenitors from an X-CGD gp91^{phox} knockout mouse by means of a retroviral vector system (Ding et al., 1996). This approach has been extended to the treatment of gene knockout CGD mice lacking either gp91^{phox} or p47^{phox}, in which bone marrow progenitors were treated ex vivo and then transplanted into irradiated syngeneic CGD mice (Björgvinsdóttir et al., 1997; Mardiney et al., 1997). In both cases, the recipient mice showed increased resistance to bacterial and fungal infection. Levels and duration of expression of the transduced oxidase subunits have been sufficiently large to justify the initiation of early clinical trials for these two forms of CGD (Malech et al., 1997).

Unfortunately, to date the results have been disappointing. In five p47^{phox}-deficient CGD patients, the fraction of gene-corrected neutrophils in the circulation was never more than 0.05 percent, and corrected cells were no longer detectable after 6 months (Malech et al., 1997). Similar results were obtained in two X-CGD patients (Malech et al., 1999). Several problems became evident: the corrected bone marrow cells had no growth advantage over the uncorrected cells (so bone marrow conditioning was likely necessary), the expression of the transgene was very weak (so the transgene cDNA needed to be optimized), and the transgene could be silenced because of its unnatural

promoter (so vectors were needed with the original myeloid promoter sequence).

A more recent clinical trial was performed with a spleen focus-forming γ-retroviral vector (Ott et al., 2006). Two adult X-CGD patients were conditioned with a submyeloablative dose of liposomal busulfan before reinfusion of the transduced (40–45 percent transduction efficiency) granulocyte colony-stimulating factor (G-CSF)-mobilized $CD34^+$ cells. The patients clinically improved within 2 months: in one patient, a chronic liver abscess resolved, and the other achieved resolution of a fungal lung infection. In both patients a limited expansion in the number of gene-corrected cells from initially 10 to 30 percent to 40 to 60 percent was observed starting 5 months after transplantation. The expansion was the result of activating retroviral insertions into three proto-oncogenes, *MDS1/EVI1*, *PRDM16*, and *SETBP1*. Thereafter, silencing of the $gp91^{phox}$ transgene expression took place, leading to barely detectable O_2^- generation by the gene-corrected cells, and death of one patient from severe sepsis with multiple organ failure (Seger, 2008). Therefore, gene therapy for CGD patients is at present only an option to overcome very recalcitrant infections, before allogeneic bone marrow transplantation can be performed.

The risk of insertional mutagenesis and transactivation of proto-oncogenes from retrovirus-mediated gene therapy necessitates the development of vectors with improved safety. Self-inactivating (SIN) vectors lacking the potent retroviral enhancer elements within the long terminal repeats (LTR) show much less transactivation potential than conventional LTR-driven vectors (Modlich et al., 2006). Transgene ($gp91^{phox}$) expression in SIN vectors is driven by an internal, tissue (myelocyte)-specific, cellular promoter, further reducing the probability of oncogene activation at the stem-cell level. Optimization of the transgene cDNA has led to increased vector titers and transgene expression (Moreno-Carranza et al., 2009). Such vectors will soon be used in clinical trials with CGD patients. Lentiviral vectors could offer additional safety by integrating into transcriptional units, as opposed to γ-retroviral vectors integrating in proximity to promoter regions. Moreover, lentiviral vectors allow gene transfer into quiescent cells and do not require extensive preculture of CD34-positive cells with cytokines. Preclinical testing for lentiviral gene therapy trials in CGD is ongoing (Roesler et al., 2002; Santilli et al., 2011).

Two recent developments indicate important progress in this area. One is the epigenetic reprogramming of somatic cells from mammals into induced pluripotent stem cells (iPS cells) (Takahashi & Yamanaka, 2006). Most often, the starting material is skin fibroblasts, but blood cells or bone marrow cells can also be used (Ye et al., 2009; Zou et al., 2011). In the original publication, these cells were then transfected with four vectors, containing cDNA for the transcription factors Oct3/4, Sox2, c-Myc, and Klf4, respectively, and cultured under embryonic stem-cell conditions. In later studies, these four vectors have been combined into one polycistronic lentiviral cassette, which can be excised after a few days so as to leave no permanent changes in the genome (Somers et al., 2009, 2010). The iPS cells possess a high reproduction capacity and can be induced to differentiate into all different somatic cells, including myeloid cells (Morishima et al., 2011; Mukherjee et al., 2011; Zou et al., 2011). This system works with human cells as well as with other mammals, thus creating the possibility to create a repository of patient-derived iPS cells. Indeed, iPS cells and somatic cells derived from iPS cells contain the same DNA mutations as do the original somatic cells (Jiang et al., 2012; Mukherjee et al., 2011; Pessach et al., 2011; Zou et al., 2011). For research purposes one can think of limitless numbers of patient neutrophils, patient myeloid precursor cells that can be transfected before differentiation into neutrophils, or generation of other somatic cells that may express the mutated protein. For treatment purposes one can think of restoring NADPH oxidase capacity in the patient's own derived hematopoietic precursor cells and transplantation of these autologous cells into the patients, or production of large numbers of autologous functional neutrophils for transfusion purposes. One unsolved question at this moment is whether the specificity and extent of all epigenetic control mechanisms in the original blood neutrophils are identical to neutrophils derived in vitro from iPS cells.

A second important new development is the progress made in gene correction—that is, replacement of that region of a gene that carries a mutation by its wild-type counterpart while leaving all neighboring sequences intact. This strategy has the inherent advantage of leading to correct protein expression under the control of the endogenous promoter and enhancer regulatory elements. This strategy was first attempted by Cole-Strauss et al. (1996) and Kren et al. (1997) by chimeric RNA/DNA oligonucleotide transfection of cultured lymphoblasts and human hepatoma cells, and later in vivo in rats (Kren et al., 1998). The oligonucleotide chimera anneals efficiently and specifically to the target sequence in the gene, causing mutagenesis (or mutation correction) by DNA repair. The chimera is delivered as a complex with a protecting polycation that in turn is modified with a ligand to promote targeting to a specific receptor (e.g., the asialoglycoprotein receptor of hepatocytes). Despite efficient mutagenesis in the rat liver, this system has not gained wide application in human gene correction. Instead, gene correction through introducing site-specific double-strand DNA breaks by engineered homing endonucleases (also called meganucleases) (Munoz et al., 2011) or zinc-finger nucleases (Nakayama, 2010; Urnov et al., 2005; Zou et al., 2011), followed by homologous recombination of the mutated gene region with a similar exogenous wild-type cDNA source through endogenous DNA repair mechanisms, has been developed. The introduction of site-specific double-strand DNA breaks greatly enhances correction efficiency and has also been shown in vivo in a hemophilia B mouse model to be sufficiently effective to restore hemostasis through 2 to 3 percent correction of circulating factor IX expression (Li et al., 2011). For gene correction of CGD this may not be the method of choice, given that many CGD patients suffer from disease caused by unique mutations. This would imply engineering homing endonucleases or zinc-finger nucleases for each patient separately. Instead, targeting specific so-called safe harbors in the genome whose disruption does not lead to deleterious consequences such as insertional mutagenesis may be an attractive alternative. One such locus, the AAVS1 locus (the common

integration site of the adeno-associated virus 2), has been used for lentiviral transduction of CGD iPS cells (Zou et al., 2011). This last approach of course lacks the attractive prospect of gene correction in situ. Although this all sounds promising, a number of problems remain to be solved. One is the risk of undesired toxicity as a result of off-target cleavage by the nucleases, which may lead to break-induced DNA sequence alterations caused by nonhomologous end-joining as well as chromosomal translocations possibly leading to oncogenic transformation. Cellular delivery of the nucleases must also be considered. Use of retrovirus or integrating lentivirus may reintroduce the risk of insertional mutagenesis, and prolonged expression of the cDNA for the nucleases may cause deleterious effects as mentioned. Therefore, nonintegrating lentivirus (NILV) vectors that allow expression only for a limited time appear attractive, although such vectors allow less efficient expression than the integrating vectors (Pessach & Notarangelo, 2011).

ACKNOWLEDGMENTS

D.R. and T.W.K. thank Martin de Boer, Karin van Leeuwen, Merlijn van den Berg, and Rob van Zwieten for their experimental and clinical investigations, all CGD clinicians for their cooperation, and the Karl Landsteiner Foundation for Blood Transfusion Research (LSBR), the CGD Research Trust (UK), and the E-Rare program of the European Commission for financial support. 53.

CELL ADHESION AND LEUKOCYTE ADHESION DEFECTS

Amos Etzioni and Ronen Alon

Leukocyte trafficking from bloodstream to tissue is important for the continuous surveillance for foreign antigens and for rapid leukocyte accumulation at sites of inflammatory response or tissue injury. Leukocyte emigration to sites of inflammation is a dynamic process, involving multiple steps in an adhesion cascade. These steps must be precisely orchestrated to ensure a rapid response with only minimal damage to healthy tissue (Carlos & Harlan, 1994; Ley et al., 2007; Springer, 1994; von Andrian & Mackay, 2000). Leukocyte interaction with vascular endothelial cells is mediated by several families of leukocyte and endothelial adhesion molecules, including the integrins, the selectins, and members of the immunoglobulin gene superfamily (IgSF). Each is involved in a different phase of leukocyte adherence to and migration across the endothelium, and the synchronization of their surface expression and activation is crucial for leukocyte trafficking.

While the importance of leukocyte movement toward sites of inflammation was well recognized more than a century ago, the molecular basis of leukocyte emigration from the bloodstream through the endothelium was only recently elucidated. The integrin family and several integrin ligands of the IgSF were described in the 1980s, whereas the selectins and their carbohydrate counter structures were discovered in the 1990. The critical role of various cytoplasmatic adaptors for integrin activation was realized only recently (Legate & Fassler, 2009). Several years after reporting the structure of the leukocyte integrin molecule, a genetic defect in the subunit of the molecule (ITGB2) was discovered (Springer et al., 1984). The resultant syndrome, now called leukocyte adhesion defect type I (LAD I; OMIM 116920), has been described in more than 250 children and is characterized by delayed separation of the umbilical cord, recurrent soft tissue infections, chronic periodontitis, marked leukocytosis, and a high mortality rate at an early age. Currently, the only definite therapy is bone marrow transplantation. In vivo and in vitro studies have shown a marked defect in neutrophil motility.

In 1992 a second defect, LAD II (OMIM 266265), was discovered in two children and was found to be due to a defect in the synthesis of selectin ligands (Etzioni et al., 1992). Although several adhesive functions of LAD II leukocytes are markedly impaired in vitro, the clinical course with respect to infectious complications is milder than that in LAD I. However, patients with LAD II present with other abnormal features, such as growth and mental retardation, which are related to the primary defect in fucose metabolism and are not observed in LAD I.

Recently, a third rare LAD syndrome has been described (Alon et al., 2003; Alon & Etzioni, 2003; Kuijpers et al., 1997a, 2009; Malinin et al., 2009; Svensson et al., 2009). Patients with LAD III (OMIM 612840) suffer from severe recurrent infections, similar to LAD I, but also have a severe bleeding tendency, resembling Glanzmann's thrombasthenia. Although integrin expression is normal and its structure is intact, a defect in inside-out integrin activation on all hematopoietic cells is the primary abnormality in LAD III. Finally, several homozygous stop codon mutations in Kindlin-3 were found in patients with the LAD III phenotype (Kuijpers et al., 2009; Malinin et al., 2009; Mory et al., 2008; Svensson et al., 2009).

In this chapter we will briefly review the various adhesion molecules involved in leukocyte–endothelial interactions and then focus on the clinical consequences of defects in these molecules.

ADHESION MOLECULES

LEUKOCYTE INTEGRINS

Integrins are transmembrane cell-surface proteins that bind externally to matrix and membrane proteins and internally to

cytoskeleton proteins and thereby communicate between the extracellular and the intracellular environments of the cell (Luo et al., 2007). Each integrin consists of noncovalently linked α and β subunits. Each subunit is composed of a large extracellular domain (1,000 to 1,150 amino acids for the α subunit and 700 to 740 for the β subunit), a single transmembrane domain of about 20 amino acids, and a short cytoplasmic domain of 40 to 50 amino acids (Askari et al., 2009; Humphries, 2000). Specificity of receptor binding to various ligands appears to depend primarily on the extracellular portion of the α subunit, although both subunits are required for functional activity of the receptor.

Integrins have been arranged in subfamilies according to the 3 main β subunits they consist of, and each of these β subunits can associate with 1 to 10 different α subunits. To date, there are 19 α- and 8 β-subunit genes identified in mammals, encoding polypeptides that combine to form up to 25 integrin heterodimers. Within this large family of integrin receptors only four members have been shown to be significantly involved in leukocyte adhesion to endothelium.

Two, LFA-1 and Mac-1, belong to the β_2 subfamily, and the other two, VLA-4 and $\alpha_4\beta_7$, belong to the β_1 and the β_7 subfamilies, respectively.

β2 Integrins

This subfamily comprises four known heterodimeric glycoproteins with a common β subunit, designated CD18 (Table 53.1). The first three heterodimers identified were lymphocyte function-associated antigen-1 (LFA-1), macrophage antigen-1 (Mac-1), and p150, 95; their α subunits are designated α_L (CD11a), α_M (CD11b), and α_X (CD11c), respectively. A fourth heterodimer, $\alpha_D\beta_2$, was subsequently identified. The α_L, α_M, α_X, α_D, and β_2 polypeptides are initially assembled in the cytoplasm, and the mature integrin heterodimer is then transported to the plasma membrane. Both subunits are therefore required for integrin expression on the plasma membrane.

β_2 integrin expression is restricted to leukocytes and to subsets of mesenchymal stem cells (Ley, 2002), but different heterodimers are differentially expressed on different subsets of leukocytes. Whereas LFA-1 ($\alpha_L\beta_2$, CD11a/CD18) is expressed by all leukocytes, Mac-1 ($\alpha_M\beta_2$, CD11b/CD18) and p150, 95 ($\alpha_X\beta_2$, CD11c/CD18) are expressed primarily by myeloid cells, subsets of lymphocytes, and natural killer (NK) cells. $\alpha_D\beta_2$ (CD11d/CD18) is expressed at moderate levels on myelomonocytic cell lines and subsets of peripheral blood leukocytes. Importantly, the β_2 integrins participate in many cellular contacts essential to various immune effector functions in addition to mediating leukocyte adherence to endothelium. These include phagocytosis, killing of bacteria, antibody-dependent cell-mediated cytotoxicity, antigen stimulation, and both homotypic and heterotypic aggregation.

An important characteristic of the leukocyte β_2 integrins is that under baseline conditions they exist in a relatively inactive nonadhesive conformation. One of the key events in leukocyte adhesion to endothelium is the activation and deactivation of these integrins at the appropriate time and place. Activation of leukocytes by a variety of mediators (e.g., for phagocytes, C5a, platelet-activating factor, leukotriene B4, or interleukin (IL)-8; for lymphocytes, chemokines and antigens) results in a transient increase in adhesion by CD11/CD18-dependent mechanisms. This increased adhesiveness occurs through qualitative changes, involving transformation of LFA-1 and Mac-1 from a low- to high-affinity state and a subsequent clustering of receptors, which increases the avidity of the cell contact (Ley, 2002). The main β_2 integrin ligands on vascular endothelium are members of the immunoglobulin superfamily (IgSF). Aside from its role in leukocyte adhesion, occupancy of CD11/CD18 by various ligands also induces intracellular signals. Thus, ligand binding could affect cellular functions such as survival, differentiation, apoptosis, cytotoxicity, proliferation, and cytokine production (Luster et al., 2005).

α_4 Integrins

β_1 or very late antigen (VLA) integrins represent the largest integrin subfamily (Table 53.1). Most of these integrins are receptors for extracellular matrix proteins, including fibronectin, collagen, and laminin. One member of this subfamily, $\alpha_4\beta_1$ (VLA-4; CD49d/CD29), is involved in lymphocyte, eosinophil, basophil, NK cell, hematopoietic stem cell, and monocyte adhesion to the CS-1 fragment of fibronectin and to the cytokine-induced endothelial cell-surface protein, vascular cell adhesion molecule-1 (VCAM-1). Circulating human neutrophils do not normally express significant levels of VLA-4 and do not use this pathway to adhere to activated endothelium; they rely almost exclusively on their β_2 integrins for stable interactions with vascular endothelia (Carman & Springer, 2003).

The $\alpha_4\beta_7$ integrin is expressed on lymphocytes and eosinophils and functions as the homing receptor to vascular beds enriched with the mucosal vascular addressin cell adhesion molecule (MAdCAM-1) (Table 53.1). A subset of activated $\alpha_4\beta_7$ can also bind, although weakly, to the VLA-4 ligands, VCAM-1 and fibronectin.

IMMUNOGLOBULIN SUPERFAMILY MOLECULES

Intercellular Adhesion Molecules

The intercellular adhesion molecules (ICAMs), of which five have been identified, were originally defined as LFA-1 ligands (Springer, 1994) (Table 53.1). Only ICAM-1 and ICAM-2 are expressed on endothelium and participate in leukocyte adhesion to endothelium. The gene for ICAM-1 is located on chromosome 19. The molecule has five Ig-like domains, with a short hinge region separating the third and fourth Ig-like domains (Luster et al., 2005). ICAM-1 is a ligand for both LFA-1 and Mac-1. The binding sites in ICAM-1 for the two integrins are, however, distinct; LFA-1 binds to domains 1 and 2 and Mac-1 binds to domain 3. Human ICAM-2 is a single-copy gene located on chromosome 17. It has only two extracellular Ig-like domains, and the binding site for LFA-1 is located in these domains (Ley et al., 2007). ICAM-2 binds LFA-1 with a lower affinity than ICAM-1. The other β_2 integrins do not bind ICAM-2.

Table 53.1 ADHESION MOLECULES INVOLVED IN LEUKOCYTE–ENDOTHELIAL INTERACTIONS

NAME	DISTRIBUTION	MEDIATORS (INDUCED BY; ACTIVATED BY)	COUNTERSTRUCTURE(S)	FUNCTION(S)
Integrins				
LFA-1 ($\alpha_L\beta_2$, CD11a/CD18)	All leukocytes	Constitutively expressed; activated by cross-linking of other surface receptors, chemokines	ICAM-1, 2	Leukocyte firm adhesion and transmigration
Mac-1 ($\alpha_M\beta_2$, CD11b/CD18)	Neutrophils, monocytes, natural killer cells, eosinophils	Constitutively expressed; activated by cytokines, chemokines, chemoattractants	ICAM-1	Phagocyte firm adhesion and transmigration
$\alpha_4\beta_7$	Lymphocytes, eosinophils, natural killer cells	Constitutively expressed; activated by chemokines	MAdCAM-1, VCAM-1, fibronectin	Leukocyte rolling and firm adhesion
VLA-4 ($\alpha_4\beta_1$, CD49d/CD29)	All leukocytes except neutrophils	Constitutively expressed; activated by cross-linking of other surface receptors, chemokines, chemoattractants	VCAM-1, fibronectin	Leukocyte rolling, firm adhesion, and migration
Ig Superfamily ICAM-1 (CD54)	Endothelial cells, lymphocytes, other cell types	Constitutively expressed; upregulated by IL-1, LPS, TNF, IFN-γ	LFA-1, Mac-1	Leukocyte firm adhesion and transmigration
ICAM-2 (CD102)	Endothelial cells,	Constitutively expressed	LFA-1	Leukocyte firm adhesion
VCAM-1 (CD106)	leukocytes Endothelial cells, other cell types	Induced by TNF IL-1, LPS, etc.	VLA-4, $\alpha_4\beta_7$	Leukocyte rolling and firm adhesion
PEC AM-1 (CD31)	Leukocytes, endothelial cells, platelets	Constitutively expressed	PECAM-1(CD31)	Transmigration
MAdCAM-1	Mucosal HEV	Constitutively expressed	$\alpha_4\beta_7$, L-selectin	Leukocyte rolling and firm adhesion
Selectins				
E-selectin (CD62E)	Endothelial cells	Induced by TNF, IL-1, LPS, etc.	Sialylated, fucosylated structures (e.g., SLeX) expressed on PSGL-1, and a variety of other glycoproteins	Leukocyte rolling
P-selectin (CD62P)	Endothelial cells, platelets	Induced by histamine, thrombin, etc.	Sialylated, fucosylated, sulfated structures on leukocyte surfaces	Leukocyte rolling
L-selectin (CD62L)	Most leukocytes	Constitutively expressed; shed by diverse activating agents	CD34, PSGL-1 (sialyated, fucosylated and sulfated) structures expressed on CD34, MAdCAM-1, GlyCAM-1, PSGL-1, and other glycoproteins	Leukocyte rolling

ICAM-1 is expressed usually at low levels on most endothelial cells but can be dramatically upregulated upon endothelial activation by lipopolysaccharides (LPS), IL-1, and tumor necrosis factor (TNF). This increased expression of ICAM-1 peaks at 4 to 6 hours and persists for days with continued exposure to cytokines. ICAM-2 expression, in contrast, is expressed constitutively and is not regulated by cytokines.

VCAM-1

VCAM-1 also belongs to the IgSF. A single VCAM-1 gene gives rise through alternative splicing to distinct isoforms that differ in the number of integrin binding sites (Wittchen, 2009). In humans the predominant isoform contains seven Ig-like domains with binding sites for the integrin VLA-4 located within the first and fourth domains (Table 53.1). VCAM-1 is induced by cytokines on endothelial cells with a time course similar to that of ICAM-1.

MAdCAM-1

MAdCAM-1 is a member of the IgSF that has a mucin-like domain and is a high-affinity ligand for the $\alpha_4\beta_7$ integrin (Briskin et al., 1993) (Table 53.1). A subset of MAdCAM-1 expressed on high endothelial venules (HEVs) is decorated with carbohydrate ligands for L-selectin, MAdCAM-1 may serve as a bridge between selectin- and β_2 integrin–dependent events, especially in mucosal tissues and gut-associated lymphoid organs (Bargatze et al., 1995).

Platelet–Endothelial Cell Adhesion Molecule-1

Platelet–endothelial cell adhesion molecule-1 (PECAM-1; CD31) is a member of the IgSF that is expressed at low levels on most leukocytes and platelets but at high levels on endothelial cells, where it is localized to intercellular junctions (Table 53.1). PECAM-1 is involved in paracellular transendothelial migration and can also regulate leukocyte migration through the subendothelial basement membrane (Sperandio et al., 2003).

SELECTINS

This family of adhesion molecules was discovered in 1989, when the cDNA sequences for three distinct cell-surface glycoproteins found on endothelium (E-selectin, CD62E), platelets (P-selectin, CD62P), and leukocytes (L-selectin, CD62L) were reported (McEver, 2002). These molecules were initially designated ELAM-1; PADGEM or GMP-140; and MEL-14 or LECAM-1, respectively. The genes for the selectins are closely linked on chromosome 1, reflecting their common evolutionary origin. All three members have common structural features, most prominently an N-terminal lectin-like domain that is central to the carbohydrate-binding properties of all three selectins (Kansas, 1996). The lectin domain is followed by a regulatory domain homologous to the epidermal growth factor (EGF), which does not interact with ligand but can modulate the ligand-binding properties of the lectin domain, and by a discrete number of domains similar to those found in certain complement binding-proteins. The term *selectin* was proposed to highlight the lectin domain that is critical for ligand binding by all selectins and to indicate the selective functions and expression patterns of these cell adhesion lectins.

Although three selectins are involved in the recruitment of leukocytes to sites of tissue injury, there are fundamental differences in their distribution, activation, and mode of expression (McEver, 2002). For example, while all three selectins take part in the first step of the adhesion cascade, the capture and rolling phase (vide infra), E-selectin participates also in slowing down rapidly rolling leukocytes.

E-selectin

E-selectin expression is restricted to endothelial cells and its transcription is induced when endothelial cells are activated by LPS, IL-1, TNF, and other stimuli (Table 53.1). These substances elevate the translation of E-selectin, resulting in peak cell-surface expression at 4 to 6 hours, decreasing to near basal levels by 24 hours (Cotran et al., 1986). Although E-selectin expression in vitro is typically transient, it is expressed chronically in certain inflammatory conditions.

P-selectin

P-selectin, expressed on platelets as well as on endothelial cells (Table 53.1), does not necessarily require de novo synthesis because it is stored in secretory granules (Weibel-Palade bodies). Thus, within seconds of activation by thrombin or histamine, P-selectin is rapidly redistributed to the cell surface. Its expression in vitro is typically very short-lived—up to 15 minutes. However, studies in vivo suggest that endothelial P-selectin is also upregulated by inflammatory stimuli at the level of de novo transcription and protein synthesis, providing a mechanism for more prolonged expression (Siegel-Axel & Gawaz, 2007).

L-selectin

In contrast to the E- and P-selectins, L-selectin is not expressed on endothelial cells or platelets but rather is constitutively expressed on leukocytes (Table 53.1). Although originally described as a lymphocyte homing receptor, it was subsequently shown to be expressed on most other leukocytes (Rosen, 2004). L-selectin can be shed rapidly, mainly in neutrophils via proteolytic cleavage of its ectodomain near the membrane insertion. Cleavage of L-selectin may serve to limit further leukocyte recruitment at inflammatory sites but may also facilitate integrin turnover during transendothelial lymphocyte migration.

SELECTIN LIGANDS

Studies of the molecular basis of selectin adhesion have focused mainly on carbohydrate recognition by the lectin domains. Identification of the physiological ligands for the selectins has been challenging because, like many lectins, the

selectins can bind a variety of carbohydrate structures in vitro (Rosen 2004). These ligands constitute the termini of either N-linked or O-linked glycans, which can be part of multiple glycoprotein scaffolds.

All selectin carbohydrate ligands share a core of sialylated and fucosylated lactosamine tetrasaccharides related to the sialylated Lewis X blood group (SLeX, CD15). SLeX is expressed at high levels on neutrophils and monocytes, whereas most peripheral lymphocytes express SLeX only after activation and exposure to specific cytokines. Both the sialic acid and the fucose moieties are critical for efficient binding to E-selectin, while additional sulfate groups on the glycan or the glycoprotein confer binding to L-selectin and P-selectin. Monoclonal antibodies against multiple SLeX-containing glycan derivatives and infusion of soluble SLeX can both attenuate the binding of neutrophils to activated endothelial cells, as well as leukocyte rolling along inflamed vessels (Asako et al., 1994). SLeX and selectin binding can be introduced to many cell types via transfection of appropriate fucosyltransferases. While the selectins bind weakly to small sialylated, fucosylated oligosaccharides, they appear to bind with much higher avidity to carbohydrate determinants presented by a limited number of glycoproteins. L-selectin binds at least five different heavily glycosylated mucin-like proteins: GlyCAM-1, CD34, and related glycoproteins like podocalyxin and endoglycan, and the integrin ligand MAdCAM-1 (Rosen, 2004). P-selectin and, to a lesser extent, E-selectin have been reported to selectively bind P-selectin glycoprotein ligand-1 (PSGL-1), which is expressed on most leukocytes and can also serve to capture leukocytes onto endothelial adherent leukocytes via L-selectin–dependent interactions. A monoclonal antibody specific for PSGL-1 completely inhibited P-selectin–mediated rolling of leukocytes under a range of physiological shear stresses (Moore et al., 1995).

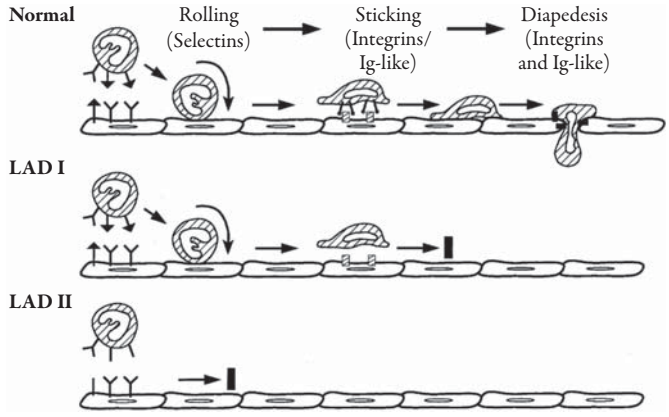

Figure 53.1 The adhesion cascade and LAD syndromes. Under conditions of flow at sites of inflammation, normal leukocytes first roll along the venular wall via selectin–carbohydrate interactions. Following integrin activation by local chemoattractants or chemokines, the rolling cells then adhere firmly via binding of leukocyte integrins to endothelial IgSF ligands. Subsequently, the adherent leukocytes diapedese between endothelial cells utilizing PECAM-1 and integrin–IgSF ligand interactions. Defects in selectin-mediated rolling or integrin-mediated sticking impair emigration. In LAD I, neutrophils deficient in β_2 integrin can roll along the endothelium but cannot adhere firmly to transmigrate. In LAD II, neutrophils deficient in fucosylated carbohydrate ligands for selectins are unable to roll and thus cannot adhere and transmigrate.

THE ADHESION CASCADE

The migration of leukocytes from the bloodstream to the tissue occurs in several distinct steps (Ley et al., 2007) (Fig. 53.1). First, under conditions of flow, loose adhesions generated between the leukocyte and the vessel wall, primarily in postcapillary venules, reversibly capture flowing leukocytes and mediate their rolling on the endothelium. This transient and reversible step is a prerequisite for activation of leukocytes by specific endothelial displayed chemotactic cytokines (Laudanna et al., 2002). This is followed by firm adhesion (i.e., sticking), after which migration occurs. Each of these steps involves different adhesion molecules and can be differentially regulated.

SELECTIN-MEDIATED CAPTURE AND ROLLING

Leukocytes that adhere to blood vessels must resist shear forces exerted on them as they interact with the vascular endothelium. Under normal conditions, leukocytes move rapidly in the laminar flow stream of blood and do not adhere to the endothelium, except for subsets of venules within lymphoid organs, where constitutive extravasation of lymphocytes must take place (Wagner & Frenette, 2008). However, with activation of essentially all peripheral postcapillary venules due to local trauma or inflammation, leukocytes immediately begin to roll along the venular wall. This phenomenon of leukocyte rolling was observed for more than a century, but its molecular basis was delineated only two decades ago. Several studies showed that although CD18-blocking antibodies interfere with leukocyte sticking, they do not prevent rolling. Monoclonal antibodies to selectins, however, markedly reduced the rolling process both in vivo and in vitro. Moreover, leukocyte rolling is diminished in P-, E-, and L-selectin–deficient mice (Mayadas et al., 1993). Patients who lack SLeX molecules on their leukocytes and mice deficient in the enzymes essential for generating this motif also show defective in vivo rolling (Homeister et al., 2001; von Andrian et al., 1993). L-selectin itself recognizes various sulfated derivatives of the SLeX moiety, which are associated with multiple glycoproteins on HEVs (Baumheter et al. 1993), as well as with as yet poorly characterized glycoproteins expressed on cytokine-stimulated systemic vasculature.

ACTIVATION OF LEUKOCYTE INTEGRINS

The initial rolling interaction of leukocytes with endothelium is reversible unless the leukocytes are activated and become firmly adherent via integrins. Rolling mediated by selectins brings the leukocytes in close proximity to endothelial displayed chemoattractants (Alon & Rosen, 2007). These chemotactic cytokines made by the endothelium or by cells in the surrounding tissue can rapidly switch the otherwise

nonadhesive leukocyte integrins into highly adhesive molecules that mediate leukocyte sticking and firm arrest. The leukocyte chemoattractants include classical chemotactic reagents such as C5a and leukotriene B4, and chemokines, which are stably tethered on glycosaminoglycans (GAGs) expressed on the apical surface of the endothelial cells (Mackay, 2001). The importance of these chemotactic agents in mediating firm adhesion was illustrated in experiments using the flow chamber model. In this model rolling leukocytes stop immediately on the β_2 integrin ligand ICAM-1 only upon exposure to a chemotactic agent (Lawrence & Springer, 1991). Rolling is not a prerequisite for integrin activation since lymphocytes encountering α_4 ligands such as VCAM-1 and a co-immobilized chemokine can immediately arrest on this ligand without prior rolling (Grabovsky et al., 2000). Increased adhesive capacity of leukocyte integrins is mediated primarily through local changes in integrin receptor affinity as well as in avidity. In phagocytes, a rapid increase in surface expression of the integrin Mac-1 also occurs through translocation of $\alpha_M\beta_2$ heterodimers from cytoplasmic granules to the plasma membrane.

ADHESION AND TRANSENDOTHELIAL MIGRATION VIA INTEGRINS AND IGSF LIGANDS

Activation of integrins results in increased binding to their Ig-like ligands on the endothelial cells, which allows leukocytes to withstand the continuous shear forces in the blood vessels. Once arrested, the leukocyte must crawl variable distances on the apical and basolateral surfaces of the endothelial lining of blood vessels. This crawling is also mediated by integrins, which form and break serial adhesive contacts (Shulman et al., 2009). Consequently, transendothelial migration of arrested leukocytes to various sites of inflammation depends on multiple integrin–IgSF interactions. Other endothelial expressed members of the endothelial IgSF, such as JAMs, PECAM-1, VE-Cadherin, and CD99, contribute to various steps of migration and also stimulate signals necessary for leukocyte crossing through subendothelial basement membrane (Carman et al., 2007). Nevertheless, whereas diapedesis of myeloid cells depends on these multiple adhesive cues, the transendothelial migration of lymphoid cells does not depend on these signals.

ADHESION MOLECULE DEFICIENCY SYNDROMES

Perhaps the best way to appreciate the in vivo importance of leukocyte-endothelial adhesion molecules and their cytoplasmic regulators in humans is to examine those rare "experiments of nature" in which a genetically determined defect in a particular adhesion pathway is associated with a defined immunodeficiency. Three such rare syndromes have been so far recognized (Hanna & Etzioni, 2012) (Table 53.2). In the first LAD syndrome (LAD I), the β_2 integrin is deficient, whereas in the second, LAD II, the fucosylated carbohydrate ligands for selectins are absent (Etzioni, 1996). Most recently, a third leukocyte adhesion deficiency, LAD III, has been identified in which the key integrin coactivator Kindlin-3 is diminished, resulting in a general defect in both leukocyte and platelet integrin activation and firm adhesiveness (Alon & Etzioni, 2003; Malinin et al., 2009; Svensson et al., 2009).

LAD I

Several reports published before 1980 documented a group of patients with recurrent bacterial and fungal infections, defective leukocyte motility and phagocytosis, impaired wound healing, and delayed separation of the umbilical cord (Boxer et al., 1974; Hayward et al., 1979). In 1980, a seminal study provided a possible molecular basis for this emerging syndrome (Crowley et al., 1980), suggesting that the absence of a high-molecular-weight neutrophil membrane glycoprotein in a young boy was directly responsible for an inherited defect in neutrophil adhesion. This abnormality was manifested in vitro by the failure of leukocytes to spread on surfaces and by impaired chemotaxis. In 1982 the association of this syndrome with a missing membrane glycoprotein was confirmed in two other patients with similar symptoms (Bowen et al., 1982).

Table 53.2 **LAD SYNDROMES**

	LAD I	LAD II	LAD III
Clinical Manifestation			
Recurrent severe infections	+++	+	+++
Neutrophilia			
Basal	+	+++	++
With infection	+++	+++	+++
Periodontitis	++	++	?
Skin infection	++	+	++
Delayed separation of the umbilical cord	+++	-	++
Developmental abnormalities	-	+++	
Bleeding tendency	-	-	+++
Laboratory Findings			
CD18 expression	Low or absent	NL	NL
SLeX expression	NL	Absent	NL
Neutrophil motility	↓↓↓	↓↓	↓↓
Neutrophil rolling	NL	↓↓↓	NL
Neutrophil adherence	↓↓↓	↓	↓↓↓
Opsonophagocytic activity	↓	NL	NL
T and B cell function	↓	NL	Impaired memory?

NL, normal.

At the same time, in separate studies, other investigators identified a new leukocyte membrane glycoprotein heterodimeric complex involved in multiple adhesion-related functions. Mac-1 and LFA-1 were identified in 1979 and 1981, respectively (Anderson & Smith, 2001). A third complex belonging to the same integrin family, p150, 95, was described several years later. A relationship between the inherited defect of neutrophil adhesion and these glycoproteins was suggested by the fact that monoclonal antibodies to the α or β chains of this complex in normal leukocytes induced in vitro defects in chemotaxis and phagocytosis similar to those observed in affected patients. Indeed, in 1984, using specific monoclonal antibodies, multiple groups reported that leukocytes of patients with this syndrome were deficient in expression of both the common β subunit as well as in the various α subunits. These findings led to the proposal that the primary defect in this syndrome is related to mutations in the β_2 subunit and that biosynthesis of the β_2 subunit is necessary for surface expression of the α subunits (Springer et al., 1984).

While many names had previously been given to this syndrome, in the interest of brevity and comprehensiveness, the term *leukocyte adhesion deficiency* (LAD) was proposed in 1987 (Anderson & Springer, 1987). LAD I (OMIMIL6920) is inherited in an autosomal recessive manner since heterozygote carriers of the defective β_2 gene exhibit no significant clinical manifestations.

Clinical and Pathological Manifestations

The prominent clinical feature of these patients is recurrent bacterial infections, primarily localized to skin and mucosal surfaces. These infections are indolent and necrotic and tend to recur. Sites of infection often progressively enlarge, and they may lead to systemic spread of the bacteria. Infections are usually apparent from birth onward, and a common presenting infection is omphalitis with delayed separation of the umbilical cord (Fig. 53.2, Color Plate 53.I). However, not all patients with LAD I have delayed separation of the cord. The most frequently encountered bacteria are *Staphylococcus aureus* and gram-negative enteric organisms, but fungal infections are also common. The absence of pus formation at the site of infection is one of the hallmarks of LAD I. Severe gingivitis and periodontitis are major features among all patients who survive infancy. Impaired healing of traumatic or surgical wounds is also highly characteristic of this syndrome.

The recurrent infections observed in affected patients result from a profound impairment of leukocyte mobilization into extravascular sites of inflammation. Skin windows yield few, if any, leukocytes, and biopsies of infected tissues demonstrate inflammation totally devoid of neutrophils. These findings are particularly striking considering that marked peripheral blood leukocytosis (5 to 20 times normal values) is consistently observed during infections. In contrast to the difficulties experienced in defense against bacterial and fungal microorganisms, LAD I patients do not exhibit increased susceptibility to viral infections, suggesting that lymphocyte extravasation, as opposed to myeloid leukocyte trafficking to sites of infection, is not impaired. Lymphoid tissue is, however, severely depleted of lymphocytes, indicating a role for LFA-1 in lymphocyte homing with possible compensation from α_4 integrins, which are not affected in this disease.

Figure 53.2 Omphalitis in a child with the severe phenotype of LAD I. (See Color Plate.)

Notably, the severity of clinical infectious complications among patients with LAD I appears to be directly related to the degree of CD18 deficiency. Two phenotypes, designated *severe deficiency* and *moderate deficiency*, have been defined (Anderson & Smith, 2001). Patients with less than 1 percent of the normal surface expression exhibit a severe form of disease with earlier, more frequent, and more serious episodes of infection, often leading to death in infancy, whereas patients with some surface expression of CD18 (2.5 to 10 percent) manifested a moderate to mild phenotype with fewer serious infectious episodes and survival into adulthood.

The hallmark pathological finding in severe LAD I is the complete absence of neutrophils in sites of infection. The necrotic areas are devoid of pus. While this finding is typical for many tissues, neutrophil migration to infected lungs may be normal, as a robust inflammatory response has been observed in lung tissue.

Laboratory Findings

The defective migration of neutrophils from patients with LAD I was observed in studies in vivo as well as in vitro (Bowen et al., 1982; Harlan, 1993). Neutrophils fail to mobilize to skin sites in the in vivo Rebuck skin-window test. In vitro studies demonstrate a marked defect in random migration as well as chemotaxis to various chemoattractants. Adhesion and transmigration through endothelial cells are severely impaired (Harlan et al., 1985). With the use of an intravital microscopy assay it was observed that fluorescein-labeled neutrophils from a LAD I boy rolled normally on inflamed rabbit venules, suggesting that they normally initiated adhesive interactions with inflamed endothelial cells (von Andrian et al., 1993). However, these cells failed to undergo activation-dependent, β_2-integrin–mediated adhesion and did

not stick, and therefore could not emigrate when challenged with a chemotactic stimulus (Fig. 53.1).

Patients with LAD I exhibit mild to moderate neutrophilia in the absence of overt infection. Marked granulocytosis with neutrophil counts in peripheral blood reaching levels of up to 100,000/μL occurs during acute infections. Defects in other myeloid functions are also observed. Binding and phagocytosis of iC3b-opsonized particles are also deficient, in agreement with the function of Mac-1 as complement receptor 3 (CR3) (Le Cabec et al., 2002). Abnormalities of neutrophil-mediated, antibody-dependent cellular cytotoxicity have been also reported in several patients (Kohl et al., 1986).

A wide variety of in vitro abnormalities of lymphocyte function have also been described in LAD I, but their in vivo relevance remains unclear. Although no humoral immune deficiency has been described in most of the patients, an impaired primary and secondary antibody response to a T-dependent neoantigen was reported (Ochs et al., 1993).

Molecular Basis

The CD11/CD18 integrin receptor is expressed on all leukocytes and plays an important role in multiple leukocyte functions. However, the predominant clinical manifestation of LAD I—markedly impaired phagocyte emigration in response to pyogenic infections—can be attributed to reduced neutrophil adhesion and impaired transendothelial migration due to the lack of CD18 expression by patient neutrophils.

Early on, several lines of evidence supported an autosomal recessive pattern of inheritance. Equal numbers of male and female patients were described, and family studies showed heterozygous male and female carriers who expressed 50 percent of the normal amount of the β_2-integrin molecules on their neutrophils. Furthermore, a frequent history of consanguineous marriages strongly supported the concept that LAD I is inherited as an autosomal trait (Anderson & Smith, 2001). The β_2-integrin subunit is encoded by a gene located at the distal end of the long arm of chromosome 21q22.3 (Solomon et al., 1988). In contrast to normal B-cell lines, which synthesize α_L and β_2 precursors that associate in the cytoplasm and then are transported to the cell surface as an $\alpha_L\beta_2$ heterodimer, lymphoblasts of LAD I patients synthesize a normal α_L-subunit precursor, which is never expressed on the cell surface and is apparently degraded in the absence of a normal β_2 subunit (Springer et al., 1984).

Heterogeneity among LAD I patients with respect to the extent of β_2-integrin deficiency on the leukocyte surface was first demonstrated by flow cytometry. As previously discussed, the severity of the clinical features and the magnitude of the functional deficits observed were directly related to the degree of CD18 deficiency, but the underlying molecular basis for this heterogeneity remained largely undefined until the β_2-subunit gene (*ITGB2*) was cloned and the relevant protein quantified (Anderson & Smith, 2001).

Several LAD I variants were subsequently reported to share a defect in β_2-integrin adhesive function despite normal surface expression of CD18. A child with classical LAD I features with normal surface expression of CD18 was reported (Hogg et al., 1999), in whom a mutation in CD18 led to a nonfunctional molecule. Another child with a moderately severe form of LAD I was found to have a novel point mutation in CD18, resulting in the expression of dysfunctional β_2 integrin (Mathew et al., 2000).

Mutation Analysis

The molecular basis for CD18 deficiency varies (Vihinen et al., 2001). In some cases the mutation causes diminished expression of CD18 mRNA. In other families there is expression of mRNA or protein precursors of aberrant size with either larger or smaller CD18 subunits. In other cases LAD I results from a failure to process normal-sized protein precursors to the mature normal product (Wright et al., 1995). Analysis at the gene level has revealed a degree of heterogeneity, which reflects this diversity. A number of point mutations have been reported, some of which lead to the biosynthesis of defective proteins with single amino acid substitutions, while others lead to splicing defects, resulting in the production of truncated and unstable proteins. In one case a 90-nucleotide deletion in the CD18 mRNA produced an in-frame deletion of a 30-amino acid region. Analysis of the genomic DNA showed this 90 bp region to be encoded by a single exon (exon 9). The 30-amino acid deletion and many additional mutations are located in a region encompassing residue 241 of the CD18 molecule that is highly conserved (Sligh et al., 1992) (Fig. 53.3). Domains within this segment are presumably required for biosynthesis of the subunit precursors and may contain critical contact sites between the α and β subunits.

Several splicing defects resulting in the production of abnormal β_2 protein products were also reported. Other mutations were found in exons 7 and 13 (Anderson & Smith, 2001). Although in most cases point mutations or small insertions or deletions in the CD18 (*ITGB2*) gene have been reported, an infant with LAD I suffered from a gross abnormality in chromosome 21 due to a deletion of q22.1–3 (Rivera-Matos et al., 1995).

Homozygosity for the *CD18* gene mutation was described in some cases, whereas in other cases compound heterozygosity was observed. So far over 20 different β_2 mutations have been identified to result in the LAD I phenotype (Fig. 53.3), but since in many cases of LAD I no molecular analysis has been performed, additional β_2 mutations may exist.

Strategy for Diagnosis

In any infant, male or female, with recurrent soft tissue infections and a very high leukocyte count, the diagnosis of LAD I should be considered. The diagnosis is even more suggestive if a history of delayed separation of the umbilical cord is present. To confirm the diagnosis, absence of the α and β subunits of the β_2-integrin complex has to be demonstrated. This can be accomplished with the use of appropriate anti-CD11 and -CD18 monoclonal antibodies and flow cytometry or by sequence analysis to define the exact molecular defect in the β_2 subunit. In rare cases, when β_2 integrins are normally expressed, functional in vitro assays must be performed to diagnose LAD I variants.

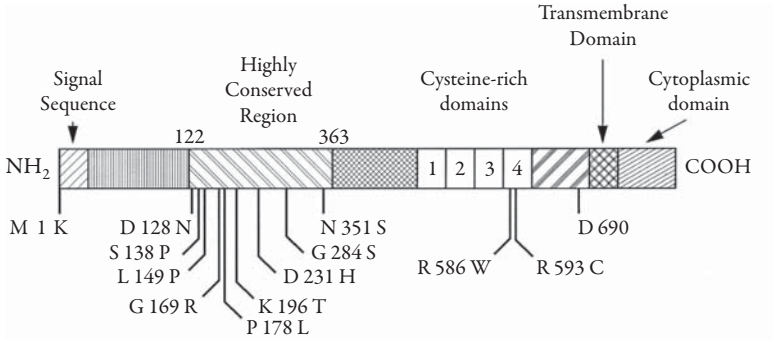

Figure 53.3 Representative mutations in the β_2-integrin subunit that have been identified in patients with LAD I syndrome.

Carrier Detection and Prenatal Diagnosis

LAD I carriers have 40 to 60 percent of normal CD18 and lack clinical symptoms. Sequence analysis shows one normal and one abnormal gene. Because leukocytes express CD18 on their surface only at and after 20 weeks of gestation, cordocentesis performed at this age can establish prenatal diagnosis (Weening et al., 1991). In families in whom the exact molecular defect has been previously identified, an earlier prenatal diagnosis is possible by chorionic biopsy and mutation analysis.

Treatment and Prognosis

Patients with the moderate LAD I phenotype usually respond to conservative therapy and the prompt use of antibiotics during acute infectious episodes. Prophylactic antibiotics may reduce the risk of infections in these patients.

Transfusion of granulocytes immediately after harvest by leukapheresis has been found to be useful in selected cases of infections that otherwise could not be controlled. Although granulocyte transfusions may be life-saving, their use is limited because of difficulties in supply of daily donors and immune reactions to the allogeneic leukocytes.

At present, the only corrective treatment that should be offered to all patients with the severe phenotype is bone marrow transplantation (Thomas et al., 1995). A recent multicenter study showed that the overall success rate in 36 patients with LAD I was 75 percent. Transplanted patients with fully matched HLA donors had a much better prognosis than those who underwent haploidentical transplantation (Qasim et al., 2009).

The introduction of a normal β_2-subunit gene (*ITGB2*) into hematopoietic stem cells has the potential to cure children with LAD I (Bauer & Hickstein, 2000). Retroviral-mediated transduction of the CD18 gene was shown to reconstitute a functional CD11a/CD18 in lymphoblastoid cell lines derived from patients with LAD I, and transduction of murine bone marrow cells with CD18 retroviral vector resulted in gene expression in a variable percentage of neutrophils at 2 weeks posttransduction (Wilson et al., 1993). Retroviral-mediated transfer of the *CD18* gene into primary LAD I bone marrow cells has also been reported (Bauer et al., 1998). Expression of CD18 was observed in a low percentage of neutrophils in two LAD I patients undergoing gene therapy without conditioning (Bauer et al., 1998). Successful LAD gene therapy with foamy viral vectors was recently reported in a canine model (Bauer et al., 2008). Taken together these studies give hope that gene therapy can be used for treatment of LAD I whenever bone marrow transplantation is unavailable.

Recently, a new approach to treat LAD I has been tried (Simon et al., 2010). As in cystic fibrosis, the use of aminoglycoside antibiotics (e.g., gentamicin) in vivo as in vitro can partially correct the premature protein termination by induction of a read-through mechanism. This approach increased the expression of CD18 but, unfortunately, did not improve leukocyte adhesion in two such treated LAD I patients.

CD18-Deficient Mice

Multiple mouse models with targeted disruption of one or more leukocyte and endothelial adhesion molecules have been generated and explored using multiple inflammatory model systems as well as intravital microscopy. Of particular interest are those knockouts that most closely mimic individual LAD syndromes both phenotypically and genetically.

Mutant mice with complete deficiency of CD18 resemble phenotypically the LAD I syndrome (Scharffetter-Kochanek et al., 1998). As in LAD I, these animals exhibit marked neutrophilia (11- to 30-fold increase over wild type). The granulocytosis observed in the CD18-deficient mice was due mainly to continuous stimulation of the bone marrow and enhanced production of myeloid cells as a consequence of the defective antimicrobial functions leading to infections (Horwitz et al., 2001). Similar to LAD I, there was almost no emigration of neutrophils in the CD18-null animals into sites of inflammation involving the skin. In contrast, the CD18-deficient mice exhibited comparable numbers of neutrophils in lavage fluid from inflamed peritoneum and increased emigration into inflamed lung when compared with wild type. The persistence of neutrophil emigration into the inflamed peritoneum in the CD18-null animals may result from the marked increase in circulating neutrophils in the CD18-deficient animals. Because the number of emigrating neutrophils is in part dependent on the number of circulating neutrophils, similar absolute numbers of neutrophils may have eventually emigrated in the CD18 null animals, although with markedly reduced rates.

CD18-Deficient Dogs and Cattle

A spontaneous mutation in the gene coding for the β_2 single integrin has been described in both dogs (Giger et al., 1987) and cattle (Shuster et al., 1992). Canine LAD (CLAD) occurs in Irish setters and results from a single missense mutation in the *CD18* gene, resulting in a substitution of cysteine to serine at position 36 (Kijas et al., 1999). In bovine LAD (BLAD) there is a also a point mutation (Asp128Gly) in the CD18 gene. Animals homozygous for this mutation exhibit persistent neutrophilia and suffer from recurrent infections associated with poor growth performance. Interestingly, the carrier frequency of the defective gene among Holstein cattle has been approximately 15 percent in bulls and 6 percent in cows (Shuster et al., 1992).

LAD II

LAD II (OMIM266265) is caused by a rare defect in fucose metabolism, resulting in the absence of SLeX and other structurally related fucosylated selectin ligands. LAD II was first described in two unrelated Palestinian boys, each the offspring of consanguineous parents (Etzioni et al., 1992). Subsequently, two additional unrelated Palestinian children and one Turkish child (Etzioni & Tonetti, 2000), a child of Brazilian origin (Hidalgo et al., 2003), and one from Pakistan (Yakubenia & Wild, 2006) have been reported, reaching a total of six reported LAD II patients.

Clinical and Pathological Manifestations

Affected children are born after uneventful pregnancies with normal height and weight. No delay in the separation of the umbilical cord has been observed. Patients with LAD II have severe mental retardation, short stature, a distinctive facial appearance, and the rare Bombay blood phenotype. They develop recurrent episodes of bacterial infections early in life, mainly pneumonia, periodontitis, otitis media, and localized cellulitis. Mild to moderate skin infections without obvious pus have also been observed (Table 53.2). The infections are generally not life-threatening and can usually be treated in the outpatient clinic (Etzioni et al., 1998). Interestingly, after the age of 3 years, the frequency of infections decreases and the children no longer need prophylactic antibiotics.

At an older age, the main infectious problem of LAD II patients is severe periodontitis, also observed in patients with LAD I. During times of infections the neutrophil count increases up to 150,000/μL. It is of interest to note that from their first days of life LAD II patients exhibit neutrophilia, ranging between 25,000 and 30,000/μL, even when they are free of infections.

Overall, the infections in LAD II appear to be comparable to the moderate rather than the severe phenotype of LAD I. It is possible that the ability of LAD II neutrophils to adhere and transmigrate via β_2 integrin under conditions of reduced shear forces (von Andrian et al., 1993) may permit some neutrophils to emigrate to sites of severe inflammation where blood flow is low due to vasodilatation. Thus, some level of neutrophil defense against bacterial infections can be obtained in LAD II patients but not in patients with severe LAD I.

As in LAD I, no pus formation at the site of infection occurs, and there is a striking absence of neutrophils in the lesions. Lymphocytic infiltration, by contrast, is clearly present (see below).

The severe mental retardation is reminiscent of congenital disorders in glycosylation (CDGs), a heterogeneous group of autosomal recessive disorders with defects in the processing and synthesis of carbohydrate moieties of multiple glycoproteins (Jaeken & Matthijs, 2007). While in early infancy the immune defect due to leukocyte adhesion deficiency is the main clinical problem, later on the general metabolic consequences of the defect in fucose metabolism govern the clinical picture. This syndrome should be therefore designated as LAD II/CDG IIc.

Laboratory Findings

The clinical picture of skin infections, pneumonia, and periodontitis associated with a very high blood neutrophil count initially suggested a neutrophil defect as the cause of this syndrome. Subsequently it was found that although the opsonophagocytic activity was normal, a marked defect in neutrophil motility was shared by all LAD II patients (Etzioni et al., 1992). Both random migration and directed migration toward chemotactic factors were markedly decreased (10 percent of normal) despite the independence of these assays on selectin–carbohydrate interactions.

Since homotypic aggregation of patient neutrophils, a process initiated by L-selectin–dependent adhesions (King et al., 2005), was found to be defective (Etzioni, 2009), these observations suggested that the problem was a defect in neutrophil adherence to surfaces; therefore, the possibility of a defect in adhesion molecules was investigated. Indeed, while patients' and their parents' neutrophils exhibited normal levels of integrin subunits, LAD II neutrophils were found to be deficient in expression of the SLeX antigen (Etzioni et al., 1992). In contrast to LAD I neutrophils, which failed to flatten and spread on phorbol ester-treated glass coverslips, the majority of LAD II neutrophils flattened and spread extensively, consistent with normal integrin functions (Phillips et al., 1995). Nevertheless, a small percentage of the LAD II cells exhibited an intermediate appearance and retained a more spherical shape. The poor migration toward chemoattractants in an under-agarose assay and the defective homotypic neutrophil adhesion could not be readily explained by the biochemical deficiency of SLeX and suggested a more global defect in cell activation or adhesion, possibly due to aberrant L-selectin–mediated signaling. Nevertheless, β2-integrin upregulation in LAD II neutrophils was normally induced by multiple agonists that bypass L-selectin signaling (Phillips et al., 1995).

Functional Aspects

To examine further the significance of the fucosylation defect, both in vitro and in vivo functions of LAD II

neutrophils were assessed. Neutrophils isolated from the peripheral blood of one LAD II patient failed to bind to purified platelet-derived P-selectin and recombinant E-selectin in vitro (Phillips et al., 1995). To determine the effect of SLeX deficiency on neutrophil–endothelial interactions, neutrophil adherence to IL-1-, TNF-, histamine-, and phorbol ester-activated human umbilical vein endothelial cells was examined. No adhesion of LAD II neutrophils was observed when the endothelial cells were activated with IL-1β (Fig. 53.4) or TNF-α, both potent inducers of E-selectin, whereas normal neutrophils bound avidly to these stimulated endothelial cells. Similarly, endothelial cells activated by histamine to express P-selectin bound normal neutrophils but not LAD II neutrophils. By contrast, normal neutrophil adhesion to endothelial cells was observed after activation of the LAD II leukocytes with phorbol myristate acetate (PMA), an activating stimulus for β_2 integrins (Fig. 53.4). Furthermore, LAD II neutrophil migration across endothelial monolayers in response to f-Met-Leu-Phe (fMLP), a CD18-dependent function, was comparable to that of normal neutrophils (Phillips et al., 1995).

Rolling, the first step in neutrophil recruitment to the site of inflammation, is mediated primarily by the binding of the selectins to their fucosylated glycoconjugate ligands. Through intravital microscopy, the in vivo behavior of fluorescein-labeled neutrophils from a normal donor and from LAD I and LAD II patients was investigated during their passage through the inflamed microcirculation of rabbit mesentery (von Andrian et al., 1993). The rolling fraction of normal donor neutrophils in this assay was approximately 30 percent, and LAD I neutrophils behaved similarly. In contrast, LAD II neutrophils rolled poorly and failed to emigrate (Fig. 53.1). Their rolling fraction was only 5 percent (Fig. 53.5), and most of the cells that did interact with endothelial cells had a higher rolling velocity, rolled only over short distances, and frequently detached from the vessel wall. This marked inability to interact with inflamed vasculature was observed only in the presence of intravascular shear force: when the mesenteric blood flow was temporarily stopped and LAD II cells were injected into the nonperfused microvasculature, numerous LAD II cells became stuck and did not detach when the blood flow was subsequently restored. These experiments indicate that the defect in LAD II is due to a shear-dependent inability of neutrophils to roll and slow down in inflamed venules and is not due to a dysfunction of the later integrin-mediated steps in the adhesion cascade.

To examine in vivo extravasation, the response of patient neutrophils to cutaneous inflammation was assessed by both skin-chamber and skin-window techniques. Neutrophil emigration was markedly diminished in both tests, the values being approximately 1.5 percent and 6 percent of normal in the skin-window and skin-chamber tests, respectively (Price et al., 1994). Monocyte migration to the skin-window site was reduced to a similar degree. Notably, neutrophils from a patient with LAD I, studied concurrently, showed the same magnitude of defect in these assays. Nevertheless, as only a residual amount of LAD leukocytes could establish firm adhesions on inflamed vessels, the lack of extravasation could not be attributed to defects in the actual diapedesis/endothelial crossing steps or to chemotactic activity of LAD cells.

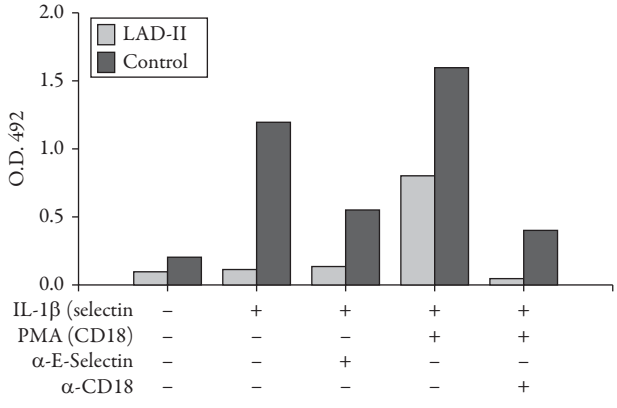

Figure 53.4 LAD II neutrophil adhesion to endothelial cells. Selectin-dependent adhesion of LAD II neutrophils in vitro is impaired in LAD II syndrome. Purified neutrophils from a normal donor (*light shaded columns*) or the LAD II patient (*dark columns*) were incubated for 5 minutes on human umbilical vein endothelial cell monolayers that had been treated with control medium or with recombinant human IL-1. In some wells neutrophil CD18 was activated by addition of PMA. An anti-CD18 monoclonal antibody or an anti–E-selectin monoclonal antibody was added to some wells during incubation. The plates were washed and neutrophil adherence was quantitated by spectrophotometric analysis of the neutrophil-specific enzyme myeloperoxidase (Etzioni et al., 1992; Phillips et al., 1995).

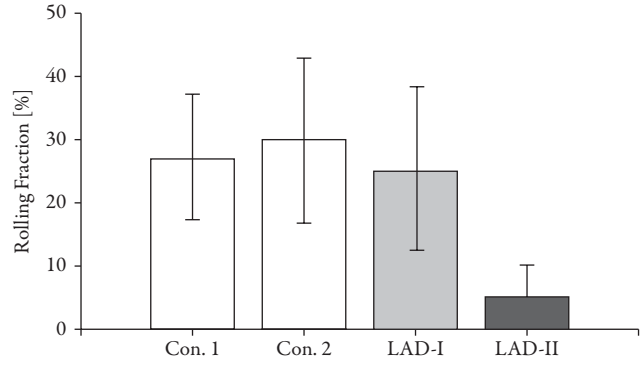

Figure 53.5 LAD I and LAD II neutrophil rolling in inflamed rabbit mesenteric vessel. Selectin-dependent rolling of neutrophils in vivo is reduced in LAD II syndrome. Neutrophil rolling from control subjects and patients with LAD I and LAD II was assessed quantitatively in inflamed mesenteric venules of rabbits. Samples of fluorescent neutrophils were injected into the terminal mesentery artery blood stream 4 to 6 hours after intraperitoneal injection of IL-1. Cells passing through venules in the downstream segment were made visible by stroboscopic epi-illumination and were recorded on videotape. Tapes were analyzed for assessment of neutrophil rolling behavior. The rolling fraction was determined as the percentage of rolling neutrophils in the total flux of fluorescent cells passing a venule during an injection (Arbones et al., 1994). A total of 10 venules was analyzed, 5 vessels for each neutrophil sample in each rabbit. Means ± SD are shown (von Andrian et al., 1993). (Reproduced from the *Journal of Clinical Investigation* 1993;191:2893–2897, by copyright permission of the American Society for Clinical Investigation.)

Adhesion molecules are known to participate in the immune reaction of T lymphocytes (Springer, 1995), and, as noted above, some lymphocyte functions are defective in LAD I (Ochs et al., 1993). In contrast, LAD II patients show a normal proportion and absolute numbers of T-lymphocyte subpopulations. They also exhibit normal proliferative responses to various mitogens, normal NK-cell activity, and normal immunoglobulin levels. Furthermore, in contrast to patients with LAD I, antibody production in response to immunization with bacteriophage 0X174 was found to be normal, with appropriate isotype switching from IgM to IgG (Price et al., 1994). However, delayed cutaneous hypersensitivity reactions were not observed upon intradermal injection of various antigens. This apparent defect may be due to absence of the skin homing T-cell antigen, CLA (Picker, 1994), a fucose-containing glycan related to the SLeX carbohydrate motif lacking in LAD II neutrophils. Therefore, the in vivo immune response to keyhole limpet hemocyanin (KLH) was investigated. Normal KLH-specific in vitro T-cell proliferation and normal in vivo anti-KLH antibody titers were found, indicating normal T- and B-cell function. However, skin testing with KLH failed to elicit a positive reaction (rubor, calor, edema) (Kuijpers et al., 1997a). A biopsy of the site of intradermal KLH injection revealed that the number and phenotype ($CD3^+$) of infiltrating lymphocytes were identical to those of a positive control (except for the lack of CLA staining in the LAD II biopsy). Upregulation of various endothelial adhesion molecules was also similar in the patient and control. The discrepancy between the almost normal histological findings and the absence of an intradermal reaction could be explained by reduced skin homing of subsets of T cells. These T-cell subsets may prime the skin-associated inflammatory reaction and initiate the classical signs of delayed-type hypersensitivity reaction in the skin, but their contribution to inflammatory processes in other tissues is minimal.

Molecular Basis

Because the first two LAD II patients identified were the offspring of first-degree relatives and the parents were clinically unaffected, autosomal recessive inheritance was assumed (Etzioni et al., 1992). In addition to being of the Bombay phenotype (absence of the fucose-containing H antigen), the cells of LAD II patients were found to lack Lewis a and b antigens. Therefore, it was concluded that the biochemical abnormality in LAD II was a general defect in fucosylation of macromolecules (Fig. 53.6). Because at least four different fucosyltransferases would have to be affected to produce complete negativity for SLeX, H, Lewis, and secretor glycoconjugates and the genes in these molecules are not physically linked in the human genome (loci include chromosomes 11, 19p, and 19q), LAD II cannot result from abnormal fucosyltransferase(s). Furthermore, LAD II patients possess normal activity of α-2-fucosyltransferase (Shechter et al., 1995). This transferase is required for H antigen biosynthesis and is defective in individuals who carry the rare Bombay blood phenotype but do not have LAD II. These findings suggest that the primary defect in LAD II must be a general defect in fucose production rather than fucose transferases.

Although the defect in the Palestinian patients was suggested to involve impaired de novo GDP-1-fucose biosynthesis (Karsan et al., 1998), the two enzymes involved in this pathway, GMD and FX protein, were found to be normal, without a mutation in cDNA isolated from LAD II patients. Subsequently, the Turkish child with LAD II was found to have decreased GDP-1-fucose transport into the Golgi vesicles (Lubke et al., 1999). Similar studies were performed in the Palestinian patients and, indeed, the same general defect in fucose transport to the Golgi vesicles was found. Still, marked kinetic differences were observed between the Turkish and the Palestinian patients (Sturla et al., 2001). These findings may explain the different response to fucose supplementation in the Turkish and the Palestinian children (see below). Subsequently, through use of the complementation cloning technique, the human gene encoding the fucose transporter was found to be located on chromosome 11 (Lubke et al., 2001). The Turkish child was homozygous for a mutation at amino acid 147, in which arginine is replaced by cysteine (Lubke et al., 2001; Luhn et al., 2001), whereas the two Palestinian patients examined had a homozygous mutation in amino acid

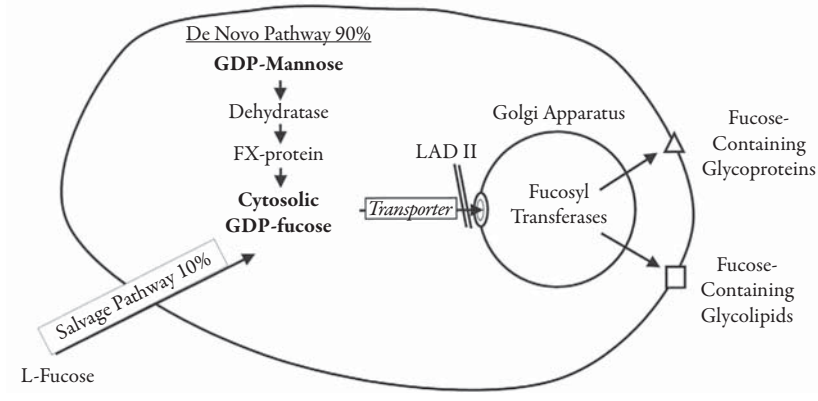

Figure 53.6 LAD II is a congenital disorder of glycosylation. GDP-l-fucose is synthesized in the cytosol and must be transported into the Golgi apparatus where fucosyl transferases are located. In the Golgi, fucosyl transferases add fucose to macromolecules. In LAD II, deficiency of the GDP-fucose transporter prevents fucosylation of membrane glycoproteins and glycolipids.

308, in which threonine is changed to arginine (Lubke et al., 2001). Both mutations are located in highly conserved transmembrane domains of the fucose transporter. The Brazilian patient identified in 2003 has a homozygous single nucleotide deletion (588delG) resulting in frameshift and premature stop codon 34 residuals after the mutation (Hidalgo et al., 2003). LAD II is thus one of the CDGs and is classified as CDG IIc (Lubke et al., 2001). Although only three unique mutations (in five affected patients) have been described thus far, there seems to be a genotype–phenotype correlation (Etzioni et al., 2002). Recently it was observed that some mutations allowed nonfunctional transporter to be present in the Golgi apparatus, while others prevented localization of the transporter in the Golgi (Helmus et al., 2006).

Strategies for Diagnosis

LAD II is a very rare syndrome, but because the clinical phenotype is striking, the diagnosis can be made based on the presence of recurrent, albeit mild, infections, marked leukocytosis, and the Bombay blood group, in association with mental and growth retardation.

Analysis of peripheral blood leukocytes by flow cytometry with an anti-CD15s monoclonal antibody that recognizes the SLeX carbohydrate can readily demonstrate lack of this carbohydrate on patient leukocytes. To confirm the diagnosis, sequence analysis of the gene encoding the GDP-fucose transporter is required.

Carrier Detection and Prenatal Diagnosis

Prenatal diagnosis was carried out successfully through use of a cord blood sample obtained from a female fetus of one of the affected families. Because of the presence of the Bombay blood phenotype, the pregnancy was aborted (Frydman et al., 1996). Once the gene causing LAD II had been cloned, carrier detection became possible, and prenatal diagnosis can be performed earlier with chorionic villus samples for DNA analysis.

Treatment and Prognosis

Each of the LAD II patients described to date suffered from recurrent episodes of infections that responded well to antibiotics. No serious consequences were observed, and prophylactic treatment was never considered in the Palestinian patients, whereas the Turkish child was placed on prophylactic antibiotics. A chronic problem for all patients has been periodontitis, a condition that is especially difficult to treat in children with severe mental retardation (Etzioni et al., 1998). The oldest LAD II patient is now 22 years old and has severe psychomotor retardation, but only mild infectious problems after removal of his teeth.

Because of the proposed defect in fucose production, supplemental administration of fucose through either addition to the diet or intravenous infusion has been suggested. Indeed, fucose supplementation caused dramatic improvement in the condition of the Turkish child (Marquardt et al., 1999). A marked decrease in leukocyte count with improved neutrophil adhesion to endothelial cells was noted in vitro. Furthermore, improvement in developmental delay was observed and no episodes of infections occurred during fucose therapy. Despite this success, the mental retardation remained untreatable.

Notably, the same protocol produced no improvement in laboratory data or clinical symptoms in two Palestinian children (Etzioni & Tonetti, 2000). This difference may be due to the genetic defect in the Turkish child, which results in decreased affinity of the transporter for fucose. An increase in cytosolic concentration of fucose would be expected to overcome, at least in part, the defect in fucose transport.

Selectin- and Selectin Ligand-Deficient Mice

Although the genetic deficiency in LAD II has no direct effect on selectin genes, the resulting defect in fucose metabolism produces a deficiency of fucosylated ligands for endothelial E- and P-selectins. The endothelium in LAD II patients, especially lymph node HEVs and chronically stimulated postcapillary venules likely, also exhibits reduced expression of fucosylated leukocyte L-selectin ligands (Karsan et al., 1998). Thus, with respect to leukocyte adhesion, LAD II patients may suffer from similar defects as mice with combined knockout of E-, P-, and L-selectin genes.

Mice deficient in E- and P-selectin (E/P) and mice deficient in E-, P-, and L- selectin (E/P/L) indeed show leukocytosis, dramatic reduction in leukocyte rolling, markedly reduced emigration into inflamed peritoneum, and increased susceptibility to mucocutaneous infections (Bullard et al., 1996; Frenette et al., 1996; Jung & Ley, 1999; Robinson et al., 1999). In contrast to the E/P- or E/P/L-deficient mice, the two older LAD II patients have had no increase in systemic infections, and the few episodes of localized infection have responded to conventional treatment as in any immunocompetent child. The phenotype of the multiple selectin-deficient animals thus appears to be much more severe than that observed in LAD II, perhaps reflecting differences between humans and mice in susceptibility to mucocutaneous infections. However, the possibility that nonfucosylated ligands participate in selectin interactions in vivo in humans more than in mice has not been completely excluded. A better mimic of LAD II would be mice deficient in biosynthesis of SLeX. The gene encoding $\alpha(1,3)$ fucosyltransferase Fuc-TVII, an enzyme that controls synthesis of SleX-containing glycans both in leukocytes and HEVs, was knocked out in mice, resulting in a phenotype reminiscent of the human LAD II, with defective adhesion and marked leukocytosis (Maly et al., 1996). The same phenotype was observed in mice deficient in core 2 $\beta 1$–6 *N*-acetylglucosaminyl transferase, another critical factor in the synthesis of SLeX (Ellies et al., 1998). However, neither murine model showed any growth abnormalities, confirming that the growth and mental retardation in LAD II is most likely due to the general defect in fucose metabolism and not to the adhesion deficiency.

Golgi GDP-1-Fucose Transport)–Deficient Mice

To investigate further the role of the Golgi GDP fucose transporter, knockout mice were generated (Sic35c1$^{-/-}$ mice). Such mice displayed severe growth retardation, an elevated postnatal mortality rate, and severe impairment of P-, E-, and L-selectin–mediated rolling functions in multiple types of leukocytes (Hellbusch et al., 2007). Furthermore, a tremendous reduction of fucosylated glycoconjugants in many organs and isolated cells was observed. In a follow-up report the Sic35c1$^{-/-}$ mice demonstrated a defect in rolling that was accompanied by strong but not completely abolished leukocyte adhesion. Although strong defective leukocyte trafficking was observed, normal lymphocyte homing to the spleen was noted (Yakubenia et al., 2008), which may explain the largely normal lymphocyte function in LAD II.

LAD III

More recently, a rare, autosomal recessive LAD syndrome distinct from LAD I and LAD II has been reported in multiple patients of Turkish, Palestinian, and Maltese origin (Kuijpers et al., 1997b; McDowall et al., 2003). All patients had similar clinical symptoms, characterized by severe recurrent infections, a bleeding tendency, and marked leukocytosis (Table 53.2).

Some of these unique patients were considered as LAD I variants (Kuijpers et al., 1997b; McDowall et al., 2003) due to the severely impaired β_2-integrin functions associated with this syndrome. Because LAD I leukocytes have defects in integrin expression or structure, it was proposed that this group of integrin-activation disorders be designated *LAD III* (Alon & Etzioni, 2003; Kinashi et al., 2004).

Although leukocyte integrin expression has been found to be normal in LAD III (OMIM612840), in situ activation of all major leukocyte integrins, including LFA-1, Mac-1, and VLA-4, by chemokines or chemoattractants is severely impaired in patient-derived lymphocytes and neutrophils. In addition, a marked defect in platelet aggregation was described and demonstrated to be associated with inability of the major platelet integrin, GpIIbb3, to undergo activation by multiple agonists (Kuijpers et al., 1997b). Whereas the rolling of LAD III leukocytes on endothelial surfaces is normal, lymphocytes fail to arrest on endothelial integrin ligands in response to endothelial-displayed chemokines, while neutrophils fail to arrest on integrin ligands after short rolling on E-selectin (Fig 53.7) (Alon et al., 2003). G-protein–coupled receptor (GPCR) signaling appears to be normal, and the ability of leukocytes to migrate toward a chemotactic gradient is not impaired. The key defect in this syndrome was originally attributed to a genetic loss of integrin activation by GPCR signaling (Alon et al., 2003). Nevertheless, in all of the LAD III cases studied, variable defects in activation of leukocyte integrins by non–GPCR-mediated signals, such as phorbol esters and integrin ligands, were observed (Kuijpers et al., 1997b; McDowall et al., 2003). Furthermore, cell lines derived from patient lymphocytes failed to spread on isolated integrin ligands even in the absence of exogenous agonists (Malinin et al., 2009; Svensson et al., 2009).

Although integrins are expressed normally on all patient cells, neither β_2 or β_3 integrins can undergo inside-out conformational activation, and both Mac-1 and GpIIbIIIa fail to bind soluble ligands in response to potent agonists (Malinin et al., 2009; Pasvolsky et al., 2007). As these processes were shown to require a variety of GTPases, the LAD III phenotype was predicted to involve the loss of a GTPase or of one of its activating guanine nucleotide exchange factors (GEF) in both leukocytes and platelets of LAD III patients.

Molecular Basis

While for several years the primary genetic defect was elusive, recent studies of integrin-activation defects in knockout mouse models revealed the molecular basis of the disease. A

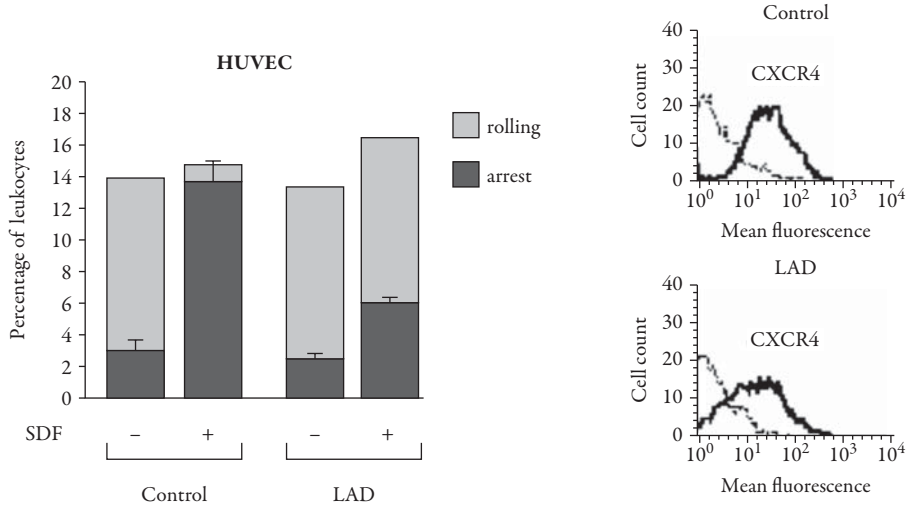

Figure 53.7 Defective adhesion of lymphocytes to human umbilical vein endothelial cells (HUVECs) after stimulation with chemokine in LAD III. While the rolling of lymphocytes is normal in LAD III, a marked decrease in lymphocyte adhesion after stimulation with chemokine (SDF1) can be observed (left panel), although chemokine ligand (CXCR4) is expressed normally (right panel).

critical component of integrin activation by GPCR signals is the GTPase Rap1. Although Rap1 expression is widespread in all tissues, "inside-out" activation of integrins triggered by GPCR signals was recently linked to a novel Rap1 GEF, CalDAG-GEF-1, which is expressed mainly in platelets, leukocytes, and brain. This GEF catalyzes the exchange of GTP for GDP bound to Rap1 and is crucial for GPCR-mediated integrin activation in platelets and neutrophils (Crittenden et al., 2004). A mouse knockout model exhibited the same defects in β_1-, β_2-, and β_3-integrin activation in both platelets and leukocytes, suggesting that this mouse model represents a model for the molecular defect in LAD III (Bergmeier et al., 2007). Indeed, a large group of LAD III patients, all from Turkish origin, exhibit a splice junction mutation in their *CalDAG-GEF-1* (official symbol *RASGRP2*) gene with nearly complete loss of messenger RNA and protein expression in patient platelets, neutrophils, and primary T lymphocytes (Pasvolsky et al., 2007). Nevertheless, other patients of non-Turkish origin were found to express normal CalDAG-GEF-1, and cell lines derived from these patients exhibited intact Rap1 activation (Malinin et al., 2009). Since these cell lines exhibited defective spreading on isolated integrin ligands as well as defects in integrin activation by non-GPCR agonists, the LAD III phenotype of these patients could represent a broader defect in integrin conformation downstream of chemokine receptors and GPCR-triggered GTPases. The cytoplasmatic tails of the different integrins affected in LAD cells are rather short but are recognized by various adaptor proteins, which bind and promote integrin affinity to their ligands either by inside-out signals or by being occupied by integrin ligands that induce extensive conformational changes of the extracellular domain of the integrin, a process termed outside-in integrin activation (Hynes, 2002). One such key adaptor with broad activities is talin, shown to activate integrin affinity and adhesiveness in many cellular systems (Moser et al., 2009b).

Talin 1, the predominant talin expressed in hematopoietic cells, plays a critical role in integrin activation in all cell types, and its deletion in mice is embryonically lethal (Legate & Fassler, 2009); however, talin deficiency was ruled out in LAD III patients.

A breakthrough in the search for the molecular defect causing LAD III was achieved when a family of integrin cytoplasmic tail binding adaptors, termed Kindlins, were identified as being of crucial importance for maximal integrin affinity regulation of talin (Ma et al., 2008). One of these three family members, Kindlin-3, is nearly exclusively expressed on hematopoietic cells (Ussar et al., 2006). Kindlin-3 (OMIM607901) is located on chromosome 11q12 and has a molecular weight of 75.9 KD. It consists of 667 amino acids and 15 exons. Platelet aggregation and GPCR-triggered integrin activation were diminished in kindlin-3 knockout mice (Moser et al., 2008). A subsequent study on neutrophils and monocytes derived from these kindlin-3 knockout mice revealed total loss of β2 integrin adhesiveness both in vivo and in vitro as well as defective activation of the monocyte β_1 integrin, and VLA-4 by chemokine signals (Moser et al., 2009a). Thus, kindlin-3 knockout mice represented a genetic model of a LAD III-like phenotype. Furthermore, Kindlin-3 was found to be also involved in osteoclast-mediated bone resorption (Schmidt et al., 2011). Interestingly, some LAD III patients develop osteopetrosis-like features (Kilic & Etzioni, 2009; Malinin et al., 2009; Sabnis et al., 2010). Since, unlike talin, Kindlin-3 expression is restricted to platelets, leukocytes, and red blood cells, the global integrin deficiency in β_3, β_2, and β_1 integrin members expressed by these multiple cell types in mice suggested that Kindlin-3 deficiency, on its own, could be the cause of LAD III in humans expressing intact CalDAG-GEF-1.

Indeed, mutation analysis of Kindlin-3 (official symbol FERMT3) revealed homozygous mutations in most LAD-III patients regardless of their origin (Table 53.3). Sequencing of the *Kindlin-3* gene revealed a homozygous nonsense mutation (R513X) in three Turkish patients that carry also a CalDAG-GEF-1 mutation (Mory et al., 2008). Kindlin-3 and CalDAG-GEF-1 are both located at 11q12–13, although the two genes are 503,029 bp apart, suggesting that both mutations were inherited as a common allele in these patients. Subsequent studies (Kuijpers et al., 2009; Malinin et al., 2009; Robert et al., 2011; Svensson et al., 2009) showed several distinct mutations in Kindlin-3 in multiple non-Turkish LAD III patients, all of Middle Eastern or Mediterranean origin. An African-

*This mutation was found in several Turkish families, while all other mutations were described as occurring only once in a single individual family.

American patient with two novel homozygous mutations on each allele (one possibly a polymorphism) was also reported recently (Table 53.3) (McDowall et al., 2010). Regardless of the location of these mutation, all patients exhibited decreased Kindlin-3 mRNA levels and total loss of protein expression. Transfection of patient-derived lymphoblast lines with wild-type Kindlin-3 rescued the LAD III defect by restoring integrin-mediated adhesion spreading and motility (Malinin et al., 2009; McDowall et al., 2010; Svensson et al., 2009). Kindlin-3 binds to an NXXY motif on the cytoplasmic tail of the β subunit of LFA-1 (Moser et al., 2009b), facilitating the binding of the cytoskeletal protein talin to the cytoplasmic tail of the β subunit, thus initiating the formation of the integrin-activating membrane complex. Thus, Kindlin-3 selectively contributes to the TCR-triggered outside-in stabilization of bonds generated between chemokine-primed LFA-1 molecules and cell-surface ICAM-1 (Feigelson et al., 2011).

Treatment and Prognosis

Patients with LAD III suffer from similar infectious episodes as those with LAD I and thus need prophylactic antibiotics. Since in addition to β_2-integrin deficiencies, α_4 integrins on lymphocytes and monocytes are also defective, the emigration of these leukocyte subsets is more severely impaired than in LAD I, in which these integrins remain functionally intact. Due to their bleeding tendency, blood transfusions are often required; several patients died from bleeding episodes (Kuijpers et al., 2007). The only possible curative therapy of this global integrin activation deficiency is bone marrow transplantation (Elhasid et al., 2010; Sabnis et al., 2010), which corrects all clinical symptoms, including recurrent infections, bleeding tendency, and osteopetrosis.

Kindlin-3–Deficient Mice

In addition to their LAD III phenotype, mice lacking kindlin-3 suffer from fatal anemia, which is caused by excessive hemorrhage due to impaired platelet aggregation and defects in red blood cell production, possibly due to defective maturation from erythroid precursors that require kindlin-3 and integrins for its proper differentiation (Kruger et al., 2008; Moser et al., 2008). This defect is not observed in affected humans. The mice also show markedly reduced size and cellularity of spleen and thymus, lack detectable lymph nodes, and have lymphopenia, which may reflect defects in B-cell production and impaired migration of precursor T-linage cells to the lymphoid organs (Moser et al., 2009a). In contrast, in LAD III patients, T- and B-lymphocyte counts are elevated due to impaired emigration to peripheral lymphoid tissues, but lymphocyte generation from precursor cells appears normal.

OTHER LAD DISEASES

E-selectin Deficiency

Another potentially inherited defect in leukocyte trafficking resulting in deficient selectin function was described in a child with moderate neutropenia and severe recurrent infections (DeLisser et al., 1999). The syndrome is associated with markedly reduced expression of E-selectin on blood vessels of inflamed tissue with increased levels of circulating soluble E-selectin, suggesting increased endothelial cleavage of otherwise normally expressed E-selectin. Notably, the E-selectin gene sequence was normal, suggesting an abnormality in endothelial proteolytic activity, which could also affect the shedding of other proadhesive and proinflammatory endothelial surface molecules.

Rac-2 Deficiency

Two patients were reported with Rac-2 deficiency who in many aspects resemble LAD I patients, presenting with omphalitis and neutrophilia with defective neutrophil adhesion and migration. However, these patients presented with a marked defect in NADPH oxidase activity and F-actin formation, findings that distinguish them from LAD I (Pai et al., 2010).

CONCLUSIONS

The crucial role of the β_2-integrin subfamily in leukocyte emigration was convincingly demonstrated after LAD I was discovered. Patients with this disorder suffer from life-threatening bacterial infections. In its severe form, death usually occurs in early childhood unless bone marrow transplantation is performed.

The LAD II disorder clarifies the role of the selectin receptors and their fucosylated ligands such as SLeX. In vitro as well as in vivo studies establish that this family of adhesion molecules is essential for leukocyte rolling, the first step in leukocyte emigration through blood vessels. Clinically, patients with LAD II suffer from a less severe form of disease, resembling the moderate phenotype of LAD I. This may be due in part to the ability of LAD II neutrophils and lymphocytes to use integrins and other adhesion receptors to emigrate from blood vessels with low blood flow rates. The molecular defect responsible for LAD III, the most severe LAD syndrome, is due to loss of the hematopoietic integrin coactivator Kindlin-3, resulting in combined defects in leukocyte and platelet adhesion, migration, and aggregation. As in severe LAD I, death usually occurs in early childhood and bone marrow transplantation is the only curative treatment available. Prenatal diagnosis can be offered to families with a known heterozygous pregnant carrier if mutations in any of the known LAD genes have been identified.

INHERITED HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS SYNDROMES

Geneviève de Saint Basile

Several hereditary disorders of the immune system are characterized by the occurrence of a similar T lymphocyte and macrophage activation syndrome, also called hemophagocytic lymphohistiocytosis (HLH) syndrome or accelerated phase of the disease, which is generally fatal in the absence of treatment (Menasche et al., 2005). Hemophagocytic syndrome is characterized by lymphoid organ and extranodal infiltration by polyclonal, activated T cells and activated macrophages that phagocytose blood cells (Henter et al., 1991a). HLH is in most cases triggered by a viral infection, especially of the herpes group (Epstein-Barr virus [EBV] and cytomegalovirus [CMV]). Four inherited disorders have been identified that lead to HLH syndrome (Menasche et al., 2005): the familial hemophagocytic lymphohistiocytosis (FHL) (MIM 267700), the Griscelli syndrome (GS) (MIM 214450), the Chediak-Higashi syndrome (CHS) (MIM 214500), and the X-linked lymphoproliferative syndromes (MIM 308240). Recently, HLH was also reported in an unique patient with a form of Hermansky-Pudlak syndrome type 2 (Enders et al., 2006). Only autosomal recessive disease will be discussed in this chapter, the X-linked disorders being addressed in other chapters (Chapter 44). The primary causes of HLH should be distinguished from lymphohistiocytic proliferation with hemophagocytosis, which develops secondary to severe infections in an immunocompromised host, or during the course of malignancies (Janka et al., 1998).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF INHERITED HLH

The clinical presentation of HLH may vary widely. In nearly all patients, high fever, frequently undulant and protracted, is the first sign, in association with hepatomegaly and splenomegaly. Pallor, anorexia, vomiting, and irritability are often noted. Transient uncharacteristic skin rash and moderate lymph node enlargement may occasionally be observed. Signs of central nervous system (CNS) involvement may be pronounced and early, but more commonly they develop later during disease progression. Neurological symptoms consist mostly of seizures, hypotonia or hypertonia, ataxia, hemiplegia, or nonspecific signs of increased intracranial pressure. Nonspecific findings such as jaundice, edema, and failure to thrive as well as purpura and bleeding resulting from thrombocytopenia may be associated (Table 54.1).

PATHOLOGICAL FEATURES

The major histological finding is infiltration of the various organs by a nonmalignant activated lymphocyte population, mainly of the $CD8^+$ T-cell phenotype, associated with macrophage cell infiltration (Billiau et al., 2005; Farquhar & Claireaux, 1952; Henter et al., 1991a). The infiltrating lymphocytes and macrophages are most prominent in the interstitial and perivascular spaces of the organs. Activated macrophages may engulf erythrocytes, leukocytes, and platelets, their precursors, and cellular fragments, a process known as hemophagocytosis (Color Plate 54.IA). These cells appear "stuffed" with other blood cells. All organs may be infiltrated, predominantly the spleen, liver, bone marrow, lymph nodes, and CNS (Haddad et al., 1997; Henter & Nennesmo, 1997). Importantly, pathological analysis should be repeated if initially negative in the presence of strong clinical and biological suspicion of HLH.

When examined at an early stage, the white pulp of the spleen is often reduced in size and depleted of lymphocytes, whereas the red pulp is expanded as a result of the mononuclear cell infiltration. In the liver, portal tracts are the place of moderate to extensive lymphocytic infiltration; in the lymph nodes, sinuses are frequently involved and dilated (Henter

Table 54.1 CLINICAL AND BIOLOGICAL FEATURES OF HLH SYNDROME

CLINICAL MANIFESTATION	BIOLOGICAL MANIFESTATIONS
High fever	Cytopenia
Edema	Hypofibrinogenemia
Hepatomegaly	Hypertriglyceridemia
Splenomegaly	Elevated liver enzymes
Icterus, skin rash	Cerebrospinal fluid pleocytosis
Neurological symptoms	Low natural killer cell activity
	Presence of activated T lymphocytes and macrophages infiltrating various organs
	Hemophagocytosis by activated macrophages

Table 54.2 T LYMPHOCYTE AND MACROPHAGE ACTIVATION MARKERS DURING HLH SYNDROME

LYMPHOCYTE ACTIVATION	MACROPHAGE ACTIVATION
Expression of HLA DR$^+$, CD25$^+$, Fas$^+$	High serum level of TNF-α, IL-6, neopterin
High serum level of soluble CD8 and CD25	Hemophagocytosis
High serum level of IFN-γ	

et al., 1998). Hemophagocytic cells are predominantly found in the T-cell areas, frequently depleted of lymphocytes in the later stages of the disease. CNS infiltration begins generally in the meninges, then perivascular changes occur, leading to diffuse infiltration of the tissue and multifocal necrosis at a later stage.

LABORATORY FINDINGS

Viral infection, principally of the herpes group such as EBV, can be identified at the onset of the disease. However, in many cases viral, bacteriological, and serological investigations fail to implicate a known infectious agent.

At the onset of the disease, most patients present with anemia, thrombocytopenia, and, to a lesser degree, neutropenia. Leukopenia at first presentation is less frequent, and an initial leukocytosis is reported in 15 percent of patients. Nearly all patients become severely pancytopenic during disease progression. In the cerebrospinal fluid, moderate pleocytosis ($5–50 \times 10^6$/L), consisting mostly of lymphocytes and occasionally monocytes as well as an increased protein level, is observed in about half of the patients early in the course of the disease (Arico et al., 1996; Haddad et al., 1997; Janka, 1983). However, spinal fluid may be normal even in children with encephalitis. Hyperdense areas, atrophy, and brain edema may be found by magnetic resonance imaging or computed tomography scan, particularly later during the prolonged course of the disease.

Signs of liver dysfunction or cytolysis are constant findings and include hypertriglyceridemia, hyperbilirubinemia, elevated serum transaminases, elevated ferritin, hyponatremia, and hypoproteinemia. Coagulation abnormalities are common during active disease, particularly hypofibrinogenemia.

IMMUNOLOGICAL FINDINGS

The proliferative response of peripheral blood lymphocytes to phytohemagglutinin (PHA) and antigen is normal. However, markedly decreased natural killer (NK) cell activity is a consistent finding of inherited HLH associated in most of the conditions (see below) with a decrease in T-cell cytotoxic activity, a function that does not normalize during the remission phase. Activated CD8$^+$ T cells and, to a lesser extent, CD4$^+$ T cells are observed during the course of an active HLH. T-cell count may be transiently increased but then decreased, as with the other hematopoietic lineages. High levels of soluble CD8 and CD25 molecules as well as hypercytokinemia with elevated serum levels of inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), and interleukin (IL)-6, are striking features of HLH and reflect the T-lymphocyte and macrophage activation (Billiau et al., 2005; Henter et al., 1991b) (Table 54.2).

UNDERSTANDING THE PATHOPHYSIOLOGY OF HLH

Our understanding of inherited disorders leading to HLH has been revolutionized in the past 10 years by the molecular characterization of most of these disorders. This has shown that genes associated with inherited forms are part of the cytotoxic granule-mediated cell death pathway (see below) and shed light on a previously unsuspected role for this pathway in lymphocyte homeostasis (de Saint Basile & Fischer, 2001; Menasche et al., 2005). Importantly, they clearly show that T cells are the trigger for HLH, and gaining better control of T-cell activation is the best way to manage and control the disease.

CYTOTOXIC GRANULE-MEDIATED CELL DEATH PATHWAY

The granule-dependent cytotoxic pathway is a rapid powerful and iteractive mechanism adapted to the killing of virus-infected cells as well as tumor cells (reviewed in de Saint Basile & Fischer, 2001; Fischer et al., 2007; Menager et al., 2007; Voskoboinik et al., 2006). Cytotoxic T cells are activated by specific antigen recognition, whereas the cytotoxic activity of NK cells is initiated by specific activating receptors or combinations thereof and is inhibited by self MHC class I recognition. Cytotoxic T lymphocytes (CTLs) and NK cells contain cytoplasmic granules that can undergo regulated secretion of their content in response to external stimuli. These granules contain perforin (the central protein for CTL-mediated killing), granzyme, and other granule components (hence the

term "cytotoxic granules"). The process of cytotoxic granule secretion itself, which is triggered by target cell recognition, is characterized by a series of sequential events in the cytotoxic cells. First, the microtubule-organizing center (also called the "centrosome") is polarized toward the cell–cell contact, where an immunological synapse (IS) forms. Next, cytotoxic granules move toward the microtubule-organizing center, are released from the microtubules, and dock with the plasma membrane at the secretory domain of the IS. Cytotoxic granules then coalesce with endosomal exocytic vesicles. The coalesced granules then are primed and fuse with the plasma membrane, and the contents of the granules are released into the synaptic secretory cleft. Then, perforin and granzyme cooperate to mediate apoptosis of the target cell within a few minutes of receptor engagement. Not all granules are exocytosed, and the remainder are ready for a new target interaction and killing.

ROLE OF CYTOTOXIC ACTIVITY DEFICIENCY IN HLH PATHOGENESIS

The most obvious explanation for this is the persistence of antigen-presenting cells, which are not properly eliminated when cytotoxicity is impaired. Although T-cell–mediated recognition leads to T-cell activation and clonal expansion, lymphocytes deficient in cytotoxic function fail to kill the infected cells and thus to remove the source of antigen stimulation. Persistently activated T cells, which produce high quantities of cytokines (e.g., INF-γ), induce macrophage activation (Fig. 54.1). The sustained macrophage activation results in tissue infiltration and the production of high levels of IL-6, IL-18, and TNF-α, which play a major role in the various clinical symptoms and in tissue damage (Binder et al., 1998; Kagi et al., 1999; Matloubian et al., 1999; Nansen et al., 1999). In fact, there is a striking resemblance between the biological changes induced by inflammatory cytokines and the clinical and laboratory findings that characterize HLH (Henter et al., 1991b). However, the fact that, in most cases, HLH is not associated with a high load of the triggering infectious agent suggests that additional mechanisms may also play a role.

An alternative—not mutually exclusive—mechanism involves cytolysis having a direct function in killing T cells engaged in a given immune response. CTLs could either commit suicide or kill each other. The former mechanism is not compatible with a positive transdominant effect of functional CTLs observed following hematopoietic stem cell transplantation in patients with HLH (Ouachee-Chardin et al., 2006). It has indeed been observed that the presence of 20 percent of donor cells is sufficient to control HLH over at least 10 to 20 years after hematopoietic stem cell transplantation (Ouachee-Chardin et al., 2006). For a CTL to kill another CTL implies that it can recognize the proper Ag-MHC complex at its surface. This mechanism could be operating because, in vitro, it has been shown by several groups that, upon target-cell killing, CTLs can reap off parts of the target membranes that can be incorporated into their own plasma membrane (Huang et al., 1999; Stinchcombe et al., 2001b), making this cell a target for a sister CTL. The key question that is difficult to address experimentally is whether this mechanism takes place in vivo in a quantitative way that is sufficient to transform billions of CTLs into target cells within a few days. Regulatory T cells armed with the cytotoxic equipment were also reported (Grossman et al., 2004), which may participate in the contraction phase of a T-cell–mediated immune response. Ultimately, a regulatory role of cytotoxic NKT cells should also be considered based on the observation that human CD4- CD8aa NKT cells can kill in vitro antigen-presenting cells or T cells in a CD1d-restricted manner and thus contain T-cell expansion (Ho et al., 2004).

INHERITED CONDITIONS WITH OCCURRENCE OF HLH

FHL

FHL, inherited as an autosomal recessive disease, was first described by Farquhar and Clairaux as familial erythrophagocytic lymphohistiocytosis (Farquhar & Claireaux, 1952). Since then, the incidence of FHL has been estimated to be 1:50,000 births (Dufourcq-Lagelouse et al., 1999a; Henter et al., 1991c). Overwhelming HLH is the distinguishing and isolated feature in this disorder with no other associated signs, unlike the other inherited conditions. Symptoms of HLH are usually evident within the first 3 months of age and can even develop in utero or at birth (Lipton et al., 2004). In contrast, familial forms have been reported with

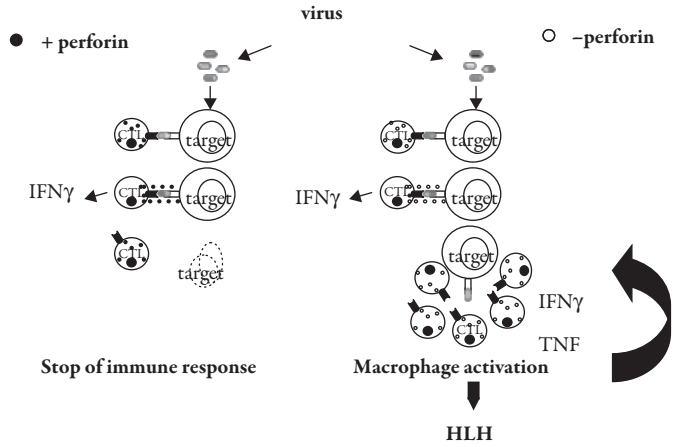

Figure 54.1 *Pathophysiology of HLH.* In response to a viral infection, antigen-specific cytotoxic T cells (CTLs) will expand, secrete soluble mediators (IFN-γ) that enhance immunity and interfere with viral replication, and mediate lysis of infected cells. These various mechanisms participate in downregulation of the immune response. In cytotoxic-deficient cells (perforin-deficient cells (– perforin) on the scheme), uncontrolled increased expansion of antigen-specific effectors occurs. Activated lymphocytes secrete high levels of INF-γ and induce a feedback loop on macrophages and T cells, which continuously activate each other and expand. High levels of inflammatory cytokines are secreted, including IFN-γ, TNF-α, and interleukins 6 and 18. Activated macrophages phagocytose bystander hematopoietic cells (hemophagocytosis). Activated lymphocytes and macrophages infiltrate various organs, resulting in massive tissue necrosis and organ failure.

a later onset (Arico et al., 1996; Henter et al., 1998; Janka, 1983). Several studies suggest that within a family, a tendency toward a similar age at onset is observed. HLH most often occurs in previously healthy young children, suggesting the need for an exogenous trigger prior to the onset of clinical manifestations. In susceptible children, infection with intracellular pathogens (viral and fungal, among others) is the most likely trigger for disease manifestation (Feldmann et al., 2002). HLH in FHL is invariably lethal unless treatment with allogeneic stem cell transplantation is performed (Jabado et al., 1997).

Molecular Basis of FHL

Previously, linkage analysis using homozygosity mapping in four inbred FHL families of Pakistani descent identified a locus (FHL1) on chromosome 9q21.3–22 (Ohadi et al., 1999). However, no causative gene has been so far associated with this locus. Association of this locus with FHL seems restricted to Pakistani families, although not all FHL cases in Pakistani families segregate with this locus (Feldmann et al., 2003). Using genome-wide linkage analysis, three additional loci have been identified on chromosomes 10q21–22 (FHL2) (Dufourcq-Lagelouse et al., 1999a), 17q25 (FHL3) (Feldmann et al., 2003), 6q24 (FHL4) (zur Stadt et al., 2005), and 19p13 (FHL5) and there is further evidence of additional genetic heterogeneity and of yet undefined gene(s) (unpublished data) (Table 54.3).

Perforin Deficiency in FHL2

The cytolytic effector perforin (PRF1), present in cytotoxic granules, is the first gene product identified as causing FHL (Goransdotter Ericson et al., 2001; Stepp et al., 1999) (Table 54.3). The perforin gene comprises three exons, of which only exons 2 and 3 are translated, encoding for the 555–amino acid polypeptide (Lichtenheld et al., 1988). As a consequence of perforin gene mutations, perforin protein expression is diminished to barely detectable in cytotoxic granules (Feldmann et al., 2002; Kogawa et al., 2002; Stepp et al., 1999), leading to defective cytotoxic activity. In normal cells, following release from lytic granules, perforin is thought to oligomerize in order to form pore-like structures in the target cell membrane, analogous to the C9 component of complement (Lukoyanova & Saibil, 2008; Stepp et al., 2000). Failure of perforin activity is etiologically linked to the development of FHL, and its deficiency accounts for one third of FHL cases (Stepp et al., 1999; Ueda et al., 2003; Zur Stadt et al., 2006). Over 50 different mutations in the perforin gene have been found in FHL2 patients; they consist of microdeletion, nonsense, or missense mutations. These mutations are distributed all along the sequence. Some perforin mutations recur in the same ethnic populations, which suggests common ancestors. For example, the Trp374 stop (1122G>A) appears to occur at high frequencies in Turkish families, the L364 frameshift (1090delCT) in the Japanese population, and the L17 frameshift (50delT) alteration in the African population (Lee et al., 2006). Some peculiar mutations of the perforin gene have been observed that specifically affect proteolytic cleavage and thus maturation of the protein (Katano et al., 2004), or its calcium-binding ability (Feldmann et al., 2005; Voskoboinik et al., 2004). Most of these mutations result in undetectable expression of perforin in lytic granules. Mutations only partially impairing perforin expression and function are rare but were shown to result in atypical (late-onset) disease. Among them the substitution Ala91Val, found with high frequency in healthy individuals (4 to 8 percent), was first considered as a neutral polymorphism. Further studies demonstrated that the A91V variant results in a partial loss (50 percent) of PRF1-dependent cytotoxicity and strongly suggested that the A91V polymorphism can predispose to atypical disease expression if inherited as a homozygote and can cause HLH if inherited with a second perforin allele with "null" activity (Voskoboinik et al., 2007). Recent reports also bring convincing evidence that some temperature-sensitive mutations in perforin may be associated with delayed FHL onset and predisposition to hematological malignancy (Chia et al., 2009).

Munc13–4 Deficiency in FHL3

Patients whose disease is associated with FHL3 locus present with typical features of FHL and are indistinguishable from patients with perforin defect (FHL2). However, in patients with FHL3, perforin is normally expressed and functional. FHL3 was found associated with mutations in the gene *UNC13D* encoding for hMunc13–4, a member of the Munc13-UNC13 family (Feldmann et al., 2003) (Table 54.3) This gene contains 32 exons that encode a 123 kDa protein. Two calcium-binding (C2) domains separated by long sequences containing two Munc13-homology domains (MHD1 and MHD2) structurally characterize hMunc13–4. Most of the mutations so far identified in *UNC13D* are missense mutations, deletions, splice-site mutations, or nonsense mutations predicted to result in major changes in the protein (Marcenaro et al., 2006; Santoro et al., 2006; Zur Stadt et al., 2006; Sieni et al., 2011). Study of exocytosis of cytotoxic granules in lymphocytes from patients with FHL3 mutations showed that Munc13–4 was required for the release of the lytic granule contents of both CTLs and NK cells, but not for other secretory pathways, including the secretion of IFN-γ from TCR-activated lymphocytes (Feldmann et al., 2003; Marcenaro et al., 2006; Ueda et al., 2006). Thus, hMunc13–4 is an essential effector of the cytolytic granule pathway. Munc13–4–deficient lymphocytes can make normal contacts with target cells, stable conjugates, and polarize the lytic machinery as efficiently as do control lymphocytes. However, when Munc13–4 is lost in CTLs, cytotoxic granules dock at the membrane in the immunological synapse but are not released. This supports a role for Munc13–4 at a late step of this pathway in exocytosis, subsequent to docking. Munc13–4 is most probably required at a priming step of lytic granule secretion, following granule docking and preceding plasma granule membrane fusion (Feldmann et al., 2003; Stinchcombe et al., 2001b). An additional role of Munc13–4 upstream of its role as a priming factor at the IS was recently show. Munc13–4 is in fact required in the formation of a pool of endosomal vesicles that coalesce with cytotoxic granules before their exocytosis (Menager et al., 2007). Of interest, Munc13–4 is expressed in multiple cell types, including platelets and lungs; however, the phenotype of FHL3 patients is not different from that of patients with perforin deficiency. FHL3 accounts for about one third of the FHL cases.

Syntaxin 11 Deficiency in FHL4

Patients with FHL4 carry mutations in the syntaxin 11 gene (*STX11*) (zur Stadt et al., 2005), a member of the soluble N-ethylmaleimide sensitive factor attachment protein receptor present on target membrane (tSNARE) family of proteins involved in membrane fusion events (Table 54.3). All of the mutations in *STX11* so far reported are null mutations and most of them were identified in patients from Turkish origin, where they account for approximately 20 percent of the FHL patients (Zur Stadt et al., 2006). Although a defective cytotoxic activity of FHL4 patients' NK cells is clearly detected, defective cytotoxic activity of syntaxin 11-deficient CTLs are more difficult to detect by standard techniques. In addition, IL-2 stimulation partially restores cytotoxic NK-cell defects (Bryceson et al., 2007). Syntaxin 11 is thus another effector of the cytotoxic machinery required for the release of cytotoxic granules contents, likely by regulating membrane fusion events (Arneson et al., 2007). The precise step of the cytotoxic pathway regulated by syntaxin 11 remains to be characterized. The fact that this genetic form of FHL (FHL4) with partial NK-cell cytotoxic defect and those with severe impairment of this activity in both NK and T lymphocytes (FHL2 and FHL3) have indistinguishable phenotypes strongly suggests that the in vitro assays used to date do not, in fact, fully reflect the in vivo behavior of cytotoxic cells. Alternatively, additional mechanism(s) with impairment of NK-cell cytotoxic activity may operate in FHL4 (Zhang et al., 2008).

Munc18–2 Deficiency in FHL5

The most recently identified cause of FHL, FHL5, is a deficiency of the syntaxin-binding-protein-2 (*STXBP2)* gene, which encodes Munc18–2 (Cote et al., 2009; zur Stadt et al., 2009). STXBP2/Munc18–2 belongs to the SM family of fusion accessory proteins. These proteins are partners of SNARE protein, playing a complementary role in membrane fusion (Toonen et al., 2003; Südhof and Rothman, 2009). Like syntaxin 11, STXBP2/Munc18–2 is widely expressed. The various mutations identified in this gene affect protein stability (Cote et al., 2009; zur Stadt et al., 2009; Cetica et al., 2010). These mutations seems to be correlated with phenotype, in terms of age at onset and disease severity (Cote et al., 2009; Pagel et al., 2012). In addition to the classic FHL findings, atypical features including sensorineural hearing deficit, abnormal bleeding and severe diarrhea were reported (Pagel et al., 2012). Syntaxin 11 levels are very low in STXBP2/Munc18–2-deficient lymphoblasts and these two proteins can be coimmunoprecipitated. Thus, syntaxin 11 is probably the main partner of Munc18–2 in lymphocytes, requiring Munc18–2 for stable expression. Consistent with the pathophysiological features of FHL, Munc18–2-deficient NK cells have impaired cytotoxic activity that is partially restored by IL2 stimulation, as previously reported for syntaxin 11-deficient NK cells (Cote et al., 2009; zur Stadt et al., 2009; Cetica et al., 2010). A role for Munc18–2 in late stages of the exocytosis pathway is supported by the observation that the perforin-containing granules of Munc18–2-deficient NK cells are normally polarized towards cognate target cells, despite the impairment of exocytosis preventing them from releasing their contents (Cote et al., 2009). Thus, the same defective cytotoxic phenotype characterizes both syntaxin 11 and STXBP2 deficiencies, providing support for the existence of a functional interaction between these two proteins in the degranulation process.

GRISCELLI SYNDROME

GS (MIM 214450) is an autosomal recessive heterogeneous disorder characterized by pigmentary dilution, with a silvery-gray sheen of the hair and a typical pattern of uneven distribution of large pigment granules easily detectable

by light-microscopic examination (Color Plate 54.IIB) (Griscelli et al., 1978; Klein et al., 1994). Sun-exposed areas of patients' skin are often hyperpigmented, and microscopic dermis–epidermis junction analysis detects accumulation of mature melanosomes in melanocytes, contrasting with the hypopigmented surrounding keratinocytes (Griscelli et al., 1978). This typical pigmentary dilution is either associated with the occurrence of an HLH (GS2) (Ménasché et al., 2000) or primary neurological feature (GS1) (Pastural et al., 1997) or can be an isolated finding in rare patients (GS3) (Menasche et al., 2003b), defining three genetic forms of the syndrome (GS1, GS2, and GS3).

Clinical and Pathological Manifestations

The single most consistent cutaneous expression of partial albinism in patients with GS is a silvery-gray sheen to their hair (Klein et al., 1994; Menasche et al., 2003b). This is more obvious in patients with black hair but is also visible in patients with blond hair. Patients generally have lighter hair than that of their unaffected family members. Hypopigmented spots on the retinas have been described in some patients (Klein et al., 1994), but this is not a constant feature. In association with this characteristic pigmentary dilution, most patients develop a recurrent hemophagocytic syndrome (or accelerated phases) with features identical to those mentioned above for HLH (Table 54.1). Similarly, the onset of HLH syndrome in this condition is frequently triggered by an infection (Klein et al., 1994) and is characterized by hyperactivation and proliferation of T cells and macrophages, in association with fever, edema, hepatosplenomegaly, pancytopenia, coagulation abnormality, liver dysfunction, and features of hemophagocytosis. These patients have been defined as having GS type 2, which results from mutation in the Rab27a gene (*RAB27A*) (Table 54.3) (Ménasché et al., 2000).

Neurological manifestations are frequently observed in association with HLH in GS2 patients, as a result of brain infiltration by activated lymphocytes and macrophages (Schmid et al., 2009; Trottestam et al., 2009). However, in a few GS patients, severe and static neurological symptoms are noticeable since birth, without any sign of HLH, and consist of hypotonia, absence of coordinated voluntary movements, and severe psychomotor developmental delay (Sanal et al., 2002). These symptoms are similar to the neurological signs described by Elejalde et al. (1979). In this condition, CNS disorder is static and never improves with time. Patients presenting with the typical hypopigmentation of GS in association with this isolated severe neurological manifestation have been shown to carry mutations in the myosin VA gene (*MYO5A*), which defines GS1 (Pastural et al., 1997).

In addition, isolated hypopigmentation with typical hair and skin features of GS was recently observed in a subject, independent of *MYO5A* or *RAB27A* mutation. Hypopigmentation in this case resulted from mutation in the melanophilin gene (*MLPH*) (Menasche et al., 2003b), defining a third form of GS (GS3).

Molecular Basis

Genetic linkage analysis performed in several GS1 and GS2 families has enabled localization of both disease loci on the same 15q21 chromosome region. Mutations in either the *MYO5A* gene or *RAB27A* gene, two genes separated by less than 1.6 cM in this genetic region, account for the GS1 and GS2 phenotypes, respectively (Ménasché et al., 2000; Pastural et al., 2000). In addition, the melanophilin gene, located on chromosome 2q37.3, leads to GS3 when mutated. In this condition, the GS phenotype is restricted to the characteristic hypopigmentation of this condition (Menasche et al., 2003b).

Functional Aspects

Myosin VA is an unconventional myosin heavy chain implicated in vesicle transport in cells and is particularly abundant in neurons and melanocytes. It has the expected structure for a member of this family—that is, a globular head domain containing the ATP- and actin-binding sites; a "neck" domain, which is the site of calmodulin (or light-chain) binding; and a tail domain, which is thought to represent the cargo-binding domain (Fig. 54.2). Myosin VA acts as a dimer and moves cargo along actin filaments in a plus-end-directed manner, allowing their capture and accumulation at the periphery of the cells. Myosin VA is required for melanosome transport in melanocytes (Wu et al., 2002). Study in *dilute* mice has shown that a defect in myosin Va leads to concentration of melanosomes in the center of the melanocytes; they are also concentrated in dendrites and dendritic tips in wild-type mouse melanocytes. This defect also impairs processing of presynaptic vesicles in the peripheral regions of neurons and the distribution of smooth endoplasmic reticulum in Purkinje cell neurons (Takagishi et al., 1996).

Rab27a is expressed in melanocytes, peripheral leukocytes, platelets, and many other cells and tissue types, except in the brain (Chen et al., 1997). Each member of the Rab protein family has a characteristic intracellular distribution pattern, suggesting their unique function in transport. Like myosin VA, Rab27a co-localizes in part with melanosomes in melanocytes and its defect leads to the abnormal melanosome distribution observed in GS (Bahadoran et al., 2001). In addition, Rab27a is necessary for cytotoxic granule exocytosis and thus cytotoxic activity of T and NK cells, which has been shown to be defective in this group of GS2 patients (Ménasché et al., 2000). In cytotoxic cells, Rab27a can associate with a member of the synaptotagmin-like protein (SLP) family, SLP2a, which allows the docking of cytotoxic granules to the plasma membrane (Fig. 54.2) (Menasche et al., 2008).

Melanophilin, another effector of Rab27a, is specifically expressed in melanocytes (Fukuda, 2003). MLPH deficiency leads to the same defective transport of melanosomes as that resulting from *MYO5A* and *RAB27A* defects. Pigmentary dilution is indistinguishable among these three molecular defects. A specific role of the three proteins Rab27a, Myosin VA, and Mlph in the capture and actin-based transport of melanosomes to the periphery of the dendrites has been

Griscelli syndrome(GS)	Hypopigmentation	Primary neurological impairment	Hemophagocytic syndrome	Molecular defect
GS 1	+	+	–	MYO5A
GS 2	+	–	+	RAB27A
GS 3	+	–	–	Melanophilin (MLPH)

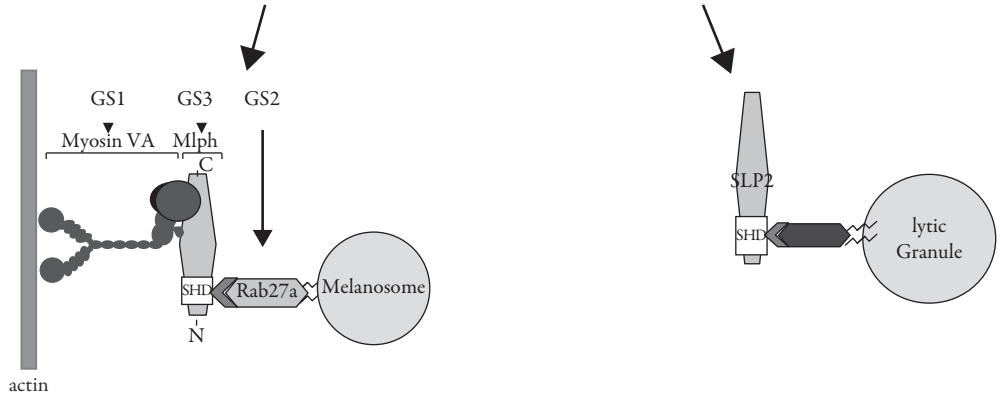

Figure 54.2 *Molecular defect leading to the three forms of Giscelli syndrome (GS).* A defect in Myosin VA, Rab27a, or Mlph leads to identical pigmentary dilution found in the three forms of GS. The formation of the heterotrimeric protein complex allows the transport of melanosome on actin fibers. Phenotypic expression of each genetic defect implies that organelle transport in melanocytes, neurons, and CTLs uses different effectors associated with Rab27a and Myosin VA. Slp2a is an effector of Rab27a in cytotoxic cells.

demonstrated. Analyses in mouse mutant models determined that Rab27a first associates with the membrane of melanosomes and then interacts with melanophilin, which recruits myosin Va through its tail region (Wu et al., 2002). Binding of the head domain of myosin Va to actin filaments links melanosomes with the peripheral actin network (Fig. 54.2).

Because of the role of myosin VA in brain tissue, however, only patients with myosin VA defect develop a primary severe neurological impairment with no immunological expression. In contrast, defective Rab27a expression is always associated with abnormal lymphocyte cytotoxic activity, which results in a lymphoproliferative syndrome, as observed in the case of the FHL caused by genetically determined perforin or hMunc13–4 deficiency (as discussed above). When neurological signs are observed in GS2 patients, they are the consequence of an accelerated phase and appear secondary to perivascular lymphohistiocytic organ infiltration.

Laboratory Findings

The light-microscopic examination and electron-microscopic findings of patients' hair and skin are characteristic. Hair shafts contain a typical pattern of uneven accumulation of large pigment granules instead of the homogeneous distribution of small pigment granules in normal hair (Color Plate 54.IIB). Fontana-stained silver sections of the skin show hyperpigmented melanocytes, contrasting with poorly pigmented adjacent keratinocytes, instead of the homogeneous distribution of melanin granules observed in melanocytes and surrounding keratinocytes in normal epidermis. Electron microscopy shows that the cytoplasm of melanocytes is filled with numerous mature stage IV melanosomes, predominantly around the nucleus, but have normal dendritic processes (Griscelli et al., 1978; Klein et al., 1994; Takagishi et al., 1996). These findings are consistently observed and identical in the three groups of patients (with *MYO5A*, *RAB27A*, or *MLPH* mutations).

Immunological abnormalities are restricted to patients with the Rab27a defect. Biological features of the accelerated phase are not specific to GS; they are identical to those observed in FHL patients. The capacity of lymphocytes and NK cells of these patients to lyse target cells is impaired or absent. This decrease in T- and NK-cell cytotoxicity, which results from an inability to secrete cytotoxic granules when *RAB27A* is not functional, is a constant feature in this group of patients (Ménasché et al., 2000). Patients have normal numbers of T, B, and NK cells as well as normal B and neutrophil functions, although decreased chemiluminescence and chemotactic responses have been reported (Klein et al., 1994). In addition, impaired skin reactions to tuberculin, streptokinase-streptodornase antigen, and *Candida* have been described in some cases. The lymphocytes proliferate in vitro in response to PHA, purified protein derivative (PPD), or *Candida*, and in mixed lymphocyte reaction (MLR). No immunological abnormalities have been observed in GS patients with a myosin VA or melanophilin defect. Myosin VA and melanophilin defects do not affect cytotoxic granule secretion, and these patients never develop an accelerated phase (Menasche et al., 2000, 2003b).

Mutation Analysis

RAB27A consists of seven exons, the first two being untranslated. It encodes a 221–amino acid polypeptide with a molecular mass of 25 kDa (Chen et al., 1997). Mutations in *RAB27A* have been characterized in about 100 independent patients (Ménasché et al., 2000; Zur Stadt et al., 2006; unpublished results). Very few missense mutations have been reported and

functionally analyzed (Menasche et al., 2003a). The other mutations are nonsense mutations, deletions, or splice-site alterations, all predicting an early protein truncation. In each case, the location of the stop codon predicts truncation of the consensus carboxylterminal motif of the protein, involved in Rab protein geranyl-geranylation, and thus should leave Rab27a protein in an inactive state.

The *MYO5A* gene contains an open reading frame of 1,855 codons that encodes a protein of 215 kDa (Mercer et al., 1991). Myosin VA is a member of the molecular motor molecules with structurally conserved heads followed by a neck domain, a tail region, and a globular C-terminal domain (Cheney et al., 1993). Alternatively spliced transcripts can be generated within the tail region of myosin VA. Most of the mutations identified in *MYO5A* lead to a predicted truncated protein (unpublished result). Alternative splicing within the tail region of myosin Va produces different spliced isoforms with tissue-restricted expression: in melanocytes, the majority of myosin VA transcripts contain the longest isoform of myosin VA, whereas brain transcripts contain a shorter isoform lacking exon F (Huang et al., 1998; Lambert et al., 1998; Pastural et al., 2000). In one patient, homozygous intragenic deletion of the MYO5A F-exon led to a phenotype restricted to typical hypopigmentation of GS without neurological symptoms, demonstrating that the F-exon of MYO5A is dispensable for neurological function (Menasche et al., 2003b).

The *MLPH* gene comprises seven exons spanning 2403 bp and encodes for a protein of 66 kDa. A homozygous R35W substitution was identified in the synaptotagmin-like protein homology domain (SHD) of the protein in one patient, which completely blocked Mlph interaction with the active form of Rab27a (Menasche et al., 2003b).

Genotype–Phenotype Correlation

As discussed above, there is a strict correlation between the type of gene affected (*RAB27A*/*MYO5A*/*MLPH*) and the phenotype displayed by patients with GS. Although pigmentary dilution is identical in these three groups of patients, only the patients with *RAB27A* mutations have decreased cytotoxic activity, resulting in the development of a hemophagocytic syndrome, whereas primary, severe, and irreversible neurological impairment characterizes patients with *MYO5A* mutations (Menasche et al., 2000, 2003b).

CHEDIAK-HIGASHI SYNDROME

Clinical and Pathological Manifestations

CHS (MIM 214500) is a frequently fatal, autosomal recessive genetic disorder characterized clinically by hypopigmentation of the skin and the hair, mild bleeding tendency, recurrent infections, neurological abnormalities, and early death from a so-called "accelerated phase" of the disorder that corresponds to the occurrence of an episode of HLH (Beguez-Cesar, 1943; Chediak, 1952; Higashi, 1954). A pathognomonic feature of the disease is the presence of intracellular giant organelles, which are seen in peripheral blood leukocytes and many other cell types (Color Plate 54.IB) (Spritz, 1999). In some patients, the diagnosis is considered only after the observation of these giant granules as an incidental finding on a peripheral blood smear. Most patients are diagnosed during the first decade of life, but in few patients with mild expression, the first diagnosis is made only in adulthood.

Dermatological manifestations in CHS show hair color varying from blond to dark but always exhibiting a silvery-gray tint, which is particularly noticeable in strong light (Stegmaier & Schneider, 1965). Microscopic examination of hair reveals the presence of clusters of melanin in the hair shaft (Color Plate 54.IIC) (Blume & Wolff, 1972; Windhorst et al., 1968). An increased red reflex, photophobia, and nystagmus in bright light can also be observed, which represent expressions of the ocular pigmentary dilution (Bregeat et al., 1966; Johnson et al., 1966). Patients' skin is less pigmented than their parents and siblings, and they are susceptible to severe sunburns. Some of these patients have chronic periodontal disease (Delcourt-Debruyne et al., 2000; Shibutani et al., 2000) or dermatological infections.

About 85 percent of patients develop HLH during the first decade (Page et al., 1962; Rubin et al., 1985; Spritz, 1985), which is frequently triggered by active EBV infection (Okano & Gross, 2000; Rubin et al., 1985). Neurological manifestation can be part of the episode of HLH, ranging from seizures to coma (Table 54.1). Nevertheless, 10 to 15 percent of patients have a relatively mild early clinical course and may survive to adulthood with few or even no severe infections and no sign of the accelerated phase. Patients who survive the childhood period, with or without complications of the hemophagocytic syndrome, often develop neurological manifestations, including mental deficiency or progressive intellectual decline, peripheral neuropathy with tremor, muscle weakness, stiffness, clumsiness, abnormal gait, and foot drop (Misra et al., 1991; Uyama et al., 1994). There is now strong evidence that these neurological manifestations, which are the first recognized manifestation of the disease in some adult patients, are primary rather than resulting from brain infiltration by activated lymphocytes and macrophages during previously undiagnosed HLH episodes (Tardieu et al., 2005). Many of these patients with the clinically milder adolescent or adult forms of CHS appear to have mutations in the *LYST* gene that allow some residual function of the CHS1 polypeptide (Karim et al., 2002).

Laboratory Findings

Giant intracytoplasmic granulations are the hallmark of this disorder and occur in all granulated cells, including hematopoietic cells (Color Plate 54.IB) and melanocytes as well as fibroblasts, renal tubular, neurons, and Schwann cells (Blume & Wolff, 1972; White, 1966; Windhorst et al., 1968). They display endosomal/lysosomal characteristics and appear preferentially distributed to the perinuclear region of the cells (Burkhardt et al., 1993; Jones et al., 1992). This pigmentary disturbance results from the abnormal aggregation of melanin into giant melanosomes and their inability to transfer melanin to the adjacent keratinocytes (Fukai et al., 1993; Griscelli et al., 1978; Windhorst et al., 1968).

Both T and NK cells present a defective cytotoxic activity, which results from their inability to secrete cytolytic proteins

stored in their giant granules (Katz et al., 1982; Klein et al., 1980). Biological features, which characterized the occurrence of the so-called accelerated phase of the disease, are indistinguishable from those during an episode of HLH (see above) (Tables 54.1 and 54.2).

Molecular and Functional Aspects

The human *LYST* (also known as *CHS1*) gene is enormous, consisting of 55 exons spanning more than 222 kb in chromosome 1q43 (Karim et al., 2002) The *CHS1/LYST cDNA* (13.5 kb) (Nagle et al., 1996) encodes for a huge cytosolic protein of 425 kDa (3801 amino acids (aa)) (Barbosa et al., 1996; Perou et al., 1997). CHS1/LYST belongs to a family of proteins, called the *BEACH* family, that share the three same C-terminal domains: a Pleckstrin-Homology domain (PH) (Jogl et al., 2002), a BEACH domain (named after BEige And Chediak-Higashi) (Nagle et al., 1996), and WD40 repeats. However, the exact function of these domains remains unknown, though they are supposed to play a role in the binding of protein partners (Gebauer et al., 2004; Jogl et al., 2002). Most of the functional information on CHS1/LYST comes from the studies of other members of the BEACH family, which define them as vesicle trafficking regulatory proteins (Martens & McMahon, 2008). The CHS1/LYST protein also contains a series of ARM (ARMadillo) (Peifer et al., 1994) and HEAT repeat motifs thought to mediate membrane associations and vesicle transport (Andrade & Bork, 1995). Recently, a lectin-like domain has been identified in the N′ terminal region of the CHS1/LYST and of other BEACH proteins (Burgess et al., 2009). It could be involved in oligosaccharide binding associated with protein traffic and sorting along the secretory pathway, especially in relation with components of the vesicle fusion machinery.

Spectrum of Mutations

Considering the length of the *LYST* gene, mutation analysis in CHS patients is a difficult task. Interestingly, most of the mutations so far reported lead to truncated proteins, either by nonsense mutation or frameshift mutations (Barbosa et al., 1996; Certain et al., 2000; Karim et al., 2002; Nagle et al., 1996). Similar homozygous mutations have been found associated with typical or, less commonly, with milder clinical courses, even within the same family (Certain et al., 2000). Thus it seems likely that factors other than *LYST* gene mutations may influence the clinical expression of CHS. Nevertheless, one important genotype–phenotype correlation has emerged. Only four patients have been described with *LYST* missense mutations resulting in amino acid substitutions (Karim et al., 2002). Two of these, with homozygous missense substitutions, had mild, adult-onset CHS. Overall, it appears that most but not all patients with null-mutant *LYST* alleles manifest a clinically severe course, whereas many or all patients with missense mutant alleles manifest a relatively mild clinical course. Maternal uniparental isodisomy for the entire chromosome 1 was also reported in a case of CHS (Dufourcq-Lagelouse et al., 1999b).

HERMANSKY-PUDLAK SYNDROME

Clinical and Pathological Manifestations

The term Hermansky-Pudlak sydrome (HPS) (MIM203300) is used to define a group of at least eight human autosomal recessive genetic disorders (HPS-1 through -8) characterized by oculocutaneous albinism and storage pool deficiency due to defects in the formation of melanosomes and platelet dense granules, respectively (Gunay-Aygun et al., 2004; Hermansky & Pudlak, 1959; Nazarian et al., 2008; Wei, 2006). The storage pool deficiency leads to easy bruising, hemorrhagic diathesis as a result of prolonged bleeding times, and lysosomal ceroid storage (Dell'Angelica et al., 2000; Huizing et al., 2000; Oh et al., 1996). Patients have a tyrosinase-positive albinism, and microscopic analysis of the hair shaft does not allow the detection of clusters of pigment, contrasting with the pigmentation features characterizing hair from CHS and GS patients. Like other forms of albinism, HPS patients have reduced visual acuity and nystagmus.

HPS type 2 (HPS2, MIM 203300) is the only form of HPS that is also associated with immunodeficiency, mainly increased susceptibility to infections due to congenital neutropenia and defective cytotoxic activity of T and NK lymphocytes (Clark et al., 2003; Enders et al., 2006; Jung et al., 2006). Some of these patients may also display lung fibrosis, facial dysmorphism, developmental delay, or hepatosplenomegaly (Huizing & Gahl, 2002; Shotelersuk et al., 2000).

Molecular and Functional Aspects

HPS2 results from mutation in *AP3B1*, the β chain of the adaptor protein-3 (AP-3) complex (Table 54.3) (Dell'Angelica et al., 1999). Only few missense and nonsense mutations or deletions in *AP3B1* have been so far reported (Enders et al., 2006; Huizing & Gahl, 2002; Shotelersuk et al., 2000). AP3 is a ubiquitous cytoplasmic complex, consisting of four different subunits, that shuttles cargo proteins from the trans-Golgi and a tubular-endosomal compartment to endosome-lysosome-related organelles (Dell'Angelica et al., 1997a, 1997b). AP3 thus functions in protein sorting to lysosomes. Defects in the β3A subunit disrupt the complex and all subunits are rapidly degraded. Misrouting of lysosomal proteins such as CD107 and CD63 to the cell membrane has been found in fibroblasts, CTL clones and platelets (Clark et al., 2003; Kurmi et al., 2012). Similarly, CD1b, which is sorted by AP3, but not other CD1 isoforms, fails to gain access to lysosomes. Protein missorting may explain several features of the HPS2 phenotype. Aberrant subcellular targeting of neutrophil elastase likely contributes to the observed neutropenia (Benson et al., 2003; Massullo et al., 2005), while missorting of tyrosinase contributes to the pigmentation disorder (Honing et al., 1998). Presentation of lipid antigens from bacteria is reduced due to less efficient sorting of CD1b to the lysosome, which may also participate in the increased susceptibility to infections of HPS2 patients (Sugita et al., 2002).

Spectrum of Mutations

Some 12 HPS2 patients with unique *AP3B1* mutations have been reported, including missense, nonsense and deletion mutations (Chiang et al., 2010; Dell Angelica et al., 199; Enders et al., 2006; Fontana et al., 2006; Huizing et al., 2002; Jung et al., 2006; Kurnik et al., 2012; Wenham et al., 2010). One of these patients had a homozygous nonsense mutation in exon 8 of *AP3B1* (p.R302X) and in addition was heterozygous for a *RAB27A* mutation; he died at age 3 years of fulminant HLH (Enders et al., 2006). Only one other patient with a *RAB27A* mutation developed symptoms of HLH (Wenham et al., 2010).

Impaired Cytotoxic Activity and HLH in HPS2

In the absence of AP3, cytotoxic T- and NK-cell–mediated killing was shown to be significantly impaired, with the presence of enlarged cytotoxic granules unable to move along microtubules toward the MTOC when the cytotoxic cell recognizes a target (Clark et al., 2003; Enders et al., 2006; Jung et al., 2006). Although all HPS2 patients tested have defective cytotoxic activity, only two cases were so far reported with the development of HLH (Enders et al., 2006; Wenham et al., 2010). It is unclear whether the additional heterozygous *RAB27A* mutation observed in one of the two patients contributed to this complication (Enders et al., 2006). However, pearl mice, representing a murin model of HPS2, when infected with lymphotic choriomeningitis virus, developed transiently key features of HLH but fully recovered even if an additional Rab27a mutation was knocked-in (Jessen et al., 2013)

Thus, a key clinical question that remains regarding HPS2 is whether the cytotoxicity defect in HPS2 predisposes to HLH and therefore represents an indication for preemptive hematopoietic stem cell transplantation. Long-term follow-up will be necessary to try to answer this question.

STRATEGIES FOR DIAGNOSIS OF INHERITED HLH

Distinguishing primary from secondary forms of HLH is an important task, not only for genetic counseling but also for determining appropriate therapeutic interventions. Onset of HLH at a young age should instigate the search for a genetic cause. Microscopic analysis of the hair shaft is an easy and reliable test to diagnose GS and CHS. In both conditions, pigmentation dilution is characteristic, with larger clumping of pigment in the hair shafts of GS than CHS patients (Color Plate 54.II). Carriers of these syndromes have normal pigmentation. The presence of giant intracytoplasmic granules in all cells from the hematopoietic lineage is a hallmark of CHS and is easy to identify in a blood smear (Color Plate 54.IB), ensuring a rapid diagnosis. If pigmentation dilution orients toward GS, sequencing of the *RAB27A* gene allows confirmation of the diagnosis of GS2. In the absence of HLH, molecular diagnosis of GS is important to rule out potential Rab27a deficiencies, which should be treated by allogeneic stem cell transplant. In CHS, given the length of the *LYST* gene, mutation screening is not used as a routine test for diagnosis and genetic counseling. Unambiguous diagnosis of this condition can be performed based on the characteristic hypopigmentation of the hair shaft and the presence of intracellular giant granules, without the need for further genetic testing. However, for genetic counseling of families, segregation analysis of polymorphic markers linked to the *CHS* locus on chromosome 1q43.2 in the family can be used (Barrat et al., 1996). In non-consanguineous families, this approach requires availability of DNA samples from both parents and the patient to determine the affected haplotype in the family. When the parents are related, the identification of a shared haplotype at the *CHS* locus in the parents may overcome the lack of a DNA sample from the patient. When HLH is not associated with hypopigmentation, the biggest difficulty lies in differentiating between the primary (inherited) disease (FHL) and a secondary HLH disease. A positive family history, with previously affected family members and/or consanguinity, is highly suggestive of an inherited form. The availability of biological samples from family members (parents, siblings) greatly helps the molecular diagnosis of genetic causes by rapid determination of the polymorphic markers segregating with the disease locus. However, the lack of a family history is not a reliable criterion to exclude FHL. Study of the cytotoxic activity of T and/or NK lymphocytes (Bryceson et al., 2007) is a consistent test to diagnose the genetic forms of HLH. NK- and T-cell cytotoxicity is defective in most of the FHL cases resulting from either a perforin defect a Munc13–4 defect, Syntaxin 11 defect or Munc18–2 defect. Perforin defects can be rapidly identified by the analysis of perforin expression in resting cytotoxic cells using an immunofluorescence study. In fact, the great majority of the mutations so far identified in FHL2 dramatically affect perforin detection. Sequencing of the perforin gene will confirm the diagnosis of FHL2. In the other group, sequencing of the *UNC13D* gene, Syntxin 11gene or STXBP2 gene allows identification of FHL3. FHL4 or FHL5 respectively. Some patients with STXBP2 mutation also display early and severe enteropathy requiring parenteral nutrition (Pagel et al., 2012), likely resulting from a prime role of Munc18–2 in gut epithelial cells. In the rest, the genetic cause is not yet characterized. Defective lymphocyte cytotoxic activity is the signature of a primary genetic cause of HLH. Although not discussed in this chapter, the diagnosis of XLP should be excluded in male patient developing HLH during EBV infection, by sequencing of the *SH2D1A* and *XIAP* genes, the two molecular causes of XLP so far characterized (Nichols et al., 1998; Rigaud et al., 2006) (See Chapter 44).

TREATMENT AND PROGNOSIS

Therapy of the inherited forms of HLH consists of two phases (Henter et al., 2007; Mahlaoui et al., 2007; Schmid et al., 2009): the aim of the first phase is to reach remission; in the second phase, hematopoietic stem cell transplantation will be

envisaged. Basically, two treatment protocols are used today to strive for remission:

- Chemotherapy (etoposide, VP-16) in combination with corticosteroids and cyclosporin A (according to the HLH1994 and HLH2004 studies) (Henter et al., 2007)
- Immunotherapy (antithymoglobulin, ATG) in combination with corticosteroids and cyclosporin A (according to the recommendation of the European Society of Immunodeficiencies [ESID]) (Jabado et al., 1997; Mahlaoui et al., 2007; Schmid et al., 2009)

These treatments induce remission in approximately 80 percent of patients. However, they also induce a severe immunosuppression that may lead to infectious complications. Etoposide is furthermore known to occasionally induce immediate hepatic and mucosal toxicity, increasing the risk of therapy-related secondary neoplasia. Infusion of ATG, on the other hand, can be associated with hemodynamic instability at the beginning of the treatment.

Intrathecal application of methotrexate, combined with hydrocortisone or high-dose steroids, should be considered in patients with severe neurological involvement.

ANIMAL MODELS

The natural mouse mutant *pearl* represents the murine counterpart of human HPS2 (Feng et al., 1999). Pearl mice show hypopigmentation, abnormal lysosomal secretion, and abnormal platelet dense granules, in association with mutations in the *Ap3b1* gene subunit of the AP3 adaptor complex. Similar findings are seen in an engineered *Ap3b1* knockout mouse strain (Yang et al., 2000). Following LCMV infection, pearl mice transiently develop the features of HLH associated with moderate defect in CTL cytotoxicity (Jessen et al., 2013). Interestingly, neutrophil counts appear normal in *Ap3b1*-deficient mice, whereas dogs with mutation in *AP3B1* have cyclic neutropenia (Benson et al., 2003).

CHS has been described in many mammalian species (Windhorst & Padgett, 1973), including mink, cattle (Padgett et al., 1964), cats (Kramer et al., 1977), foxes, killer whales, rats (Nishimura et al., 1989; Ozaki et al., 1994), and mice (Lutzner et al., 1967). Several natural mouse mutants of lyst exist (*Lyst*-mutated) (*souris* and *beige*), which have been characterized in molecular terms (Barbosa et al., 1996; Nagle et al., 1996). The phenotype of the souris and *beige* mouse corresponds to human CHS in virtually all aspects, including pigmentary dilution, reduced chemotactic and bactericidal activity of granulocytes (Gallin et al., 1974), reduced NK and T-lymphocyte cytotoxic function (Saxena et al., 1982), enlarged melanosomes in pigment cells, and enlarged lysosomes in many cell types (Novak et al., 1984; Windhorst & Padgett, 1973). Only the *souris* but not the *beige* strain develop features of HLH following LCMV infection, which may be explain by the difference in degree of cytotoxicity defect between these two mutants (Jessen et al., 2011).

The three forms of GS naturally occurred in three different mutants—*dilute* (d), *ashen* (ash), and *leaden* (lead) mice, which result from Myosin Va, Rab27a, and Mlph deficiency, respectively. All murine mutants present with identical pigmentary dilution and normal pigment granule synthesis but abnormal melanosome transport. The melanosomes are localized mainly in the perinuclear region of the melanocytes (Provance et al., 1996; Wilson et al., 2000). *Dilute* null mice also show a neurological defect, characterized by opisthotonus and ataxia, which results in the death of the animal 2 to 3 weeks after birth (Dekker-Ohno et al., 1996; Takagishi et al., 1996). Isolated pigmentation dilution characterizes the *leaden* mice and results from a deletion of seven residues in the SHD of the melanophilin gene (Matesic et al., 2001). *Ashen* mice exhibit the same pigmentary dilution, but in association with defective cytotoxic activity (Haddad et al., 2001; Stinchcombe et al., 2001a). As in GS2, this defective function results from the role of Rab27a in cytotoxic granule exocytosis. A splicing defect resulting from a single transversion in the exon 4 donor splice site, activation of a cryptic downstream site, and abnormal Rab27a transcript was identified in these mice (Wilson et al., 2000).

Two FHL animal models have been generated. The perforin-deficient mouse (*Prf1*$^{-/-}$) (Kagi et al., 1994) was obtained by disruption of the perforin gene and is the mouse counterpart of FHL2. The Munc13–4 deficient mouse, also known as *Jinx* mouse, was obtained by ENU-induced germline mutation that introduced a splice defect in the *Unc13d* sequence, resulting in an early truncation of the Munc13–4 protein in this mouse model of FHL3 (Crozat et al., 2007).

The mouse models of human HLH that have identified defective cytotoxic activity (i.e., the *Prf1* knockout mice, the *Jinx* mice, the *ashen* mice, the syntaxin-11 mice (Sepulveda et al., 2012; Kögl et al., 2012), the pearl mice and the *souris* mice) are all healthy when maintained under standard housing conditions, although they do have defective granule-dependent cytotoxic activity. When challenged with certain strains of viruses, such as LCMV, every one of these knock-out mice developed an overreactive, virus-specific T-cell response, although with different severity and duration, with splenomegaly, cytopenia (anemia, neutropenia, and thrombocytopenia), and increased levels of IFN-γ, TNF-α, and other inflammatory cytokines (Crozat et al., 2007; Jordan et al., 2004; Pachlopnik Schmid et al., 2008). Activated macrophages with hemophagocytosis can be found in the liver of these mice. Thus in this setting, mouse models of FHL2, FHL3, FHL4, ,GS2, CHS and HPS2 develop a pathology identical to that of human HLH. Most of the *Prf1*$^{-/-}$ mice die within a few weeks as a consequence of HLH, whereas the others murin models show a substantially better survival rate. Several studies have shown that death of these infected deficient mice results not from a defect in viral clearance but from persistence of the bulk of activated CD8^{+} cells and the deleterious action of the cytokines they secrete (Badovinac et al., 2003; Jordan et al., 2004; Kagi et al., 1999; Matloubian et al., 1999; Rossi et al., 1998). A critical role of the CD8^{+} T lymphocyte population and the high level of IFN-γ this population produces have been shown to be critical for the occurrence of HLH in these mouse models, since depletion of the CD8 population or neutralization of INF-γ prevents the immune disease. The therapeutic administration of an antibody that blocks IFN-γ was shown to induce recovery from HLH in two genetic models tested, the *Prf1* knockout and the *ashen*

(Rab27a knockout) mice, as based on prevention of death of the former and correction of the various features of HLH in both murine models (Pachlopnik Schmid et al., 2009).

CONCLUDING REMARKS AND FUTURE CHALLENGES

The past few years have seen great progress in understanding the molecular bases of the various inherited forms of HLH (FHL, GS, CHS). As a result, genetic identification of the defect has generally translated into improved diagnosis and genetic counseling of these conditions. Likewise, discovery of the causal genes for these diseases has resulted in a better understanding of the pathophysiology of HLH. Analyses of the mouse models of HLH strongly suggested a primary role of the lymphocyte activation and IFN-γ production in the excessive macrophage activation and the proinflammatory cytokine production, which lead to disease pathogenesis. Similarly, there has been important progress in the treatment of these inherited conditions, largely brought about by the improved management of patients undergoing hematopoietic stem cell transplantation, and improvement of immunosuppressive treatment during the remission phase. Nevertheless, considerable challenges remain to find an efficient but less toxic therapy, as suggested by IFN-γ neutralization experiment in murine models. In addition, a few inherited FHLs remain to be molecularly identified.

GENETICALLY DETERMINED DEFICIENCIES OF COMPLEMENT COMPONENTS

Kathleen E. Sullivan and Jerry A. Winkelstein

OVERVIEW

The Nobel Prize in Physiology was given to the Belgian microbiologist Jules Bordet in 1919 for his description of the complement system. Bordet purified proteins from guinea pig serum and identified a heat-stable fraction with antibody activity and a heat-labile fraction that "complemented" the antibody fraction in a lytic assay.

In the past century, we have come to understand this "complementing function" well. The complement system is a group of 14 proteins, comprising the complement cascade, and more than 10 regulatory proteins. In addition, there are at least seven receptors that mediate the biological functions of the complement cleavage products. Complement proteins are very abundant in serum and rise with infection or inflammation. Nearly 5 percent of all serum proteins are complement proteins, and this number can rise to 7 percent of serum proteins in inflammatory states. The abundance reflects its important function, as does its conservation throughout evolution. Complement has been evolutionarily conserved, and the primary role of complement throughout evolution relates to "marking" of pathogens with C3b, a process called opsonization. The term "opsonization" is derived from the Greek word for condiment or delicacy and refers to the facilitation of phagocytosis by neutrophils. The neutrophils engulf bacteria more readily when they are coated with complement. This role of complement as an opsonin is its most important role in host defense.

The majority of serum complement is produced in the liver, although C1q, properdin, and C7 are produced predominantly by myeloid cells and factor D is produced by adipocytes and is also known as adipsin (Anthony et al., 1989; Schwaeble et al., 1994; Scoazec et al., 1994; Wilkison et al., 1990; Ziccardi, 1983). For this reason, liver disease is associated with a significant defect in serum complement levels. The tissue-specific and inducible expression of most complement proteins is regulated at the level of transcription.

This chapter will address the biochemistry of the complement cascade and discuss inherited disorders of complement components. The complement cascade's main role is to deposit C3b on the surface of microbes and to generate small-molecule mediators to regulate inflammation (Walport, 2001a, 2001b). Direct killing of bacteria, clearance of apoptotic cells, and the regulation of the adaptive immune system are also important roles.

The nomenclature of the complement cascade is unfamiliar to many people, and a few of the more common terms are defined in Table 55.1. The nomenclature follows certain patterns, with the classical pathway components generally indicated with an uppercase C followed by a number that roughly correlates with the position in the cascade (C4 appears out of order). Alternative pathway members are generally referred to as a "factor" and are designated with a letter (factor B, factor D, factor H). Lectin pathway members start with the letter M (for mannose). As protein fragments are cleaved off, they are given lowercase letter identifiers, with the "a" most often designating the smaller fragment (the exception is C2a, which is larger than C2b). In some cases, the two fragments can be further cleaved, and those smaller fragments are named with additional lowercase letters. When a cleavage product is inactive, it is preceded by the letter "i."

INTRODUCTION TO THE COMPLEMENT SYSTEM

A simple model for the organization of the complement cascade has three activation arms: the classical pathway,

the lectin activation pathway, and the alternative pathway (Fig. 55.1). These three pathways cleave the central protein, C3, and allow it to bind to the nearest surface, usually a pathogen. A complex including activated C3 can cleave C5, leading to the assembly of the terminal components. These proteins catalyze the formation of a pore, generated by C8 and stabilized by C9.

THE CLASSICAL PATHWAY

The classical pathway is activated primarily by immune complexes. A subtle conformational change occurs when antibody engages antigen, which renders the antibody molecule capable of interacting with C1 (Gal et al., 1994; Sim & Reid, 1991). Not all antibody is equivalent in terms of its ability to activate complement: only IgG and IgM activate complement, and IgM is much more efficient than IgG. In addition, not all isotypes of IgG are equivalent: IgG3 is the most efficient, followed by IgG1 and IgG2. IgG4 is not able to activate complement. In addition to immune complexes, C-reactive protein, serum amyloid P, β-amyloid, DNA/chromatin, cytoskeletal filaments, SIGN-R1, and some pathogens can activate the classical pathway (Riley-Vargas et al., 2005; Sjoberg et al., 2006).

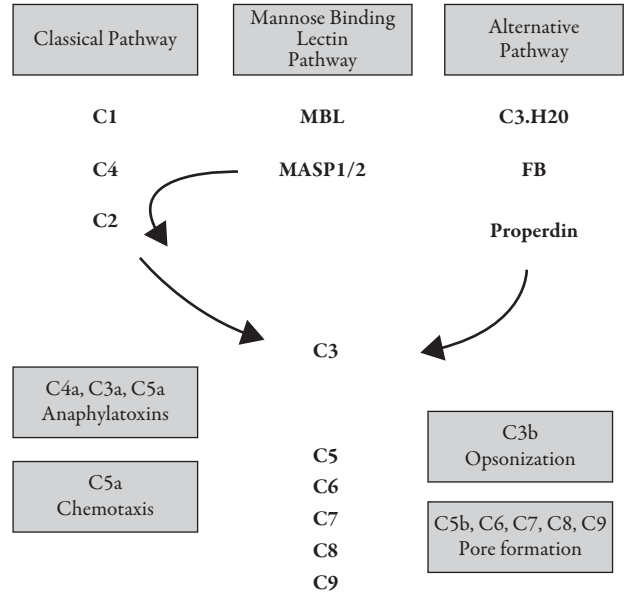

Figure 55.1 The complement system consists of three activation arms, converging on the cleavage of C3 and the activation of the terminal components. The classical pathway is activated predominantly by immune complexes, while the lectin activation arm and the alternative pathway are truly innate and are activated directly by pathogens. The fluid-phase cleavage products shown in the gray boxes on the left have anaphylatoxic and chemotactic activities. The membrane-bound components listed in the gray boxes on the right are more directly involved in pathogen killing.

Table 55.1 DEFINITIONS

Classical pathway	**C1, C4, C2, C3, and the terminal components**
Alternative pathway	**Factor B, Factor D, properdin, and the terminal components**
Lectin activation pathway	**MBL, MASP1, MASP2, C3, and the terminal components**
Anaphylatoxins	**C3a, C4a, C5a. These are mediators of smooth muscle contraction, degranulation of mast cells, enhanced neutrophil aggregation, increased vascular permeability.**
Opsonization	**Renders a particle more easily phagocytosed**
C3 tick-over	**This term is used to describe spontaneous C3 hydrolysis.**
Membrane attack complex (terminal components):	**C5, C6, C7, C8, C9**
CH50	**The assay is used to define the dilution of serum capable of lysing 50% of the sensitized sheep red cells. This assay measures the intactness of the classical pathway through the terminal components.**
AH50	**The assay is used to define the dilution of serum capable of lysing 50% of nonsensitized rabbit red cells. This assay measures the intactness of the alternative pathway through the terminal components.**

The C1 complex is made up of C1q (which in turn is made up of six polypeptide chains) and two C1r and two C1s proteins. Interaction of C1 with immune complexes leads to a conformational change in C1 that allows autoactivation of C1r. C1r cleaves the two molecules of C1s, which cleaves C4 into C4a and C4b (not to be confused with the genetically distinct C4A and C4B genes). C4b is a highly reactive molecule that binds to the pathogen surface near the antibody–C1 complex (Law et al., 1984). The C4b–$C1s_2$ complex cleaves C2 into C2a and C2b. The smaller C2b is released and the C2a becomes incorporated into the growing complex. C3 binds to this complex and is cleaved by C2a, with C3a being released into the surrounding space and C3b binding to the pathogen surface.

The small fluid-phase cleavage products are biologically active. C4a, C3a, and C5a are termed anaphylatoxins (Schlaf et al., 2004; Weigle et al., 1982), and each binds a specific receptor, which leads to mast cell degranulation and neutrophil aggregation. Histamine from mast cells drives increased vascular permeability and vasodilatation (Hawlisch et al., 2005; Weigle et al., 1982). C5a is the most important of the anaphylatoxins, acting as both an anaphylatoxin and as a chemotactic factor for neutrophils (Robbins et al., 1987). Thus, within minutes of an antibody binding to a pathogen, the complement system has ensured that neutrophils are recruited to phagocytose and kill the pathogen and have enhanced the phagocytosis of the pathogen by coating it with C3b. The anaphylatoxins increase

blood flow to the site and increase vascular permeability such that additional complement proteins and antibodies can enter the tissue. C5a serves to direct neutrophils to the location of the pathogen. It is therefore no surprise that deficiencies of classical pathway components are associated with an increased predisposition to infection with bacteria.

THE ALTERNATIVE PATHWAY

The alternative pathway does not require the existence of preformed antibody, and it and the lectin activation pathway constitute the truly innate activation arms of the complement cascade (Pangburn, 1989a, 1989b). Alternative pathway activation relies on a biochemical quirk of C3. C3 spontaneously hydrolyzes in serum at a low rate (Pangburn & Muller-Eberhard, 1983). This spontaneous hydrolysis is often referred to as "C3 tick-over." The hydrolyzed C3 undergoes a conformational change that allows it to interact with factor B. Factor D cleaves factor B only when complexed with hydrolyzed C3. C3bBb is the alternative-pathway C3-converting enzyme, which is stabilized by properdin, and this enzymatic complex cleaves additional C3 into C3b and C3a (Nolan et al., 1991). Factor H on our own cells displaces factor B from C3b and catabolizes C3b, preventing activation of complement on our own cells (Fig. 55.2). Activation proceeds on surfaces such as mannose or N-acetyl glucosamine-rich pathogen surfaces, where factor H does not bind.

In summary, the alternative pathway is generally activated through the recognition of oligosaccharide and charge differences common to pathogens. The alternative pathway exploits the instability of the native C3 molecule and, on pathogen surfaces, nucleates a complex of C3bBb that cleaves additional C3.

THE LECTIN ACTIVATION PATHWAY

Mannose binding lectin (MBL) recognizes oligosaccharides specific to pathogens (Childs et al., 1989; Matsushita & Fujita, 1995; Sastry et al., 1989). Mammalian glycoproteins are generally decorated with galactose and sialic acid, not recognized by MBL, while MBL avidly binds to oligosaccharides associated with bacteria, yeast, and parasites such as mannose, N-acetylglucosamine, fucose, and glucose (Childs et al., 1989). Upon binding to the carbohydrate ligand, MBL activates two associated enzymes, MASP1 and MASP2. The arrangement of these enzymes with MBL is quite similar to the C1q-C1r-C1s arrangement. MASP2 cleaves C4 and MASP1 cleaves C3. Once C4b is bound to the pathogen surface, the remaining protein–protein interactions are identical to those in the classical pathway. MBL also binds to agalactosyl IgG with high affinity (Malhotra et al., 1995). This unusual IgG is produced primarily at sites of inflammation, and this antibody could activate both the classical pathway and the lectin activation pathway.

In summary, the lectin activation pathway represents an important arm of the innate immune system. This pathway is activated directly by pathogen oligosaccharides. The C3 convertase produced in the lectin activation pathway is identical to that of the classical pathway and the inflammatory mediators perform the same functions.

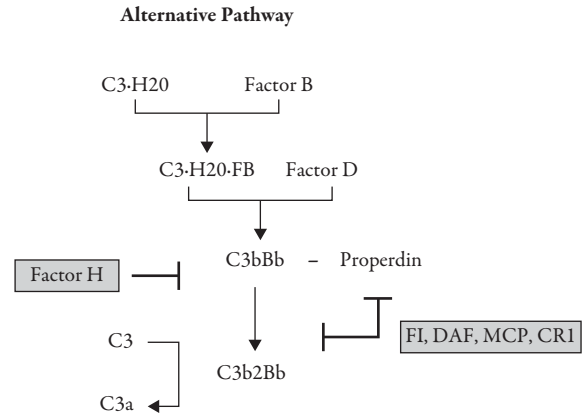

Figure 55.2 The alternative pathway is activated when factor B binds hydrolyzed C3. This complex either is cleaved by factor D, when a pathogen surface supports activation, or is inactivated by factor H on self-tissues. Properdin stabilizes C3bBb and in the presence of additional C3 can promote the formation of the C5 convertase complex, $C3b_2Bb$.

THE MEMBRANE ATTACK COMPLEX

Once C3 is cleaved by any of the activation arms described above, it becomes a part of the next enzymatic complex, the C5 convertase. This C5 convertase will be either C4b2a3b (classical and lectin activation pathways) or $C3b_2Bb$ (alternative pathway). The cleavage of C5 follows the typical pattern, with the larger fragment becoming attached to a surface and the smaller fragment diffusing into the fluid phase. C5b binds to C6 and C7, and they collectively serve to anchor the complex to the lipid bilayer (Halperin et al., 1993; Salama et al., 1983). C5b, which remains more external than the other components, binds directly to C8, which disrupts the physical integrity of the membrane and leakage of cytoplasmic proteins, and ions begin to occur. The addition of multiple molecules of C9 leads to the formation of true pore, as opposed to a leaky patch (Bhakdi & Tranum-Jensen, 1986). Nucleated cells can repair membrane damage and are coated with regulatory proteins, which prevent the lytic activity of the terminal components. Thus, it is often the red cells that are affected by complement activation clinically.

In summary, the terminal components, also known as the membrane attack complex, serve to induce lysis of a target. They are most efficient at lysing gram-negative bacteria.

RECEPTORS AND BIOLOGICAL FUNCTIONS

Receptors for complement mediate many of the biological functions of complement (Table 55.2). The G-protein–coupled anaphylatoxin receptors are widely expressed on mast cells, basophils, eosinophils, neutrophils, platelets, endothelial cells, and smooth muscle cells (Martin et al.,

Table 55.2 COMPLEMENT RECEPTORS

RECEPTOR	LIGAND	ROLE	COMMENTS
CR1	C3b, C4b, iC3b	Immune complex clearance, phagocytosis	Four allelic forms differ in size, CD35
CR2	C3d, C3dg, iC3b	B-cell activation	CD21
CR3	iC3b, C3d, C3b ICAM-1	Neutrophil adhesion, phagocytosis	β2 integrin, 165 kD α chain, 95 kD β chain, CD11b/CD18
CR4	iC3b, C3b	Neutrophil adhesion	β2 integrin, 150 kD α chain, 95 kD β chain, CD11c/CD18
CRIg	C3b, iC3b	Intravascular pathogen clearance	
C1qRp	C1q, MBL, surfactant protein A	Phagocytosis	126 kD, CD93
cC1qR	C1q, MBL, surfactant protein A	Phagocytosis	Recognizes collagen domain
C3aR	C3a >>> C4a	Increases vascular permeability, mast cell degranulation, chemotaxis	48 kD protein
C5aR	C5a, C5a desArg	Chemotaxis, mast cell degranulation, increases vascular permeability	43 kD protein, CD88

1997). These receptors mediate histamine release, aggregation of neutrophils, stimulation of mucus release from goblet cells, and activation of macrophages (Takahashi et al., 1996). In the face of an infection, these functions may all be viewed as protective (Fig. 55.3). The vasodilatation acts to deliver additional neutrophils to the site of inflammation, mucus release may facilitate clearance of organisms, activation of macrophages enhances phagocytosis, and aggregation of neutrophils reflects enhanced transendothelial migration into the affected tissue.

The C5a receptor can also mediate neutrophil chemotaxis. Thus, the early inflammatory response, mediated by small-molecule mediators, serves to deliver increased blood flow to the area and increases extravasation of antibody and complement into the tissues, and then C5a provides directionality for the recruited neutrophils (Fig. 55.3). This is a very efficient system to direct a response to a focal infection; however, in overwhelming sepsis, high levels of serum C5a can cause neutrophil aggregation, blockage of pulmonary vessels, and adult respiratory distress syndrome (ARDS). C5a also appears to be one of the major contributors to disseminated intravascular coagulation in sepsis (Czermak et al., 1999).

C1q receptors mediate phagocytosis and can enhance microbicidal activity. They also appear to be important for the clearance of apoptotic cells. The CR1 (CD35) receptor is widely expressed and primarily binds C3b, C4b, and iC3b (Medof et al., 1982; Weiss et al., 1989). Its main functions are the clearance of immune complexes to prevent unwanted inflammation and enhancement of phagocytosis. CR1 also has a regulatory role in the inactivation of C3 and the destabilization of the C3 and C5 convertase complexes (Wilson et al., 1987). The CR2 receptor (CD21) is the receptor for the Epstein-Barr virus and is expressed on B cells, follicular dendritic cells, epithelial cells, and some T cells (Cooper et al., 1990; Marquart et al., 1994).

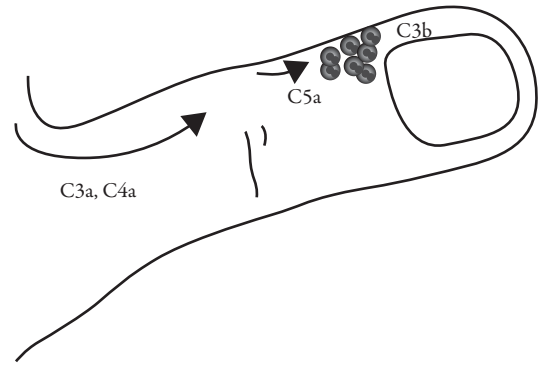

Figure 55.3 Complement plays multiple roles in ensuring the delivery of cells and proteins to sites of infections. The anaphylatoxins lead to vasodilatation and vascular leak, thus ensuring the delivery of cells and proteins to the site. C5a provides a chemotactic gradient for neutrophils and C3b acts as an opsonin to facilitate neutrophil phagocytosis.

Its main function is as a B-cell costimulatory molecule (Ahearn et al., 1996; Fischer et al., 1996; Marquart et al., 1994). Antigen linked to C3d activates B cells much more strongly than pure antigen (Dempsy et al., 1996).

CR3 and CR4 are both members of the β2 integrin family (Wagner et al., 2001). These receptors bind iC3b and C3b. The CR3 receptor also binds C3d. These receptors act primarily as adhesion molecules and recognize the opsonized pathogen. The CRIg receptor is the primary receptor mediating clearance of complement-tagged bloodborne pathogens (Wiesmann et al., 2006).

A typical bacterial infection would activate the complement cascade, and recognition of that act by specific cell-surface receptors would facilitate clearance of the pathogen. The anaphylatoxin receptors would enhance blood flow to the site and augment local concentrations of antibody and

Table 55.3 COMPLEMENT REGULATORY PROTEINS

PROTEIN	LOCALIZATION	FUNCTION	COMMENTS
C1 inhibitor	Serum	Binds to C1r and C1s and dissociates the C1 complex	105 kD
C4 binding protein	Serum	Cofactor for factor I cleavage of C4b	550 kD
Factor I	Serum	Cleaves C3b and C4b	
Factor H	Serum	Defines activator surface	
Decay accelerating factor (DAF)	Ubiquitous/cell membrane	Dissociates both C3 and C5 convertases	GPI-anchored CD55
Membrane cofactor protein (MCP)	Hematopoietic cells except erythrocytes	Cofactor for C3b cleavage by factor I	CD46
C8 binding protein	Most hematopoietic cells	Binds to C8 and prevents interaction with C9	GPI-anchored, also known as homologous restriction factor
CD59	Hematopoietic cells, endothelial cells, epithelial cells, glomerular cells	Inhibits the membrane attack complex	GPI-anchored, also known as HRF20

complement. C5aR would recruit neutrophils, CR1 and C1q would enhance phagocytosis, and the CR3 receptor would act as the major opsonic receptor. CR2 would act to improve antibody production to the pathogen. This beautifully integrated system plays a substantial role in host defense, and deficiencies of complement components demonstrate the important function of complement.

REGULATION OF COMPLEMENT ACTIVATION

The regulators of complement are divided into fluid-phase regulators and membrane-bound regulators (Table 55.3). C1 inhibitor is a fluid-phase inhibitor, and it regulates C1 by binding to C1s and C1r, leading to dissociation. It is thought that C1 inhibitor acts on MBL and MASP1/2 through a similar mechanism. C1 inhibitor has important roles inhibiting factor XII (Hageman factor) and prekallikrein of the contact system of coagulation (Cicardi et al., 2005; Davis, 2004), functions of paramount importance for the clinical features of C1 inhibitor deficiency.

C4 binding protein is another fluid-phase regulator of complement, and it acts to displace C2a and dissociate the classical pathway convertase (Gronski et al., 1988; Hessing et al., 1990). Factor I, alongside factor H, regulates the alternative pathway (Discipio & Hugli, 1982; Isenman, 1983; Kinoshita & Nussenzweig, 1984; Masaki et al., 1992). Factor H identifies nonactivator surfaces though the recognition of nonpathogen oligosaccharides and displaces Bb from C3b on those surfaces. Factor I inactivates C3b by cleaving it to iC3b, and its activity is enhanced in the presence of factor H. Together, these two regulators ensure that the spontaneous activation of the alternative pathway remains at a low level and prevents attachment of the complex to our own cells.

Factor I also acts to inhibit C4b from the classical pathway (Hardig et al., 1997; Masaki et al., 1992). In this setting, it interacts with C4 binding protein and cleaves C4b into C4c and C4d. C4 binding protein has an interesting structure and regulates the complement cascade as well as the coagulation cascade, as is true for C1 inhibitor.

The membrane-bound regulators of complement consist of the ubiquitous 70kD molecule termed DAF, membrane cofactor protein (MCP, CD46), C8 binding protein, and CD59 (Hansch et al., 1988; Lublin et al., 1986, 1987, 1988; Masaki et al., 1992; Rollins et al., 1991; Taguchi et al., 1990). DAF serves to dissociate the C3 convertase, and MCP serves as a cofactor for factor I cleavage of C3b and C4b. CD59 directly inhibits the membrane attack complex. Several receptors also act as complement regulatory proteins, and in these cases, the regulatory activity may be viewed as termination of that specific complement function after the signal has been delivered.

THE MECHANISMS UNDERLYING THE CLINICAL MANIFESTATIONS OF COMPLEMENT DEFICIENCIES

The clinical expression of genetically determined deficiencies of the complement system is variable and depends on the role of the deficient component in normal host defense and inflammation (Tables 55.4 and 55.5). Individuals with genetically determined deficiencies of complement components often have an increased susceptibility to infection or systemic lupus erythematosus (SLE). Less frequently, complement-deficient patients have a phenotype related to dysregulated vascular tissues.

INFECTION

Complement is especially important during the first few hours of infection (Winkelstein et al., 1975) and in containing the infection at its initial site (Bakker-Wondenberg et al., 1979).

Table 55.4 INHERITED COMPLEMENT DEFICIENCIES

DEFICIENCY	CHROMOSOMAL LOCATION	NUMBER OF CASES REPORTED	CLINICAL FEATURES, DIAGNOSTIC STRATEGY
C1q	1p36.12	10–100	SLE, infections, CH50 near zero
C1r/s	12p13	10–100	SLE, infections, CH50 near zero
C4	6p21.3	10–100	SLE, infections, CH50 near zero
C2	6p21.3	Many	SLE, infections, some asymptomatic, CH50 near zero
C3	19p13.3–13.2	10–100	Infections frequent and severe, glomerulonephritis, CH50/AH50 near zero
Factor D	19p13.3	<10	*Neisseria*, AH50 near zero
Factor B	6p21.3	<10	*Neisseria*, AH50 near zero
Properdin	Xp11.3–11.23	>100	*Neisseria*, AH50 near zero
MBL	10q11.2–21	Millions	Most asymptomatic, MBL assay required
C5	9q33	10–100	*Neisseria*, CH50/AH50 near zero
C6	5p13	>100	*Neisseria*, CH50/AH50 near zero
C7	5p13	>100	*Neisseria*, CH50/AH50 near zero
C8	1p32, 9q34.3	>100	*Neisseria*, CH50/AH50 near zero
C9	5p13	Many	*Neisseria*, CH50/AH50 diminished
Factor I	4q25	10–100	*Neisseria*, hemolytic uremic syndrome, C3 may be diminished, many require mutation analysis
Factor H	1q32	10–100	*Neisseria*, hemolytic uremic syndrome, C3 may be diminished, many require mutation analysis
MCP	1q32	<10	Hemolytic uremic syndrome, mutation analysis required
C1 inhibitor	11q12–13.1	Many	Angioedema, C1 antigen and functional levels
CR3/CR4	16p11.2	>100	Leukocyte adhesion deficiency, very severe systemic infections, lack of pus, flow cytometry
CD59	11p13	<10	Paroxysmal nocturnal hemoglobinuria, flow cytometry
DAF	1q32	10–100	Inab phenotype, blood typing
C4bp	1q32	<10	Autoimmunity, mutation testing

If dissemination should occur, complement contributes to the clearance of microbes from the bloodstream (Helmy et al., 2006; Hosea et al., 1980). Furthermore, complement plays an important role in resistance to infection in both the "immune" host with high levels of antibody and in the "nonimmune" host with little if any antibody.

Although studies in experimental animals have shown that the complement system has the potential to contribute to the host's defense against a wide variety of bacteria, fungi, and viruses, clinical experience would suggest that the greatest susceptibility of complement-deficient patients is to bacterial infections (Figueroa & Densen, 1991; Ross & Densen, 1984). The kinds of bacteria that most commonly cause infections in complement-deficient patients reflect the specific role of the missing component in normal host defense. For example, the major cleavage products of C3 (C3b and C3bi) are important opsonins. Therefore, patients with a deficiency of C3 have a markedly increased susceptibility to infection with those bacteria for which opsonization is the primary mechanism of host defense (e.g., *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Haemophilus influenzae*). Patients with a deficiency of C1, C4, or C2 also have an increased susceptibility to these same encapsulated bacteria, since these components are necessary for the activation of C3 via the classical pathway. However, they do not appear to be as susceptible as patients with C3 deficiency, since their alternative pathway is intact and able to activate C3.

Although bloodborne, systemic infections such as bacteremia and meningitis are the most common bacterial infections reported in complement-deficient patients (Figueroa & Densen, 1991; Ross & Densen, 1984), localized infections such as sinusitis, otitis, and pneumonia have also been seen. Infections in complement-deficient individuals are usually caused by the common encapsulated bacteria to which normal hosts are also susceptible, such as the pneumococci, streptococci, and meningococci. However, systemic infections with unencapsulated strains of pathogenic bacteria such as the meningococci, which are extremely rare in normal individuals, have been described in a number of complement-deficient individuals (Hummel et al., 1987).

Activation of the terminal components, C5 to C9, results in the assembly of the membrane attack complex and the

Table 55.5 COMPLEMENT COMPONENT DEFICIENCIES: GENETIC BASIS

COMPONENT	GENE NAME	INHERITANCE PATTERN
C1q	*C1QA, C1QB, C1QG*	AR
C1r/C1s	*C1R/C1S*	AR
C4	*C4A, C4B*	AR
C2	*C2*	AR
C3	*C3*	AR
C5	*C5*	AR
C6	*C6*	AR
C7	*C7*	AR
C8A/B	*C8A/C8B*	AR
C8G	*C8G*	AR
C9	*C9*	AR
Factor B	*BF*	AR
Factor D	*DF*	AR
Factor H	*HFI*	AR and AD
Factor I	*IF*	AR and AD
MCP	*MCP*	AR and AD
Properdin	*PFC*	X-linked recessive
C4bp	*C4BPA/C4BPB*	Unknown
C1 inhibitor	*C1NH*	AD
DAF	*DAF*	AR
CD59	*CD59*	AR
MBL	*MBL*	AD and AR

AD, autosomal dominant; AR, autosomal recessive.

generation of bactericidal activity for gram-negative bacteria. Therefore, patients with deficiencies of one of the terminal components have an increased susceptibility to infection with those gram-negative bacteria, such as *Neisseria meningitidis*, that are most susceptible to the bactericidal activities of the complement system. As expected, infections with gram-positive bacteria, such as the pneumococci, are not seen with any greater frequency in patients with deficiencies of a terminal component because these bacteria are not susceptible to the bactericidal activity of the complement system.

Some clinical features of meningococcal infections are different in complement-deficient individuals from those of meningococcal infections in individuals with an intact complement system. It has been hypothesized that once the infection is contained with antibiotics, complement-mediated inflammation contributes to the severity and sequelae (Figueroa & Densen, 1991; Platonov et al., 1993; Ross & Densen, 1984).

SYSTEMIC LUPUS ERYTHEMATOSUS

Complement plays a role in tolerance, immune complex clearance, and clearance of apoptotic cells (Botto et al., 1998; Carroll, 2004; Navratil & Ahearn, 2000; Schifferli et al., 1986). These three mechanisms are believed to underlie the susceptibility of patients with C1, C4, and C2 deficiencies to SLE. As cells undergo apoptosis, intracellular constituents are reorganized and appear on the surface of the cell in blebs. Autoantigens targeted in patients with SLE, such as SSA and/or SSB, are often found on the surface in these blebs (Casciola-Rosen et al., 1994), rendering visible a normally invisible antigen.

There is a hierarchy of risk for SLE among the complement components. For example, less than half of patients with C2 deficiency and nearly 100 percent of patients with C1 deficiency develop SLE (Walport et al., 1997). In contrast, fewer than 2 percent of patients with deficiencies of C5, C6, C7, C8, or C9 have SLE. The hierarchy is partly explained by the ability of individual components to participate in immune complex clearance (Schifferli & Peters, 1983; Schifferli et al., 1985) and the clearance of apoptotic cells (Mevorach et al., 1998). C1 and C4 appear to be the most important for tolerance (Carroll, 2004), and this may explain why deficiencies of these two components are the most strongly associated with SLE.

A variety of other autoimmune diseases, including discoid lupus, dermatomyositis, scleroderma, anaphylactoid purpura, vasculitis, and membranoproliferative glomerulonephritis, have also been reported in patients with complement deficiencies (Figueroa & Densen, 1991; Ross & Densen, 1984). The mechanisms underlying these associations and the true frequencies are not known.

There are some clinical differences between the SLE seen in patients with C2 deficiency and the SLE seen in individuals without inherited complement deficiencies. The SLE seen in C2-deficient patients often has its onset in early adulthood, is frequently characterized by a prominent annular photosensitive dermatitis, and may have relatively mild pleuropericardial and renal involvement. In addition, it is not uncommon for C2-deficient patients to have low (or absent) titers of antibodies to nuclear antigen and/or native DNA (Glass et al., 1976; Meyer et al., 1985; Provost et al., 1983). In contrast, the prevalence of anti-Ro antibodies is reported to be higher than in non–C2-deficient patients with lupus (Jonsson et al., 2007; Provost et al., 1983). The SLE seen in patients with C1q deficiency tends to have severe end-organ effects and is usually associated with positive titers to nuclear antigen (Bowness et al., 1994; Vassallo et al., 2007).

HEMOLYTIC UREMIC SYNDROME

Complement regulatory proteins prevent the activation of complement on host tissues. The vasculature represents a particularly dangerous location, as all the cells are in constant contact with the complement proteins. Hemolytic uremic syndrome occurs due to defects in complement regulatory proteins and an inability to protect fenestrated endothelium in the glomerulus from complement-mediated damage (Pangburn, 2002). The anionic nature of the basement membrane can support complement activation. Microtrauma arises frequently due to the high oncotic pressure, and the

basement membrane is able to support complement activation if not protected. Complement-mediated destruction of the renal vasculature is the main mechanism of disease.

EPIDEMIOLOGY OF COMPLEMENT DEFICIENCIES

Infections and SLE are common clinical manifestations of genetically determined complement deficiencies. Accordingly, a number of studies have attempted to estimate the incidence of complement deficiencies in these disorders to determine how frequently complement deficiencies contribute to their pathogenesis and to evaluate the utility of screening certain groups of patients for complement deficiencies.

INFECTION

The prevalence of complement deficiencies is significantly higher in individuals with systemic meningococcal infections than in the general population. The frequency of complement deficiencies in sporadic cases of systemic meningococcal infections has been estimated to be between 1 and 18 percent (Ellison et al., 1983; Leggiadro & Winkelstein, 1987; Merino et al., 1983; Platonov et al., 1993; Rasmussen et al., 1987; Swart et al., 1993). In general, the prevalence is even greater in those patients who have had recurrent meningococcal disease (40 percent) (Nielsen et al., 1989b; Platonov et al., 1993), a positive family history of meningococcal disease (10 percent) (Nielsen et al., 1989b), or an unusual serotype of the meningococcus (20 to 50 percent) (Fijen et al., 1989). Chronic meningococcemia may also be associated with complement deficiencies. On the basis of these studies, it appears reasonable to screen any patient with a systemic meningococcal infection for a complement deficiency. Since there is a relatively high risk for recurrence, early identification of complement deficiency in patients with systemic meningococcal infections may prevent subsequent meningococcal infections.

The evidence that screening patients with systemic pneumococcal, streptococcal, or *H. influenzae* infections for complement deficiencies is less compelling (Densen et al., 1990; Ekdahl et al., 1995; Rasmussen et al., 1987; Rowe et al., 1989). Although sepsis and meningitis caused by these organisms are very common among patients with inherited complement deficiencies (Figueroa & Densen, 1991; Ross & Densen, 1984), one study demonstrated only a single complement-deficient patient in a series of 389 patients with bacteremia and/or meningitis caused by bacteria other than the meningococcus (Densen et al., 1990).

SYSTEMIC LUPUS ERYTHEMATOSUS

The prevalence of homozygous C2 deficiency is significantly higher in patients with SLE than in the general population. Genetically determined C2 deficiency is found in approximately 1 in 10,000 (0.01 percent) Caucasian individuals in the general population (Ruddy, 1986; Sullivan et al., 1994). In contrast, the prevalence of homozygous C2 deficiency in large series of patients with SLE has varied between 0.4 and 2.0 percent (Glass et al., 1976; Hartung et al., 1989; Sullivan et al., 1994). Although a number of patients with genetically determined C2 deficiency have also had other rheumatic diseases (Figueroa & Densen, 1991; Ross & Densen, 1984), there have been no studies that have documented a significantly increased prevalence of C2 deficiency in these disorders. Patients with early complement component deficiencies have a much higher risk of dying than typical SLE patients; therefore, screening for complement deficiency among all SLE patients may be warranted (Jonsson et al., 2005). Screening of SLE patients with an early onset of SLE or with a history of infections is more clearly indicated.

HEMOLYTIC UREMIC SYNDROME

Classical hemolytic uremic syndrome is due to *Shiga* toxins elaborated by bacteria. Pneumococcal infections can also cause a hemolytic uremic syndrome through a less-well-characterized mechanism. Atypical hemolytic uremic syndrome differs from classical hemolytic uremic syndrome because it is not related to clear-cut bacterial infections. Among patients with atypical hemolytic uremic syndrome, approximately 20 percent will have mutations in factor H. Mutations in MCP account for approximately 10 percent of cases, and another 10 percent of cases are ascribed to factor I mutations (Richards et al., 2007). Factor B and C3 mutations have been seen rarely. There are also factor H-related proteins that have been implicated in atypical hemolytic uremic syndrome, but the role of these proteins is not well understood. Two important aspects of these defects in regulatory proteins are that penetrance is incomplete and most mutations are heterozygous.

DISORDERS ASSOCIATED WITH COMPLEMENT DEFICIENCY

Most genetically determined complement deficiencies are inherited in an autosomal recessive fashion (Table 55.5). Properdin deficiency is X-linked and C1 inhibitor deficiency is autosomal dominant (heterozygous). Inherited complement component disorders are typically associated with a CH50 or AH50 of near zero and can be specifically defined in reference laboratories using a complementation system whereby patient sera are added to mixes generated with a single missing component. Mutation studies can be helpful for regulatory protein deficiencies but are not clinically warranted for intrinsic cascade proteins.

C1 DEFICIENCY

C1 is a complex of C1q, C1r, and C1s. C1q interacts with the antibody and has a tulip-shaped structure composed of three distinct proteins: C1QA, C1QB, and C1QC. C1r and C1s are embedded in the stem of the tulip and are the active enzymatic components of the complex. Patients with C1q deficiency (MIM 120550, 120570, 120575) present

nearly uniformly with early-onset SLE (Botto & Walport, 2002; Hannema et al., 1984; Slingsby et al., 1996). The autoantibody profile is similar in these patients compared to other SLE patients, although anti-dsDNA antibodies may be somewhat less common (Bowness et al., 1994; Walport et al., 1998). Clinically, the patients have more dramatic cutaneous and central nervous system (CNS) manifestations than in the typical patient with lupus, and the disease may be more severe. It is also believed that the lupus seen in C1q-deficient individuals is less steroid-responsive and has an earlier age of onset (Bowness et al., 1994; Walport et al., 1998). Patients with C1q deficiency also have an increased rate of infection, and this no doubt relates to compromised opsonization and a decrease in B-cell costimulation.

The molecular defects causing C1q deficiency are diverse, although there is a nonsense mutation at amino acid position 186 of C1qA that is common among C1q-deficient patients from Turkey (Berkel et al., 2000; Petry et al., 1996). C1q deficiency is not restricted to a specific ethnic heritage and has been identified in people of European, Asian, and Arabic heritage. Mutations in each of the three chains have been identified. In one case with a premature termination codon and undetectable A chain, B and C polypeptide chains were also absent, which suggests that C1A must be present for the formation and secretion of C1q (Petry et al., 1995). Because there are many mutations causing C1q deficiency, carrier detection and prenatal testing rely on the identification of each individual mutation in affected family members. Allele-specific polymerase chain reaction (PCR) has been used to identify carriers of the common Turkish mutation.

Fewer than 20 individuals with C1r deficiency (MIM 216950) have been described (Dragon-Durey et al., 2001; Inoue et al., 1998; Lee et al., 1978; Rich et al., 1979). Typically, C1r levels are markedly reduced (1 percent of normal) and C1s levels are 20 to 50 percent that of normal (Lee et al., 1978; Loos & Colomb, 1993). The mutations in patients with C1r deficiency have not been identified, but the fact that 7 of the first 12 patients identified with C1r deficiency have been of Puerto Rican descent suggests that there may be a founder effect.

C1s deficiency is less common than C1r deficiency. In these few cases, C1s has been markedly reduced, while C1r levels were 50 percent that of normal (Suzuki et al., 1992), a finding suggesting that neither monomer is stable in the absence of the other. Three mutations have been identified in patients with C1s deficiency (MIM 12058). One patient had a 4 bp deletion in exon 10, and two others had nonsense mutations in exon 12 (Dragon-Durey et al., 2001; Endo et al., 1999; Inoue et al., 1998).

C4 DEFICIENCY

There are two distinct genes for C4, termed C4A and C4B (MIM 120810, 120820). They are highly homologous, although C4A binds more avidly to protein while C4B binds more avidly to carbohydrate. Within each C4 gene, there can be deletions or duplications or simple inactivating mutations (Ballow et al., 1979; Fredrikson et al., 1991). One to two percent of the general population and up to 15 percent of patients with SLE have complete C4A deficiency. While C4A deficiency is a risk factor for SLE, the severity of the disease is often less in patients with C4A deficiency compared to complement-sufficient hosts (Colten, 2002; Howard et al., 1986; Meyer et al., 1985; Moulds et al., 1993; Welch et al., 1998). One to two percent of the population has complete C4B deficiency, but up to 15 percent of patients with invasive bacterial disease are C4B-deficient (Bishof et al., 1990). In contrast to the common partial deficiencies, complete C4 deficiency due to four inactive alleles is quite rare. Well over 50 percent of the C4-deficient individuals have SLE (Colten, 2002; Colten & Rosen, 1992; Mascart-Lemone et al., 1983). Cutaneous manifestations are common and severe, and the age of onset is often quite early. The renal disease has the typical appearance, although immunofluorescence for C4 is absent (Fig. 55.4). The usual array of autoantibodies are found, although anti-dsDNA antibodies may be somewhat less frequent in C4-deficient individuals compared to normal hosts. Infection appears to be a significant problem for patients with C4 deficiency, and infection is the major cause of death (Figueroa & Densen, 1991; Ross & Densen, 1984). The mechanisms underlying the predisposition to infection are probably related to impaired opsonization and a compromised B-cell response to antigen.

The mutations associated with complete C4 deficiency are diverse. Gene conversion accounts for the majority of C4B null alleles and a 2 bp insertion accounts for the majority of C4A null alleles; however, extensive mutation analyses have not been done in subjects from diverse racial backgrounds (Yang et al., 2004).

C2 DEFICIENCY

C2 deficiency (MIM 217000) is the most common of the inherited complement component deficiencies in Caucasians. Although rare in some ethnic groups, in Caucasians it is found with a frequency of 1:10,000. Most C2-deficient individuals are asymptomatic, in contrast to those patients with C4 and C1 deficiency. Between 20 and 40 percent of C2-deficient individuals will develop SLE (Figueroa & Densen, 1991; Jonsson et al., 2005; Ross & Densen, 1984). The age of onset is early adulthood, as is true for SLE in the general population. Although cerebritis, nephritis, and arthritis are less common in C2-deficient SLE patients compared to the typical SLE patient, cutaneous manifestations appear to be more common (Jonsson et al., 2007). Anti-Ro antibodies are extremely common in C2-deficient patients with SLE, although anti-dsDNA antibodies are infrequent (Vandersteen et al., 1982). Other autoimmune disorders have been described in patients with C2 deficiency although there may be an element of ascertainment bias, as CH50 assays are commonly run on patients with autoimmune disorders.

Over 95 percent of C2-deficient individuals are homozygous for a 28 bp deletion at the end of exon 6, which causes a splicing abnormality and premature termination of transcription (Johnson et al., 1992; Sullivan et al., 1994; Truedsson et al., 1993). The 28 bp deletion is associated with a conserved MHC haplotype: HLA-B18, BF*S, C2*Q0, C4A*4, C4B*2, DR2. The gene frequency of this deletion has been found to

be 0.005 to 0.007 percent in Caucasian populations (Sullivan et al., 1994; Truedsson et al., 1993), a frequency consistent with previous estimates of the prevalence of homozygous C2 deficiency of approximately 1:10,000 (Ruddy, 1986). In addition to the common 28 bp deletion, a 2 bp deletion has been found that results in a premature stop codon (Wang et al., 1998), and two different missense mutations have been identified that impair secretion of mature C2 (Wetsel et al., 1996). Detection of the 28 bp deletion through PCR has been used for both carrier detection and prenatal diagnosis (Sullivan & Winkelstein, 1994).

Infections are increased in C2-deficient individuals, as would be expected, and the most common cause of death among C2-deficient patients is sepsis (Jonsson et al., 2005). Other systemic infections such as meningitis, pneumonia, epiglottitis, and peritonitis have been seen, and the most common organisms have been *S. pneumoniae* and *H. influenzae* (Figueroa & Densen, 1991; Ross & Densen, 1984). With improved vaccination against these organisms, it is possible that the infection pattern will be altered.

C3 DEFICIENCY

C3 deficiency (MIM 120700) is the rarest of the four early component deficiencies, and it has the most severe phenotype by far (Botto et al., 1990, 1992; Grumach et al., 1988; Peleg et al., 1992; Singer et al., 1994). Membranoproliferative glomerulonephritis is seen in approximately a third of the cases of C3 deficiency, and SLE is rare (Figueroa & Densen, 1991; Ross & Densen, 1984). One specific C3 mutation has been associated with hemolytic uremic syndrome. All patients have a profound predisposition to infection, and the infections are sometimes characteristic of neutrophil dysfunction (abscesses), humoral deficiencies (sinopulmonary disease), and complement deficiencies (sepsis, meningitis). The severity of the infection phenotype dominates the clinical picture. Staphylococcal abscesses probably reflect an inability to opsonize and to generate the C5a chemotactic factor. Recurrent sinopulmonary infections reflect a significant compromise in B-cell costimulation. Systemic infections are due to a complete failure of C3b opsonization. These multiple defects contribute to the severe infectious manifestations of C3 deficiency (Reis et al., 2006).

One other feature of C3 deficiency deserves mention. During infections, a vasculitic rash may appear, and symptoms of serum sickness may occasionally be seen. These unusual findings are due to the lack of immune complex solubilization by C3. They are typically transient in nature but can cause confusion with lupus, particularly in the presence of glomerulonephritis.

C3 deficiency is rare, with fewer than 30 cases reported in the literature. There is a founder effect in South Africa among the Afrikaans-speaking population (Botto et al., 1992). The other mutations are diverse. Slightly more common is a partial deficiency of C3, termed hypomorphic C3 (McLean et al., 1978, 1985). This partial deficiency has been seen in a number of autoimmune disorders but is difficult to diagnose and is probably underascertained.

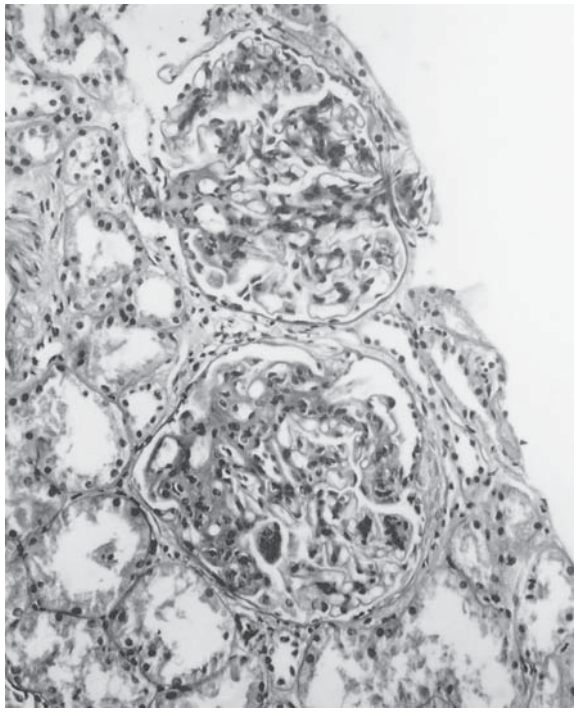

Figure 55.4 Glomerulonephritis in a patient with C4 deficiency. Inherited deficiencies of early complement components are associated with SLE and glomerulonephritis. This patient, with C4 deficiency, developed a malar rash and glomerulonephritis in early adolescence. A renal biopsy demonstrated increased mesangial matrix and cellularity. Immunofluorescence revealed deposits of IgG, C3, and C1q. (Courtesy of Thomas R. Welch, MD)

MBL DEFICIENCY

MBL deficiency (MIM 154545) was originally identified as associated with a variety of infectious diseases; however, it is quite common, with 2 to 7 percent of people having MBL deficiency (Thiel et al., 2006). Structural mutations and promoter mutations (Garred et al., 2006) both affect function. Because each mutation/polymorphism is relatively common, there are combinations of mild mutations that lead to complete loss of function.

A large number of studies have attempted to characterize the risk of infection in MBL-deficient individuals (Casanova & Abel, 2004; Thiel et al., 2006). It is felt to be more of a cofactor for infection in immune-compromised individuals than a direct cause of significant infection (Hansen et al., 2003; Sutherland et al., 2005).

MBL deficiency has also been examined as a risk factor for autoimmune diseases. It is associated with a risk of SLE (Garred et al., 2001), but in rheumatoid arthritis it is a modifier of disease, with the presence of MBL deficiency increasing radiological progression of disease (Graudal, 2004).

MASP2 DEFICIENCY

MASP2 deficiency (MIM 605102) was originally described in a single patient with autoimmune disease (Stengaard-

Pedersen et al., 2003). This patient suffered from ulcerative colitis and SLE. Laboratory evaluations revealed hypocomplementemia. Testing for MASP2 revealed very low levels, and a mutation was identified that interfered with MBL binding. It is now known that MASP2 deficiency occurs in 3.6 percent of Caucasians (Sorensen et al., 2005). MASP2 deficiency is frequently due to the D120G mutation, which abrogates its interaction with MBL (Thiel et al., 2007). Two mutations with founder effects among Africans and Amerindians have also been identified but are not as well characterized functionally (Lozano et al., 2005).

FACTOR B DEFICIENCY

Factor B deficiency (MIM 134350) was originally reported in association with neisserial infection (Densen et al., 1996b). The patient was identified after developing meningococcemia, and laboratory studies revealed an absent AH50. No mutation was characterized; however, abnormal protein was seen on electrophoresis. Several additional kindreds have been identified with gain-of-function mutations where the phenotype has been atypical hemolytic uremic syndrome (Goicoechea de Jorge et al., 2007).

FACTOR D DEFICIENCY

Neisserial infections are the most common manifestation of factor D deficiency (MIM 134350) (Figueroa & Densen, 1991; Kluin-Nelemans et al., 1984; Ross & Densen, 1984). Systemic streptococcal infections have also been seen (Weiss et al., 1998). Factor D is also known as adipsin, and mutations can also be associated with obesity (Flier et al., 1987). Other complement levels are typically normal in factor D deficiency; however, there is almost no ability to activate the alternative pathway.

PROPERDIN DEFICIENCY

Properdin deficiency (MIM 312060) is the only X-linked complement deficiency. It is one of the more common complement deficiencies and occurs largely in Caucasians. Approximately half of the properdin-deficient individuals have had one or more episodes of meningococcal disease (Densen et al., 1987; Figueroa & Densen, 1991; Fredrikson et al., 1996; Nielson & Koch, 1987; Ross & Densen, 1984; Sjoholm et al., 1982). Other bacterial infections are also seen but are much less common. There is a particularly high fatality rate in meningococcal disease in properdin-deficient patients, in contrast to the protection from mortality seen in patients with terminal complement component deficiencies. There may be a founder effect in Tunisian Jewish people; however, properdin deficiency is seen in subjects from all ethnic backgrounds.

In some families, properdin is undetectable, whereas in others affected males may have levels as high as 10 percent of normal. In still other kindreds, serum levels of antigenic properdin are normal but the protein is dysfunctional (Fijen et al., 1999). The serum of patients with properdin deficiency is unable to support the activation of C3 via the alternative pathway.

Mutations have been identified in several properdin-deficient patients. Three patients with no detectable serum properdin had mutations resulting in early stop codons (Fredrikson et al., 1996; Spath et al., 1997; Westberg et al., 1995). In kindreds in whom low levels of properdin were detected, different mutations were identified that resulted in amino acid substitutions (Westberg et al., 1995). One kindred with normal levels of dysfunctional properdin had a single base pair mutation in exon 9 resulting in the substitution of aspartic acid for tyrosine, rendering the molecule unable to interact with C3b (Fredrikson et al., 1996).

The role of properdin is to stabilize C3bBb, and in patients lacking this stabilizing function, activation of the alternative pathway is impaired. It is not completely clear why neisserial species are more subject to complement-mediated lysis than other gram-negative species. In vitro, most gram-negative organisms are susceptible to complement-mediated lysis, and it has been suggested that neisserial species are unusual in that they typically induce colonization of the nasopharynx prior to active infection. It may be that the site of inoculation is important, and other gram-negative organisms would be encountered predominantly in the gastrointestinal tract, where IgA is the dominant antibody and complement is not a prominent form of host defense.

C5 DEFICIENCY

C5-deficient patients (MIM 120900) have the same phenotype as the other terminal component deficiencies even though C5a is the major endogenous chemotactic factor for neutrophils (Figueroa & Densen, 1991; Ross & Densen, 1984; Wang et al., 1995). C5 deficiency is found in persons from a variety of ethnic and racial backgrounds. The mutations identified have included nonsense mutations and splice defects (Pfarr et al., 2005; Wang et al., 1995).

C6 DEFICIENCY

C6 deficiency (MIM 217050) is one of the more common complement disorders and occurs more frequently in African Americans and in people from South Africa. As is true for the other terminal component deficiencies, C6 deficiency is associated with meningococcemia, meningococcal meningitis, and disseminated gonococcal disease (Figueroa & Densen, 1991; Nishizaka et al., 1996a; Ross & Densen, 1984; Zhu et al., 1996). There are occasional reports of C6 deficiency associated with autoimmune disease, but it is likely that this represents ascertainment bias.

The most common form of C6 deficiency is characterized by undetectable serum levels of C6 and absent serum bactericidal activity. The basis for complete C6 deficiency in African Americans has been determined (Nishizaka et al., 1996a; Zhu et al., 1996). A homozygous single base pair deletion in exon

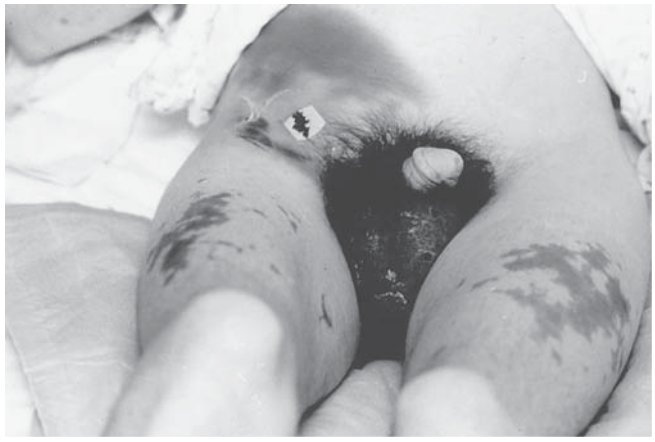

Figure 55.5 Meningococcal sepsis in a patient with C8 deficiency. Inherited deficiencies of terminal complement components are associated with an increased risk of meningococcal disease. This patient with C8 deficiency developed meningococcal meningitis and sepsis. (Courtesy of Peter Densen, MD)

12 that results in a frameshift and premature termination was found. Additional mutations have been identified and are diverse. Complete C6 deficiency occurs most frequently in South Africa, where haplotype determinations of flanking genes have demonstrated that the majority of C6 null alleles in this population arose from the same distant ancestor (Fernie et al., 1995, 1996b). However, in a minority of cases, the C6 null allele was found on a different haplotype, suggesting that there is some diversity even in this population. These haplotype determinations have been used to identify carriers in individual families.

There are two variations on C6 deficiency. In one case, a splice defect leads to a smaller-than-usual protein, C6SD (Wurzner et al., 1995). This protein functions less efficiently than wild-type C6; however, it is not clear whether bearing C6SD leads to compromised host defense. The other variation is combined C6 and C7 deficiency (Fernie et al., 1996a, 1996b).

C7 DEFICIENCY

C7 deficiency (MIM 217070) is not particularly common, and the few patients reported in the literature have had varied presentations. The most common presentation was neisserial disease (Figueroa & Densen, 1991; Nishizaka et al., 1996b; Ross & Densen, 1984). C7 deficiency can been seen in association with C6 deficiency, and the mutation is due to an arginine-to-serine change (Fernie et al., 1996b).

C8 DEFICIENCY

C8 is composed of three chains: α, β, and γ. The α and γ chains become covalently attached during synthesis and bind to the β chain. Interestingly, it is the α and β chain genes that are in linkage disequilibrium and map to chromosome 1p32. C8β deficiency (MIM 120960) is more common in Caucasians, while C8α-γ deficiency (MIM 120950, 120930) is more common among African Americans (Kaufmann et al., 1993; Kojima et al., 1998; Kotnik et al., 1997). The majority of the C8β mutations are due to a single base pair transition leading to a premature stop codon (Bellavia et al., 1996). The majority of the C8α-γ mutations are due to a 10 bp insertion leading to a stop codon (Densen et al., 1996a).

Regardless of the genetic basis, all types of C8 deficiency are associated with diminished bactericidal activity in vitro and an in vivo susceptibility to neisserial disease (Fig. 55.5) (Figueroa & Densen, 1991; Ross & Densen, 1984). Meningococcal meningitis, meningococcemia, and disseminated gonococcus have been seen. Rarely, C8 deficiency has been identified in patients with autoimmune disorders. The relationship of C8 deficiency to autoimmunity is not certain.

C9 DEFICIENCY

C9 deficiency (MIM 120940) is seen with high frequency in Asia (Hayama et al., 1989; Kang et al., 2005; Kira et al., 1999). Upwards of 0.05 percent of the population in Japan are C9-deficient. It is less frequent outside of Japan; however, it is also more difficult to diagnose than most of the other complement deficiencies described here because the CH50 is diminished but not absent (Hobart et al., 1997). C9-deficient serum can support some lytic activity, and the CH50 is typically one third to one half of normal in patients with C9 deficiency. This CH50 level would not typically lead to further evaluation. As is true for the other terminal complement component deficiencies, C9 deficiency is associated with neisserial disease, although the penetrance appears to be less than that seen in other terminal component deficiencies (Fukumori et al., 1989).

C1 INHIBITOR DEFICIENCY

Hereditary angioedema is due to heterozygous deficiencies of C1 inhibitor (C1INH). Infections and SLE are more common in this population but are subsidiary to the angioedema phenotype. The angioedema has no distinguishing features. It is not associated with urticaria, although a lacey reticular rash often precedes the onset of angioedema (Agostoni et al., 2004). The historical features most helpful in identifying potential C1 inhibitor-deficient individuals are recurrent episodes of angioedema, involvement of the airway in the absence of anaphylaxis, abdominal episodes, a positive family history, or angioedema arising after trauma (Agostoni et al., 2004).

There are two forms of C1INH deficiency (MIM 106100), both inherited as autosomal dominant traits (Rosen et al., 1965). In the more common form (type I), accounting for approximately 85 percent of patients, the serum of affected individuals is deficient in both C1INH protein (5 to 30 percent of normal) and C1INH functional activity (Cicardi et al., 1982; Frank et al., 1976; Rosen et al., 1971). The lower-than-expected levels of C1INH functional activity in heterozygotes are thought to be the result of increased catabolism of the normal protein (Ernst et al., 1996). In the less common form (type II), a dysfunctional protein is present in normal

or elevated concentrations, but the functional activity of C1INH is markedly reduced (Cicardi et al., 1982; Donaldson et al., 1985). In patients with type I C1INH deficiency, the diagnosis can be established easily by demonstrating a decrease in serum C1INH protein when assessed by immunochemical techniques. However, in patients with type II C1INH deficiency, the diagnosis must rest on demonstrating a decrease in C1INH functional activity. In either case, C4 levels are usually reduced below the lower limit of normal both during and between attacks (Austen & Sheffer, 1965; Pickering et al., 1968) because of their uncontrolled cleavage by C1s, thus making their measurement useful as a diagnostic clue.

This division of C1INH-deficient patients into two forms has no correlation with clinical phenotype and only limited correlation with genotype, as there are some examples of C1INH gene mutations in which a dysfunctional protein is produced but is degraded so rapidly that it is not detectable in the serum (Agostoni & Cicardi, 1992; Davis et al., 1993). Alu-mediated deletions and duplications account for the most common genotypes (Davis et al., 1993; Stoppa-Lyonnet et al., 1991). Four of the seven introns in the C1INH gene (C1NH) contain a total of 17 Alu-repetitive DNA elements. These Alu elements are responsible for most of the large deletions and duplications leading to C1INH deficiency. A variety of single base changes and smaller deletions and duplications have also been identified. Most patients with detectable but dysfunctional C1INH have a mutation that replaces the reactive center arginine residue. The other mutations identified in patients with dysfunctional protein are found in the hinge region and result in blockade of the reactive center loop, thereby inactivating the C1INH (Davis et al., 1993; Verpy et al., 1995).

The main manifestations of C1 inhibitor deficiency are recurrent episodes of submucosal or subcutaneous edema, although 5 percent of people who carry a C1 inhibitor mutation are asymptomatic (Agostoni et al., 2004). Half of patients have had episodes before the age of 10 years. The episodes may be as infrequent as one per year or as frequent as one per month, and the frequency and the severity of episodes do not correlate with laboratory features and are often inconsistent within a family. The extremities, face, and genitalia are most often involved (Color Plate 55.I). Involvement of the gastrointestinal tract can lead to disabling abdominal pain. Abdominal episodes begin with pain and are often accompanied by vomiting, or more rarely, diarrhea. Nearly three quarters of patients have this distressing feature. In one study, one third of patients with C1 inhibitor deficiency had undergone an appendectomy or exploratory laparotomy for abdominal pain (Agostoni et al., 2004). The most feared type of angioedema is that involving the airway. Although the lungs are not involved, the upper airway can swell, leading to respiratory arrest. This complication can occur in as many as two thirds of patients with C1 inhibitor deficiency, although improved management has made it somewhat less common. Prior to modern management, slightly over 10 percent of patients underwent a tracheostomy as a result of airway episodes.

The angioedema typically progresses for 1 to 2 days and resolves in another 2 to 3 days. Common precipitants are illness, hormonal fluctuations, trauma, and stress. Although many patients can identify triggers, many episodes have no identifiable trigger, which increases anxiety and feelings of loss of control. The C1 inhibitor promoter is androgen-responsive, which is why men have fewer problems, in general, than female patients (Falus et al., 1990; Lener et al., 1998; Prada et al., 1998). It may also explain the common complaint that symptoms vary with menstruation. The main therapeutic modality in the United States is based on the androgen responsiveness of the promoter and serves to increase expression of the intact gene.

The mechanism of angioedema is due to the production of bradykinin through the coagulation pathway. Hageman factor, also known as factor XII of the coagulation system, is activated by trauma-induced exposure of collagen on capillaries. C1INH inhibits the ability of activated Hageman factor to initiate kinin generation, and it inhibits kallikrein activation of the kinin system directly. Blister fluids from C1INH-deficient patients contain active plasma kallikrein, and their serum has decreased amounts of prekallikrein and kininogen (Curd et al., 1980), which suggests activation of the kinin system during attacks of edema. Furthermore, treatment with drugs that inhibit the release of vasoactive mediators is effective (Frank et al., 1972; Schneider et al., 2007; Sheffer et al., 1977) (Fig. 55.6).

C4 BINDING PROTEIN DEFICIENCY

C4 binding protein consists of multiple alpha chains and a single beta chain. It acts as a cofactor for factor I-induced cleavage of C4b and C3b. A single kindred with C4 binding protein deficiency (MIM 120830 120831), manifested by altered complement function, has been identified (Trapp et al., 1987). The proband presented with angioedema, vasculitis, and arthritis. The manifestations were thought to relate to uncontrolled activation of the classical pathway and release of anaphylatoxins. C4 binding protein interacts with protein S, and certain polymorphisms of C4 binding protein are associated with an increased risk of thrombosis.

FACTOR I DEFICIENCY

Factor I consists of two disulfide-linked polypeptides that act to regulate the alternative pathway-cleaving enzyme (C3b, Bb). One polypeptide carries serine protease activity that cleaves C3b to produce iC3b (inactive C3b), a C3-cleavage product that cannot function in the C3-cleaving enzyme of the alternative pathway.

Factor I deficiency (MIM 217030) has two phenotypes, and it is not yet clear whether a genotype–phenotype relationship exists. The first phenotype described relates to the role of factor I as a cofactor for C3bBb dissociation. When factor I is lacking, C3bBb continues to cleave C3 unabated and a secondary deficit in C3 occurs. Both the CH50 and AH50 are depressed, but not absent, and C3 antigen levels are low (Bonnin et al., 1993; Leitao et al., 1997; Vyse et al., 1994, 1996). The infectious consequences of low C3 are similar to those seen in true C3 deficiency (Figueroa & Densen, 1991; Ross & Densen, 1984). Neisserial disease has been seen as well as infections with more typical organisms such as

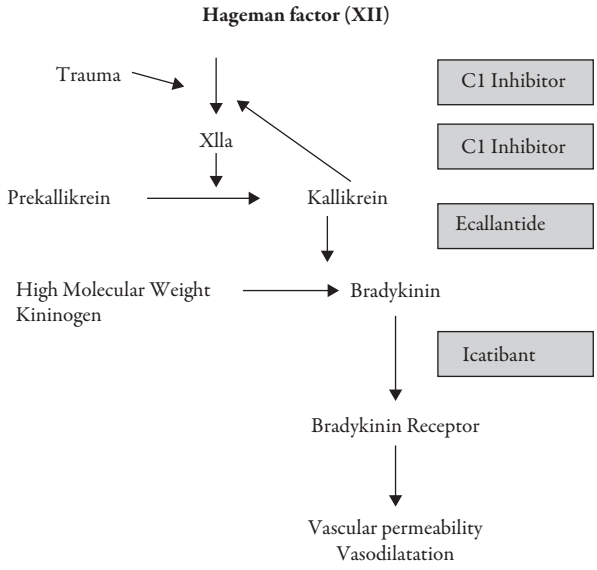

Figure 55.6 Hageman factor (factor XII) is predominantly activated by exposed collagen on damaged vascular tissue. Activated Hageman factor can cleave prekallikrein into active kallikrein. Kallikrein is part of a feed-forward loop, which leads to additional activation of Hageman factor and also cleaves high-molecular-weight kininogen into bradykinin. The gray boxes indicate the steps at which the various medications act.

S. pneumoniae and *H. influenzae*. As is true for inherited C3 deficiency, some patients have developed a serum sickness-like picture.

The second phenotype is atypical hemolytic uremic syndrome or membranoproliferative glomerulonephritis II (Fremeaux-Bacchi et al., 2004; Genel et al., 2005; Kavanagh et al., 2005). Hemolytic uremic syndrome is characterized by microangiopathic hemolytic anemia, renal disease, and hypertension. Atypical hemolytic uremic syndrome cases lack the common trigger of infectious diarrhea. Factor I deficiency is difficult to identify because complement studies are often normal. C3 levels may be depressed but are not necessarily depressed. The factor I level is typically normal as the mutations are not null. The mutations adversely affect binding to C3b and endothelium. The fenestrated endothelium of the glomerulus represents a landscape of polyanions where the basement membrane is exposed by the fenestration. Thus, the role of complement regulatory proteins would be greatest on those surfaces. Lack of protection due to lack of complement regulatory proteins would lead to endothelial damage in the glomerulus and hence hemolytic uremic syndrome.

FACTOR H DEFICIENCY

The gene for factor H (MIM 134370) lies within the RCA gene cluster on chromosome 1 (Holers et al., 1985). Factor H is synthesized in hepatocytes, macrophages, B cells, endothelial cells, and platelets. Factor H, like factor I, is an inhibitor of the alternative pathway. It competes with factor B for binding to C3b in the assembly of the alternative pathway C3-cleaving enzyme, C3bBb, and also displaces Bb once the enzyme has been assembled.

Infections, atypical hemolytic uremic syndrome, and macular degeneration are the main phenotypes seen in factor H deficiency (Dragon-Durey et al., 2004; Klein et al., 2005; Nielsen et al., 1989a; Sanchez-Corral et al., 2002). The infections are due to consumption of C3 and a secondary partial C3 deficiency (Reis et al., 2006). These can be easily suspected on the basis of diminished C3 levels and low but not absent CH50 and AH50, and typically the antigenic levels of factor H are low. Membranoproliferative glomerulonephritis has been identified in factor H deficiency, but the most common phenotype is atypical hemolytic uremic syndrome. Factor H deficiency was found to be the underlying basis for 15 to 30 percent of patients with atypical hemolytic uremic syndrome (Richards et al., 2007). Both autosomal recessive and heterozygous mutations have been seen. The age of onset is quite young in most cases, and the disease is recurrent (Caprioli et al., 2005). Death is not uncommon. These patients often have diminished C3 levels, although the antigenic level of factor H is typically normal or elevated. Because of the inconsistent complement laboratory analyses, mutation analysis is required for diagnosis.

A common tyrosine-to-histidine polymorphism of factor H was identified as a significant risk factor for macular degeneration in a genome-wide association study (Haines et al., 2005; Klein et al., 2005). Homozygous bearers of this polymorphic variant have a relative risk of 7.4 for the development of macular degeneration. Drusen are the characteristic retinal deposits seen in macular degeneration. These deposits contain factor H and terminal complement components. It has been hypothesized that the abnormal factor H provides less protection to the choroidal vessels, allowing smoldering complement activation and gradual damage to the endothelium.

MEMBRANE COFACTOR PROTEIN (CD46) DEFICIENCY

Deficiencies of membrane cofactor protein (MCP) are associated with a later onset of atypical hemolytic uremic syndrome compared to factor H and factor I deficiencies (Caprioli et al., 2005, 2006; Richards et al., 2003; Zimmerhackl et al., 2006). MCP mutations (MIM 120920) are thought to account for approximately 10 percent of all atypical hemolytic uremic syndrome cases. There is no other known phenotype for MCP deficiency. As MCP is a membrane protein, this defect is intrinsic to the kidney. In contrast to factor H and factor I deficiencies, renal transplantation can be successful. Traditional complement analyses are normal.

CD59 DEFICIENCY

A single patient with CD59 deficiency (MIM 107271) has been described, and the major manifestation was chronic hemolytic anemia (Yamashina et al., 1990). CD59 is expressed on most hematopoietic cells and endothelial cells, where it confers protection from intravascular complement-mediated lysis. This defect in CD59 was suspected because of the phenotypic resemblance to paroxysmal nocturnal hemoglobinuria (PNH).

DAF DEFICIENCY (CD55)

DAF deficiency (MIM 125240) is also termed the Inab blood group phenotype (Hue-Roye et al., 2005; Reid, 1990; Telen & Green, 1989). The Cromer blood group antigens reside on DAF, and the null phenotype is referred to as the Inab phenotype. Certain kindreds with DAF deficiency have had protein-losing enteropathy, while others have been completely healthy and have been identified at the time of blood donation or crossmatching for a transfusion. None of the patients have had hemolysis, suggesting that CD59 is substantially more important in regulating red cell lysis by complement.

CR3/CR4 DEFICIENCY

This disorder is a defect in the three β2 integrin adhesion molecules. It will be discussed in more detail in Chapter 53. The more common terminology for this β2 integrin deficiency is leukocyte adhesion deficiency type I (LAD 1). Mutations in the common β chain (CD18) (MIM 600065) lead to failure to express adequate α chains: CD11a, CD11b, and CD11c (Arnaout et al., 1990; Kishimoto et al., 1987). These three proteins are also known as LFA-1, CR3, and CR4.

The manifestations of the disorder are due to the combined effects of ineffective opsonization and an inability to migrate from the vascular space into the tissue space. β2 integrins are essential for the firm adhesion step and diapedesis. Lacking β2 integrins, the neutrophils remain in the vascular space, where they are unable to participate in the defense against bacteria.

DIAGNOSIS OF COMPLEMENT DEFICIENCIES

Most of the deficiencies of the classical pathway (C1 through C9) can be detected by using a hemolytic assay that assesses the functional integrity of the pathway. The most common of these, the CH50 assay, determines the ability of the patient's serum to lyse antibody-sensitized sheep erythrocytes. Since lysis depends on the functional integrity of the complete cascade, patients who have severe deficiencies of any of the individual components of the classical pathway will usually have less than 5 percent of normal total serum hemolytic activity. One exception is C9 deficiency. Because lysis of antibody-sensitized erythrocytes can occur in the absence of C9 (Stolfi, 1968), albeit to a lesser degree, patients with C9 deficiency have some total serum hemolytic activity, but usually between 30 and 50 percent of the normal level.

Deficiencies of components of the alternative pathway (factors B, D, H, I, and properdin) can be detected by using a hemolytic assay that tests the functional activity of the alternative pathway (AH50). The most common of these use rabbit erythrocytes, which are potent activators of the human alternative pathway (Polhill et al., 1978). Thus, patients with deficiencies of components of the alternative pathway, as well as patients with deficiencies of C5 to C9, will fail to lyse rabbit erythrocytes. Some factor H and factor I mutations do not affect the lytic ability in this assay. These are typically associated with atypical hemolytic uremic syndrome, and mutation testing is required for diagnosis in these cases.

Identification of the specific component that is deficient usually depends on both functional and immunochemical tests. Highly specific functional assays are available for each component. In each case, they depend on reagents that lack the specific component in question but provide the other components of the appropriate hemolytic pathway in excess. Monospecific antibodies are also available for each of the components and can be used in a variety of immunochemical assays to assess the presence or absence of the component in question. In most instances, the component will be deficient when assessed by both functional and immunochemical methods. However, there are some exceptions. Therefore, it is important to assess both antigen levels and functional levels when the index of suspicion is high.

MANAGEMENT OF COMPLEMENT DEFICIENCIES

Management of complement deficiencies requires specifically identifying the affected protein. For example, in inherited forms of atypical hemolytic uremic syndrome, renal transplants are indicated for MCP deficiency but not factor H or factor I deficiency. There are few genotype–phenotype correlations, and the main purpose of genetic testing for complement deficiencies is to confirm the defect. Where accurate protein identification is available, mutation testing is not required. The suggested strategies represent possible interventions based on the current literature. There are few clinical trials supporting a specific management strategy.

EARLY CLASSICAL COMPONENT DEFICIENCIES

The major features of early classical component deficiencies are SLE and infection. Patients with SLE are usually treated using standard modalities. One European study of C2-deficient SLE patients found replacement of C2 to be therapeutically useful; however, this product is not widely available (Erlendsson et al., 1993; Steinsson et al., 1989).

Therapy for infection is controversial, however. Patients are often given vaccines to raise the titers of antibodies to encapsulated organisms to high levels. In the case of terminal component deficiencies, high levels of antibody have been shown to partially compensate for the complement deficiency. For early complement component deficiencies, the major risks seem to be *S. pneumoniae* and *H. influenzae* (Figueroa & Densen, 1991; Jonsson et al., 2005; Ross & Densen, 1984). Vaccines to these entities exist, and there are theoretical reasons to believe that having high titers of antibody may offer protection. Prophylactic antibiotics are also often used to prevent life-threatening infections in patients. In one study, half of the C2-deficient patients had serious infections such as sepsis, and infection was the leading cause of death, accounting for over 10 percent of the deaths in this cohort (Jonsson et al., 2005). The range of age of deaths was quite broad, suggesting that

antibiotic prophylaxis might be required lifelong. Meningitis was also commonly seen. Thus, prevention of infection is desirable, and vaccination and prophylactic antibiotics should be given consideration. Patients taking immunosuppressive medication for rheumatological disorders may require more intensive efforts to prevent infection.

C3 DEFICIENCY

The optimal therapy for C3 deficiency is unknown. Infections in these patients are the most severe of any of the complement deficiencies, and management must address loss of opsonization, loss of B-cell costimulation, and loss of immune complex solubilization (Reis et al., 2006). One could consider the use of immune globulin replacement to compensate for the compromised B-cell function, and prophylactic antibiotic use could ameliorate some of the infections. Renal transplantation has been used in the setting of renal failure due to membranoproliferative glomerulonephritis. There is some recurrence risk. Nevertheless, as not all C3-deficient patients develop membranoproliferative glomerulonephritis, renal transplantation should be given consideration in patients with end-stage renal disease. Plasma infusions and liver transplantation as interventions remain theoretical options.

MBL DEFICIENCY

While MBL deficiency is common, infections arising in patients with MBL deficiency are not common (Garred et al., 2006; Thiel et al., 2006). Of those with infection, cofactors should be sought and treated. In the absence of treatable cofactors, antibiotics may be considered.

FACTOR D AND PROPERDIN DEFICIENCY

Patients with factor D and properdin deficiency have secondary consumption of C3. Neisserial disease is common and infections with *S. pneumoniae* and *H. influenzae* are also seen. Vaccination to achieve high titers of antibody to those entities could theoretically provide benefit. Traditionally, prophylactic antibiotics have been used for some patients in an effort to prevent infections (Biesma et al., 2001; Hiemstra et al., 1989; Sjoholm et al., 1988).

TERMINAL COMPLEMENT COMPONENT DEFICIENCIES

Deficiencies of C5, C6, C7, C8, and C9 are all associated with an increased risk of neisserial disease. Meningococcal disease is by far the most common, but disseminated gonococcal infections have been seen with significant frequency, and patients should be warned about the possibility. The prevention of meningococcal disease has been studied thoroughly in Russia and Europe, and two things have emerged from these studies. Patients with terminal complement component deficiencies have a rather abrupt onset of meningococcal disease but have a shorter and milder course ultimately (Platonov et al., 1993). Thus, patients in rural areas may be at increased risk due to potential delay in the initiation of treatment. The other important lesson is that vaccination every 3 years with the meningococcal vaccine decreases the frequency of meningococcal episodes but does not eliminate them (Drogari-Apiranthitou et al., 2000; Fijen et al., 1998; Platonov et al., 1995; Schlesinger et al., 2000). The frequency is decreased to 20 percent of what nonvaccinated individuals experience. No study has examined prophylactic antibiotics, and it may be that careful monitoring and hyper-vaccination is sufficient.

C1 INHIBITOR DEFICIENCY

Treatment of C1INH deficiency is different from that of other complement deficiencies in that there are specific measures available to ameliorate symptoms and prevent recurrences. In many patients, episodes of angioedema may occur frequently enough or be so difficult to manage as to justify long-term prophylaxis. Attenuated androgens such as oxandrolone or danazol are highly effective (Gelfand et al., 1976; Gompels et al., 2005) and act by increasing transcription of the normal allele of C1INH (Agostoni et al., 1980b). Another class of agents used for long-term prophylaxis are the antifibrinolytic agents (Frank et al., 1972; Sheffer et al., 1977; Van Dellen, 1996). Tranexamic acid and aminocaproic acid act by blocking plasmin generation. Although their efficacy is less than that of attenuated androgens, the incidence of side effects is also less than that of attenuated androgens. Antifibrinolytics may have usefulness in childhood but are difficult to obtain and have been largely supplanted by other modalities. Long-term prophylaxis with C1 inhibitor is available but is extremely expensive and requires twice-weekly intravenous infusions. For patients with frequent episodes, it represents a significant advance in normalizing their lives.

In some instances, patients may require short-term prophylaxis for surgery or oral procedures. Attenuated androgens, fibrinolytic agents, fresh-frozen plasma (FFP), and C1 inhibitor concentrate have all been used successfully for short-term prophylaxis. C1 inhibitor concentrate would be considered the most effective approach at this time.

Acute attacks can be life-threatening and can require urgent, aggressive intervention. C1 esterase inhibitor concentrate, bradykinin B2 receptor antagonist, and a kallikrein inhibitor are options (Agostoni et al., 1980a; Waytes et al., 1996). Each has advantages, with the currently approved products requiring a medical support system except for the bradykinin B2 receptor antagonist, which can be self-administered. Supportive care and close observation are essential for pharyngeal swelling because it can progress to airway compromise in a few hours (Figure 55.7 and Color Plate 55.I). Narcotics are appropriate for abdominal pain episodes. When the more modern agents are not available, antifibrinolytics are thought to reduce the severity and length of the episode, and attenuated androgens may do the same; however, they do not begin to have an effect for 24 hours. At various times, FFP and aprotinin have been used for acute episodes; however, FFP is thought to provide active substrate to enhance further edema and is not routinely used, and side effects with aprotinin have

limited its use. Epinephrine, antihistamines, and corticosteroids are of no proven benefit in C1INH-deficient patients.

Medical interventions for short-term prophylaxis, long-term prophylaxis, and acute therapy are given in Table 55.6. There are a number of strategies that should be reviewed with each patient (Agostoni et al., 2004). Genetic counseling should be offered to each family. The use of bracelets with medical information is an individual choice. For patients with anticipated travel or events that might lead to isolation from friends and family familiar with the disorder, bracelets might have some role to inform paramedics and physicians in the event of an emergency. Patients should be counseled to avoid certain medications. Angiotensin-converting enzyme (ACE) inhibitors can induce angioedema, as can estrogen-containing birth control pills or postmenopausal hormone replacement. In men, hormonal modulation may also affect their angioedema.

The last category of management is fertility and obstetrical management. Polycystic ovary syndrome is seen in approximately one third of female patients with C1 inhibitor deficiency regardless of prior therapy (Agostoni et al., 2004). The typical endocrine findings of increased luteinizing hormone and testosterone are not seen. Ultrasounds demonstrate polycystic ovaries, and the only laboratory feature is often reduced levels of follicle stimulating hormone. Menstrual irregularities are common, and the underlying pathogenesis is the aberrant regulation of complement activation in follicular fluid (Perricone et al., 2000).

Despite common menstrual irregularities, fertility is largely preserved, and pregnancy poses a particular risk to

Table 55.6 **THERAPEUTIC OPTIONS FOR C1 INHIBITOR DEFICIENCY***

TREATMENT	ADULT	PEDIATRIC	COMMENTS
Tranexamic acid (Cyclokapron)	1–3 g/d PO as divided doses for prophylaxis, 1 g po q3–4h until episode resolves for acute episodes	25–50 mg/kg BID or TID as prophylaxis, 1.5 g/d for acute episodes (available as IV form)	Not available in the USA
Epsilon aminocaproic acid (Amicar)	1 g po TID as prophylaxis, 1 g/h as IV therapy for acute attacks	100 mg/kg q4–6h not to exceed 30 g/d as therapy. Oral syrup available for prophylaxis but doses not established: 6 g/d for children <11 y and 12 g/d for children >11 y has been used successfully.	The only antifibrinolytic available in the USA. Modest efficacy. Cannot be used in neonates. Oral dosing has significant GI side effects.
Danazol (Danocrine)	200 mg po QD as a starting point for prophylaxis (titrate to effect), 400–600 mg po QD for acute episode or short-term prophylaxis	50–200 mg po QD as a starting point for prophylaxis; titrate to effect and consider QOD or Q 3 days in preadolescent children; can use up to 400 mg po QD as short-term prophylaxis	Concern about androgenization and premature closure of the epiphyses limits the use of attenuated androgens in children. Titration to desired effect is recommended rather than to laboratory criteria.
Oxandrolone (Oxandrin)	2.5–20 mg po TID as prophylaxis (titrate to effect). Not proven as short-term prophylaxis or treatment.	0.1 mg/kg/d as prophylaxis. Not proven as short-term prophylaxis or treatment in a formal clinical trial.	Has fewer androgenizing effects than danazol
Fresh-frozen plasma (FFP)	2 U IV as short-term prophylaxis. May be required for up to 36 hours after surgery.	10–15 mL/kg as short-term prophylaxis. May be required for up to 36 hours after surgery.	Not typically used for acute episodes due to danger of accelerating angioedema; inexpensive for short-term prophylaxis for surgery or dental extractions
C1 inhibitor concentrate (Cinryze, Berinert)	20 U/kg as IV treatment using Berinert, 1,000 U IV every 3–4 days for prophylaxis using Cinryze	10–30 U/kg as treatment (up to 500–1,000 U total)	Very rapid effect; especially useful in pregnancy; self-infusion possible with training
Ecallantide (Kalbitor)	10 mg subQ ×3	Not FDA approved for children	High rate of anaphylaxis; requires medical supervision
Icatibant (Firazyr)	30 mg subQ into abdomen for acute episodes	Not FDA approved for children. Injection site pain may limit use in young children.	Bradykinin receptor antagonist. Cannot be used with angiotensin-converting enzyme (ACE) inhibitors.

* Supportive care:

Airway protection, fluid replacement, and pain relief are of paramount importance. Some episodes require no intervention. For long-term prophylaxis, consider monitoring liver by ultrasound and blood studies. Although epinephrine is ineffective systemically, it may provide some benefit when used topically in airway obstruction.

both the mother and the fetus. The hormonal shifts of pregnancy lead to an increased risk of angioedema, although late pregnancy seems to offer some protection. Delivery is itself traumatic, and an affected mother has a 50 percent chance of transmitting the disorder to her offspring. Thus, potentially both mother and child are at risk during delivery. There is no consensus on management. C1 inhibitor may be given prophylactically or if problems arise.

FACTOR H, FACTOR I, FACTOR B, AND MCP DEFICIENCY

It is thought that certain mutations in factor H, factor I, and factor B deficiency predispose to meningococcal disease while others predispose to hemolytic uremic syndrome. In kindreds with meningococcal disease, the same strategies utilized for patients with terminal complement component deficiencies would be expected to be of benefit. In kindreds with hemolytic uremic syndrome, the management is less clear. As is done for thrombotic thrombocytopenic purpura (TTP), some patients receive pheresis and FFP replacement for acute episodes (Caprioli et al., 2006; Goodship, 2006). One study evaluating factor H replacement demonstrated benefit, suggesting that FFP alone might be of benefit as prophylaxis. In the case of MCP, where the affected protein is membrane-bound, it is less clear that pheresis and FFP would provide benefit, but it could potentially act to clear inciting agents or complement activation products. For patients with end-stage renal disease, the recurrence of disease in patients with factor H or factor I deficiency is unacceptably high and renal transplantation is not recommended. In contrast, renal disease in MCP typically does not recur in the transplanted kidney.

56.

ASSESSMENT OF THE IMMUNE SYSTEM

Francisco A. Bonilla and Klaus Warnatz

INTRODUCTION

In this chapter, we discuss the assessment of immune function in the context of a diagnostic approach to the patient with suspected primary immunodeficiency. We will begin by discussing general elements of the clinical history and physical findings in the broad spectrum of primary immunodeficiency diseases (PIDDs) and how these guide the choices of screening tests to be performed in the initial laboratory evaluation. We will then discuss more specific tests that may be used to further define functional deficits in an attempt to focus ultimately on one or a few molecular tests to establish (wherever possible) a definitive diagnosis at the molecular level. We strongly advocate diagnosis at the molecular level for the following reasons: (1) unequivocal diagnosis, (2) accurate genetic counseling, (3) planning future pregnancies or their outcomes, (4) definition of genotype–phenotype associations, and (5) identification of candidates for gene-specific therapies (Bonilla et al., 2005).

In our discussion, we will mainly follow the World Health Organization/International Union of Immunological Societies classification of PIDDs (Al-Herz et al., 2011). Our goal is to provide a practical guide for clinical and laboratory assessment. Rather than list specific diagnostic criteria or describe disease-specific testing for each PIDD, the reader is referred to each disease-specific chapter for this information.

The Internet affords additional sources of information accessible to the public and to health-care professionals. In many cases, this information is of high quality and current and can assist physicians with diagnosis and management problems. Table 56.1 lists several sources of information available on the Internet.

CLINICAL ASSESSMENT

AGE OF ONSET

It is a common misconception that all PIDDs have their onset in infancy or early childhood and will be so evident as not to escape detection. Although this is certainly true of many severe disorders, even among these, a failure to consider the possibility of immunodeficiency underlying a severe infection leads to undue morbidity and mortality. Mild or partial variants of many of the "severe" forms of PIDDs may more easily escape attention until later in childhood or even adulthood. Furthermore, it is important to appreciate the sometimes extreme (years to decades long) delay in diagnosis of PIDD patients after the onset of their recurrent infections and other complications. Finally, a significant fraction of these disorders will present initially in adulthood. See Wood et al. (2007) for a discussion in the general setting of antibody deficiency.

The only PIDD that characteristically presents at any age, including adulthood, is common variable immunodeficiency (CVID; see Chapter 28). Most other disorders have their onset in infancy or childhood. However, as already mentioned, they may escape detection for some time, or the patient may die without a diagnosis. There are abundant reports of mild cases of many forms of PIDD such as combined immunodeficiency, agammaglobulinemia, neutrophil defects, and complement component deficiencies that either have their clinical onset in adulthood or are not diagnosed until then. These are mainly due to so-called "hypomorphic" gene mutations that lead to only partial loss of function of the gene product and milder disease phenotype (see specific chapters for each PIDD). However, other genetic factors also play a role, and some individuals who have the same mutation will have severe disease

of early onset, while others will have mild late-onset disease, or may even be completely asymptomatic (Bonilla et al., 2005). X-linked agammaglobulinemia is a good example of this phenomenon (see Chapter 25). Table 56.2 lists the general pattern of age at presentation for the main categories of PIDD.

INFECTIONS

PIDD most commonly comes to clinical attention due to a burden of infection that is considered to be excessive with respect to frequency or severity, displays a poor response to therapy, or is associated with unusual organisms. The frequency of infection and the types of organisms found will vary widely depending on a variety of related factors. These include age (more infections at the extremes of young and old age; High, 2004; Ulloa-Gutierrez et al., 2003), socioeconomic status, day care or school attendance, breastfeeding, and number of children in the household (Simoes, 2003). Even lifestyle choices such as frequent exercise may be associated with reductions in acute upper respiratory infections (Matthews et al., 2002). Factors such as geographical location, public hygiene (Esrey et al., 1991), and other environmental exposures such as pollution (Ciencewicki & Jaspers, 2007) also have an impact.

Innate and adaptive immune mechanisms operate in concert in most infections regardless of the type of infecting agent (viruses, bacteria, mycobacteria, mycoplasma, fungi, protozoa). However, a molecular lesion in one element of either innate or adaptive immunity may lead to a relatively narrow or selective spectrum of infectious agents and a pattern of infection that is characteristic and may provide some basis for structuring the immune evaluation (Al-Herz et al., 2011; Bonilla et al., 2005). It is not practical to provide a complete list, as a tremendous variety of specific infections may occur in many of these diseases. Table 56.2 provides a general list of the types of infections predominantly or characteristically associated with the major classifications of PIDD.

AUTOIMMUNITY

Autoimmune disease is a frequent complication of many forms of PIDD. The most consistent associations are seen with CVID (Cunningham-Rundles, 2008; Lopes-da-Silva & Rizzo, 2008), Wiskott-Aldrich syndrome (WAS) (Ochs et al., 2008), and complement deficiency (Wen et al., 2004). However, autoimmunity is observed in many other syndromes and is the principal clinical problem in autoimmune lymphoproliferative syndrome (ALPS; Chapter 30) and the syndromes of autoimmunity, polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED, Chapter 31) and immune dysregulation, polyendocrinopathy X-linked (IPEX, Chapter 32). Table 56.2 lists some general associations.

LYMPHOPROLIFERATION

Lymphoproliferative disease and lymphoma are also frequently seen in a number of PIDDs. Again, the most consistent associations are with CVID and WAS. Other syndromes with a high incidence are X-linked lymphoproliferative disease (XLP, Chapter 44), ALPS, and DNA breakage syndromes (Chapters 46 to 49). In CVID and ALPS, association with Epstein-Barr virus (EBV) is infrequent, while in WAS and XLP, EBV-association is common. Table 56.2 also lists PIDDs associated with lymphoproliferative disease.

ATOPY

IgE-mediated hypersensitivity may occur in any PIDD in which IgE responses are possible. However, it is seen with greater frequency in mild antibody deficiencies such as selective IgA deficiency (see Chapter 28), IgG subclass deficiency (Olinder-Nielsen et al., 2007), and specific antibody deficiency (Paris & Sorensen, 2007), as well as in some syndromes such as WAS (Chapter 43) and Netherton syndrome (Renner et al., 2009). In IPEX, IgE-mediated food allergy is essentially universal. However, in this disorder the enteropathy is due primarily to lymphocytic infiltration. In the hypomorphic severe combined immunodeficiency (SCID) variants grouped under the name Omenn syndrome (Chapter 13) and in hyper-IgE syndrome (Chapter 38), a very large amount of IgE is produced. Most of the IgE in these disorders is not specific for definable antigens, although occasional antigen-specific IgE is observed. Staphylococcal-binding IgE is often found in hyper-IgE syndrome. The main differential non-PIDD diagnoses of elevated IgE are parasitic infestation and atopy (especially atopic dermatitis, where staphylococcal-binding IgE is also frequently present).

Table 56.2 CLINICAL CHARACTERISTICS OF PIDDS

	CATEGORY OF PIDD					
CLINICAL CHARACTERISTIC	PREDOMINANTLY ANTIBODY DEFICIENCIES	CELLULAR DEFECTS	COMBINED DEFECTS	COMPLEMENT DEFICIENCIES	PHAGOCYTIC CELL DEFECTS	DEFECTS OF INNATE IMMUNITY
Age of onset	AGAM: infancy/ early childhood CVID: any age, often adulthood IGGSD, IGAD, SAD: usually childhood, occasionally adulthood	Usually infancy or early childhood	Usually infancy, rarely later	Often infancy/ childhood, but may have delayed presentation	Usually infancy/ childhood, occasionally adulthood	Usually infancy/ childhood
Infections	Respiratory tract viral and bacterial infections (mainly encapsulated organisms), other invasive bacterial infections, enteroviral infections, giardiasis	Mycobacterial infections, tuberculosis and atypical, salmonella	Opportunistic infections (PCP), disseminated infections with all categories of pathogens	Respiratory tract and other invasive bacterial infections (sepsis, meningitis), mainly with encapsulated organisms. Esp. *Neisseria* infection with terminal component defects.	Respiratory and deep-seated bacterial abscesses with staphylococci, also fungi (*Aspergillus*)	Extremely variable depending on specific defect
Autoimmune Disease	AGAM: rare CVID: common IGGSD, IGAD, SAD: common with IGAD, otherwise infrequent	Uncommon	Occasional	Frequent, esp. with early classical pathway defects	IBD is common in CGD, otherwise rare	Variable depending on defect
Lymphoproliferative disease	AGAM: rare CVID and IGAD: frequent, otherwise rare	Rare	Occasional	Rare	Rare	Uncommon
Atopy	AGAM/CVID: not seen, otherwise common	Uncommon	Variable, depends on defect	Similar to the general population	Similar to the general population	Uncommon

OTHER MANIFESTATIONS OF PIDD

Many PIDDs have "nonimmunological" associated features that may aid in guiding the evaluation and raising suspicion regarding specific diagnoses. Table 56.3 lists several examples of these types of clinical features along with some of the particular infectious complications associated with specific defects.

DIAGNOSTIC APPROACH

STEPWISE APPLICATION OF TESTING

In patients with suspected PIDD, laboratory evaluation usually proceeds through several stages (Bonilla et al., 2005). Initial testing is largely dictated by the type of deficit anticipated according to the clinical presentation (Tables 56.2 and 56.3). These screening tests attempt to establish a deficient area of immune function that can be studied with more refined or detailed tests in an attempt to achieve a definitive diagnosis (Table 56.4).

SUSPECTED ANTIBODY DEFICIENCY

Recurrent respiratory tract bacterial infections are one of the hallmarks of defects of antibody formation. Initial testing of humoral immunity consists of measurement of serum immunoglobulin levels and random antibody titers to vaccines. The measurement of IgG subclasses is controversial since there is no consensus regarding the clinical definition and significance of IgG subclass deficiency. If antibody levels for one or more vaccines are low, booster immunization and repeat measurement 4 weeks later should be undertaken wherever possible, unless IgG levels are so low as to make this untenable (<1 g/L). Significant hypogammaglobulinemia or impairment of specific antibody formation requires enumeration of peripheral blood B cells, usually performed as part of a panel quantifying T-cell subsets and natural killer (NK) cell

Table 56.3 CLINICAL FEATURES AND INFECTIOUS COMPLICATIONS ASSOCIATED WITH COME PIDDS

SYNDROME	LYMPHATIC	HEMATOLOGICAL	DERMATOLOGICAL	SKELETAL/DENTAL	RESPIRATORY	GASTROINTESTINAL	NEUROLOGICAL	ENDOCRINE	CARDIOVASCULAR
X-linked SCID	Aplasia of tonsils and thymus	Lymphopenia, eosinophilia	Candidiasis			Candidiasis	Encephalitis		
Autosomal recessive SCID due to defects of cytokine signaling	Aplasia of tonsils and thymus	Lymphopenia, eosinophilia	Candidiasis	Short stature (STAT-5b)			Encephalitis, myopathy (ORAI1 and STIM1 deficiencies)	Growth hormone insufficiency (STAT-5b)	
SCID due to RAG deficiency	Aplasia of tonsils and thymus	Lymphopenia, eosinophilia					Encephalitis		
Omenn syndrome	Splenomegaly, lymphadenopathy	Lymphopenia, eosinophilia	Eczema, alopecia			Hepatomegaly			
ADA deficiency		Lymphopenia, eosinophilia					Cognitive impairment		
PNP deficiency		Lymphopenia, AIHA					Cognitive impairment, ataxia		
MHC class I deficiency			Mucosal ulceration						Vasculitis
MHC class II deficiency			Candidiasis			Persistent diarrhea			
Hyper-IgM due to CD40 or CD40 ligand deficiency		Neutropenia, AIHA	Mucosal ulceration	Arthritis	Bronchiectasis	IBD, hepatomegaly, sclerosing cholangitis	Cryptococcal meningitis, toxoplasmosis		
Autosomal hyper-IgM syndromes	Lymphadenopathy, splenomegaly				Bronchiectasis				
XLA	Aplasia of tonsils				Bronchiectasis	Gastritis, Crohn's disease	Enteroviral encephalitis, myositis, bacterial meningitis, progressive neurodegeneration		
Autosomal recessive agammaglobulinemia	Aplasia of tonsils				Bronchiectasis	Gastritis		Growth hormone insufficiency (special variant)	

(continued)

Table 56.3 CONTINUED

SYNDROME	LYMPHATIC	HEMATOLOGICAL	DERMATOLOGICAL	SKELETAL/DENTAL	RESPIRATORY	GASTROINTESTINAL	NEUROLOGICAL	ENDOCRINE	CARDIOVASCULAR
CVID	Lymphadenopathy, splenomegaly	AIHA, AITP; neutropenia	Hypopigmentation	Arthritis	Interstitial lung disease, granuloma, bronchiectasis	Gastritis, IBD, celiac disease, nodular lymphoid hyperplasia, hepatomegaly, granuloma	Granulomatous disease (rare)	Autoimmune thyroiditis	
ALPS	Lymphadenopathy, splenomegaly	AIHA, ITP, neutropenia	Alopecia			Hepatomegaly			
APECED			Candidiasis, ectodermal dystrophy, alopecia	Enamel hypoplasia		Mucosal candidiasis		Hypothyroidism, hypoparathyroidism, Addison disease, type 1 diabetes, ovarian failure,	
IPEX	Lymphadenopathy	AIHA, neutropenia, ITP	Erythema, eczema, alopecia			Hepatosplenomegaly, enteritis, villous atrophy		Type 1 diabetes, autoimmune thyroiditis	
Periodic fever syndromes					Pleuritis	Peritonitis			
Defects of the IL-12/23-IFN-γ axis		*Salmonella* infections		Osteomyelitis due to atypical mycobacteria	Tuberculosis (often atypical mycobacteria)	Persistent *Salmonella* infections			
Innate immunodeficiencies			Skin abscess, impaired wound healing	Arthritis, osteomyelitis	Recurrent bacterial infections, tuberculosis		Herpes simplex encephalitis		
Ataxia-telangiectasia			Café-au-lait spots, hypopigmentation, telangiectasia		Bacterial infections		Cognitive impairment, ataxia		Telangiectasia
Wiskott-Aldrich syndrome		Thrombocytopenia, neutropenia, AIHA, eosinophilia	Eczema	Arthritis	Bacterial infections	Bloody diarrhea			Vasculitis
XLP	Splenomegaly, lymphoma	Anemia				Hepatitis	Vasculitis		
DiGeorge syndrome	Aplasia of thymus	Lymphopenia, AIHA	Erythema	Arthritis, micrognathia			Cognitive impairment	Hypoparathyroidism	Cardiac malformation

Hyper-IgE syndromes		Eosinophilia	Eczema, skin abscesses, candidiasis, warts (AR)	Joint hyperextensibility, fractures, persistence of deciduous teeth	Abscesses, pneumatoceles, bronchiectasis, aspergillosis				CNS vasculitis (AR)
Cartilage-hair hypoplasia		Neutropenia, anemia	Fine sparse hair	Short stature		Hirschsprung disease		Defective spermatogenesis	
Anhidrotic ectodermal dysplasia with ID			Fine sparse hair, anhydrosis	Conical teeth, osteopetrosis	Bronchiectasis	IBD, celiac disease			
CGD	Lymphadenopathy, splenomegaly	Eosinophilia	Skin abscess	Osteomyelitis	Granuloma, bronchiectasis, extrinsic allergic alveolitis	Gastritis, IBD, hepatomegaly, granuloma, liver abscess, aspergillosis	Aspergillosis		Cardiomyopathy
Leukocyte adhesion defects	Bleeding tendency (LAD3)	Leukocytosis	Mucosal ulceration, impaired wound healing	Periodontitis, microcephaly (LAD2)		Perityphlitis (LAD1)	Cognitive impairment (LAD2)		
Cyclic and congenital neutropenia		Neutropenia, eosinophilia	Mucosal ulceration, skin abscess	Periodontitis			Cognitive impairment (Kostmann s.), bacterial meningitis		
Chediak-Higashi syndrome	Splenomegaly	Bleeding tendency	Hypopigmentation				Seizures, cognitive impairment		
Familial hemophagocytic syndromes	Splenomegaly	Anemia, neutropenia, hemophagocytosis	Hypopigmentation (some)			Hepatomegaly, elevated liver enzymes	Cognitive impairment		CNS vasculitis
Complement deficiencies		Sepsis (late complement components)	Lupus- like erythema (early complement components)				Meningococcal meningitis		Vasculitis

ABBREVIATIONS: AIHA, autoimmune hemolytic anemia; ITP, immune thrombocytopenic purpura; AR, autosomal recessive; CNS, central nervous system; IBD, inflammatory bowel disease; ID, immunodeficiency. See text for other abbreviations.

Table 56.4 SCREENING AND ADVANCED TESTS FOR EVALUATING IMMUNE SYSTEM FUNCTION

SYSTEM	SCREENING TESTS	ADVANCED TESTS
Innate immunity		
Humoral: complement	• CH50 (classical pathway activity) • AH50 (alternative pathway activity) • Lectin pathway activity	• Determination of level or function of individual components • Molecular methods
Cellular: phagocytic	• Cellular blood count with differential • Examination of a stained blood smear • Measurement of oxidase function (nitroblue tetrazolium test, or DHR dye reduction)	• Flow cytometry for adhesion molecules • Measurement of chemotaxis, phagocytosis, or intracellular killing • Enzyme assays (myeloperoxidase, G6PDH) • Bone marrow biopsy • Molecular methods
Cellular: NK cells	• Flow cytometry to enumerate NK cells • NK-cell function (spontaneous K562 lysis)	• ADCC • Surface marker expression • Molecular methods
Cellular: TLRs	• Cytokine production in response to TLR agonists	• Molecular methods
Adaptive immunity		
Humoral: antibody and B cells	• Serum immunoglobulin isotype levels • Specific antibody levels • Flow cytometry to enumerate B cells	• Antibody response to booster immunization • Antibody response to neoantigen • In vitro immunoglobulin production • Flow cytometry for surface and cytoplasmic markers • Molecular methods
Cellular: T cells	• Flow cytometry to enumerate T-cell subsets • Cutaneous delayed hypersensitivity • Mitogen/antigen proliferation assays • Anti-CD3 proliferation assay	• Flow cytometry for expression of surface markers (with/without activation) • Flow cytometry or other assays of cytokine production (with/without activation) • Flow cytometry for phosphorylation of signaling intermediates (e.g., pSTAT5b in X-linked SCID) • Cytotoxicity assay • Enzyme assay (ADA, PNP) • Molecular methods

Abbreviations: ADCC, antibody dependent cellular cytotoxicity; G6PDH, glucose-6-phosphate dehydrogenase. See text for other abbreviations.

populations at the same time. Assessment of memory B-cell populations (class-switched and nonswitched) is becoming increasingly common. Abnormalities in immunoglobulin and/or antibody production may arise from defects intrinsic to B cells or to T-effector/helper cells; both compartments may require investigation, depending on the clinical presentation and results of screening tests.

Some complement defects may mimic clinically the disorders of antibody production (see Chapter 55). This is not surprising considering the role of complement in the opsonization of encapsulated bacteria coated with antibody. In the absence of complement, phagocytosis is less efficient.

SUSPECTED CELLULAR OR COMBINED IMMUNE DEFICIENCY

Initial testing for suspected cellular or combined immunodeficiency (CID) generally includes both tests of humoral immunity and tests of cellular immunity. Screening tests of the latter generally include measurement of lymphocyte subpopulations and a functional test such as cutaneous delayed hypersensitivity or in vitro lymphocyte proliferation tests. Early-onset severe immunodeficiency may indicate SCID or a SCID variant. Significantly diminished T-cell number and near-absent T-cell function will be present in the majority of cases of SCID, and directed molecular testing is dictated by the lymphocyte phenotype (see Chapter 9). SCID-variant phenotypes or other CID with early onset may be difficult to distinguish, and several rounds of molecular testing may be necessary based on the predicted likelihood of various defects consistent with the specific clinical and laboratory phenotype.

RECURRENT ABSCESSES

Skin and other organ abscesses caused by bacteria and fungi are characteristic of phagocytic cell defects. Screening tests of humoral and cellular immunity are often performed to establish that they are normal, but the main focus initially should be on determining neutrophil number and morphology. When these tests are normal, a test of oxidative function is appropriate to investigate the various forms of chronic granulomatous disease (CGD). In adults, when hyper-IgE syndrome has been excluded, an underlying defect responsible for recurrent abscesses can often not be determined with current methods.

LATE ONSET

PIDDs with late onset may represent CVID or hypomorphic variants of disorders that characteristically present earlier or may be due to late acquisition of the defining illness in those disorders with very restricted sensitivity to one or a few pathogens. It is important to consider acquired immunodeficiency due to HIV infection, malignancy (especially lymphoma), or secondary immunosuppression in these cases also.

LYMPHOPROLIFERATION

Lymphoproliferation leads to splenomegaly and lymphadenopathy, which should be assessed by appropriate imaging modalities (ultrasound or computed tomography for spleen and abdominal lymph nodes, chest X-ray for screening, and tomography for confirmation of thoracic involvement). A central concern in the diagnostic approach to lymphoproliferative disease is the exclusion of malignancy. Therefore, a biopsy should be undertaken whenever possible. There are no serologic or cellular markers in the peripheral blood that are sufficient to exclude malignant disease. Similarly, the observation of oligoclonal populations in the peripheral blood and tissue does not permit a definitive diagnosis of malignant transformation, since these changes have also been found in reactive lymph nodes (Sander et al., 1992). In addition, lymphoproliferation in PIDD might be secondary to infection, including EBV, and mycobacteria, including atypical organisms. Therefore, the consulting pathologist must be experienced in the assessment of secondary lymphoid tissues of patients with PIDD.

SCORING SYSTEMS

There have been a few attempts to devise validated scoring systems to aid in identifying individuals with PIDD, but both sensitivity and specificity have been poor (Cunningham-Rundles et al., 2004; Hosking & Roberton, 1981; Lyall et al., 1991). Not surprisingly, chronic sinusitis, bronchitis, otitis media, and chronic diarrhea occurred more in immunodeficient patients but were also prevalent in patients with other diseases.

Patient and physician education and support groups have developed awareness-raising tools with respect to PIDD. The "10 Warning Signs" were developed 20 years ago (and recently revised) by the Jeffrey Modell Foundation and the American Red Cross (Table 56.5). These are generally similar to elements of history and physical examination that have emerged as highly associated with PIDD in the analyses mentioned above, as well as in retrospective literature reviews (Wood et al., 2007). These warning signs have not been formally validated, but it is expected that they would have similar (low) sensitivity and specificity as has been found in other analyses using similar criteria (see above). A similar set of "six warning signs for PIDD in adults" has been adapted by the European Society for Immunodeficiency (ESID) to the adult population (www.ESID.org).

A disease-specific scoring system has been established for the hyper-IgE syndrome (see Chapter 38) (Grimbacher et al., 1999). This scoring system has good predictive value for identifying individuals with a high likelihood of having mutations in *STAT3* (Holland et al., 2007). A scoring system has also been developed for distinguishing the various clinical expressions of *WAS* mutation (Ochs & Thrasher, 2006).

Table 56.5 **THE 10 WARNING SIGNS OF PIDDS**

1. Four or more new ear infections within 1 year
2. Two or more serious sinus infections within 1 year
3. Two or more months on antibiotics with little effect
4. Two or more pneumonias within 1 year
5. Failure of an infant to gain weight or grow normally
6. Recurrent, deep skin or organ abscesses
7. Persistent thrush in mouth or fungal infection on skin
8. Need for intravenous antibiotics to clear infections
9. Two or more deep-seated infections, including septicemia
10. A family history of primary immunodeficiency

The presence of two or more warning signs should prompt evaluation for immunodeficiency. From the Jeffrey Modell Foundation (www.jmfworld.com).

FOLLOW-UP EVALUATION

The clinical and laboratory manifestations of many PIDDs are not static. Situations that are unclear initially may evolve into more characteristic constellations of findings that eventually prompt the testing that leads to the definitive diagnosis. Even when a definitive diagnosis is established, there may still be important changes in function over time that require modification of the treatment plan. Furthermore, a wide range of immune-related complications (e.g., autoimmune disease, lymphoproliferative disease, malignancy) may arise during the course of many PIDDs. Some of these result from abnormal regulation and function caused by the fundamental defect, and some from the therapies used to reconstitute function or to treat infections (and other complications). Each of these requires its own set of diagnostic and therapeutic interventions in the context of the underlying PIDD. For all of these reasons, periodic reevaluation of various aspects of immune function is normally undertaken in the course of management of many PIDDs. In addition, follow-up evaluation of PIDD patients should regularly address the course of end-organ damage, including lung, liver, and kidney function, the gastrointestinal tract, the endocrine system, and others.

LABORATORY ASSESSMENT

INNATE IMMUNITY

Phagocytic Cells

PIDDs associated with phagocytic cell defects are discussed in Chapters 50 to 54. The initial evaluation of suspected phagocyte defects must include a blood cell count with differential

and microscopic examination of a peripheral blood smear. Congenital or acquired neutropenias may first be identified in this way. Conversely, a marked leukocytosis may raise suspicion for an adhesion molecule defect. Simple examination of a stained smear may suffice to make a provisional diagnosis of such entities as Chediak-Higashi syndrome or specific granule deficiency, in which morphological abnormalities are characteristic.

Routinely applied clinical tests of phagocyte function include measures of chemotaxis, phagocytosis, and the respiratory burst. One test of chemotaxis uses a device called a Boyden Chamber, in which peripheral blood phagocytic cells are placed in a well above a porous membrane (Chen, 2005). A chemoattractant (e.g., f-Met-Leu-Phe) is placed in the lower chamber and the number of neutrophils passing through the membrane is measured. In another method of measuring chemotaxis, neutrophils are placed in a well in a soft agar medium containing a gradient of a chemotactic factor. The distance migrated by the neutrophils is measured (Mouynet et al., 1994).

Phagocytosis may be determined by a flow-cytometric method in which neutrophils, either purified or in lysed whole blood, are incubated with fluorescent labeled particles such as opsonized yeast and counted in a flow cytometer (Chow et al., 2004). These assays may be performed with or without immunoglobulin and/or complement to assess different mechanisms of phagocytosis. Other assays measure phagocytosis indirectly by stimulation of the respiratory burst (see below).

The most widely applied tests of neutrophil function measure the activity of the NADPH oxidase complex to diagnose the various forms of CGD. The classic example of this is the nitroblue tetrazolium test in which the dye formazan is taken up by neutrophils incubated on endotoxin-coated coverslips (Ochs & Igo, 1973) or loaded into neutrophils via opsonized latex beads (Virella et al., 1990). After activation with phorbol ester or endotoxin, the yellow dye formazan turns blue after reduction in the phagosome. The failure of this color change visualized by microscopic examination or by calorimetric analysis indicates a defect of the oxidase complex (or failure of phagocytosis).

A more quantitative method uses the dye dihydrorhodamine 123 (DHR), which becomes fluorescent upon reduction in the phagosomes of activated neutrophils (Jirapongsananuruk et al., 2003; Vowells et al., 1995). This may be analyzed in a flow cytometer to measure the fluorescence intensity and the proportion of responding cells (Fig. 56.1). Both methods are also useful for carrier detection for X-linked CGD in females who have two populations of neutrophils (with and without oxidase function) due to random X-chromosome inactivation.

In the chemiluminescence assay, phagocytosis and respiratory burst function may be measured simultaneously. Neutrophils are activated with phorbol ester or with opsonized particles. Oxidase activity leads to spontaneous emission of photons, which can be enhanced with addition of a luminophore. The light emitted can be measured in a liquid scintillation spectrometer or other light-sensing instrument (Dahlgren & Karlsson, 1999).

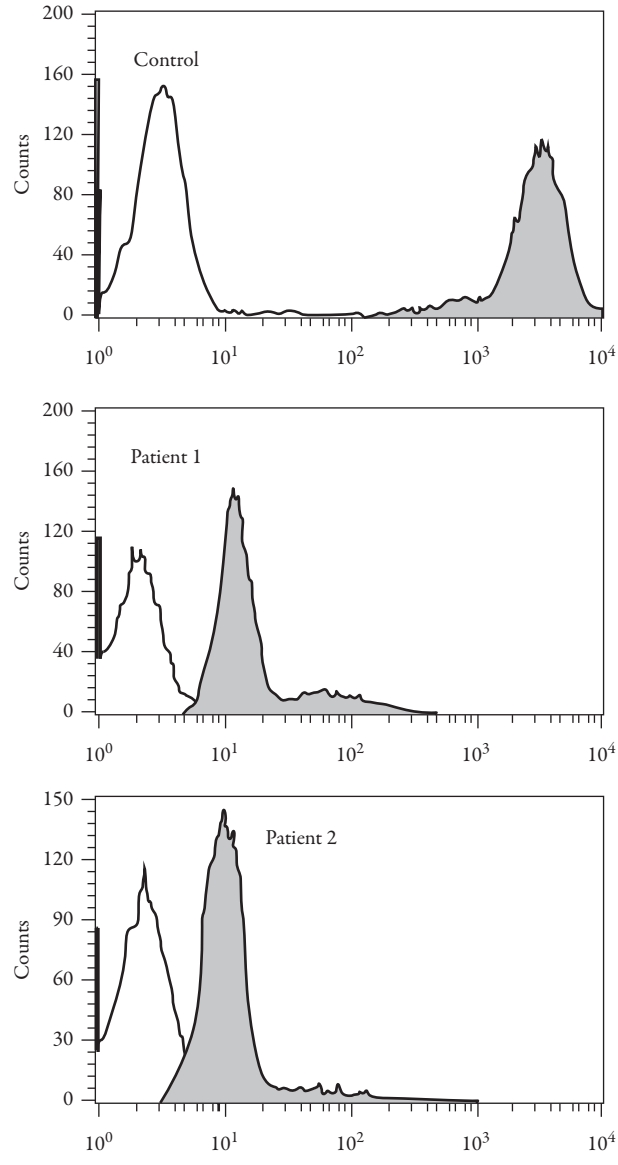

Figure 56.1 DHR assay histograms. The x-axis is fluorescence intensity and the y-axis is the count of cells. The empty peak at the left represents unstimulated cells and the filled peak to the right is after PMA stimulation. The upper panel shows the results for neutrophils from a healthy adult blood donor; the lower two panels show the activity of cells from two sisters with CGD due to defects of p47phox. Clearly, the shift in fluorescence of the patients' cells is markedly less than the control. (Images provided by Petar Zarev, MD, PhD, Laboratory Scientist, Cellular Immunology and Flow Cytometry Laboratory, Department of Laboratory Medicine, Boston, Children's Hospital.)

A bacterial killing assay measures the ability of neutrophils to take up viable bacteria from solution and kill them intracellularly. Bacteria (*Staphylococcus aureus* is often used) are incubated in various conditions (e.g., with or without immunoglobulin or complement) with neutrophils. At various time points, the cells are collected and lysed and the number of viable bacteria is counted by colony formation on agar (Hampton & Winterbourn, 1999). Similar assays may be performed using *Candida albicans*.

Leukocyte adhesion defects (LADs) are rare disorders of neutrophil migration due to mutations of structure or function of surface glycoproteins required for neutrophil tethering and adhering to blood vessel walls and diapedesis into areas of infection (see Chapter 53). LAD type I is caused by a defect of the CD18 integrin β_2 chain; LAD type II results from mutations of a fucosyl transferase enzyme leading to lack of surface expression of sialyl-Lewis^X (SLe^X), a ligand for E-selectin (CD62E). The absence of these molecules on the neutrophil surface may be determined by flow cytometry using appropriate monoclonal antibodies: anti-CD18 for LAD type I and anti-CD15 for Sle^X for LAD type II.

Complement

Disorders of the complement system are discussed in Chapter 55. The complement system may be activated along three distinct sequences of reactions, the so-called classical, alternative, and lectin pathways. All of these converge into the same sequence of terminal reactions after activation of C3. Defects of all pathways have been associated with clinical disease, although the importance of the lectin pathway in this regard remains the subject of some controversy.

The standard assay of classical pathway complement activity is called the CH50 (classical pathway hemolysis 50 percent). In its original form, various dilutions of a serum specimen are added to a suspension of sheep red blood cells (SRBC) sensitized with a complement-fixing immunoglobulin such as rabbit IgM anti-SRBC. The amount of hemolysis is measured in a spectrophotometer and the result is reported as the reciprocal of the calculated dilution that yields lysis of 50 percent of the SRBC (Schur, 1983).

More modern methods may use artificial liposome targets loaded with the enzyme glucose-6-phosphate dehydrogenase and labeled with a defined antigen such as dinitrophenyl (DNP). Liposomes are lysed by the addition of complement-fixing anti-DNP antibody and serum. The released enzyme acts on glucose-6-phosphate and nicotinamide adenine dinucleotide in solution and the color change is measured in a spectrophotometer (Yamamoto et al., 1995)

Analogous to the CH50, the standard assay of the alternative pathway is the AH50. Rabbit red blood cells are susceptible to spontaneous lysis by the alternative pathway in the absence of antibody (Platts-Mills & Ishizaka, 1974). More modern variations have also been developed for measurement of alternative pathway function. For example, serum is placed in a well in a plate covered with agar containing a suspension of guinea pig erythrocytes. As complement components diffuse into the agar, they cause lysis of the red cells. The result is determined by the diameter of the ring of lysis around the well (Arnaout et al., 1977).

Hemolytic methods have also been developed to measure the function of the lectin pathway (Herpers et al., 2009). A different commercially available functional test of the lectin pathway uses a solid-phase method in which plates are coated with mannan and incubated with serum under conditions that permit mannose-binding lectin to be fixed and activated while C1q binding is inhibited. Purified C4 is added and converted to soluble C4a and C4b, which adheres to the plate. The amount of C4b deposited may be measured using a labeled monoclonal antibody to C4b (Petersen et al., 2001).

When a complement deficiency is suspected, both CH50 and AH50 tests may be performed. If the CH50 only is abnormal, this indicates an abnormality of one of the early classical pathway components. If the AH50 only is abnormal, one of the alternative pathway components is deficient. If both CH50 and AH50 are low, then one of the terminal components is deficient (Wen et al., 2004). When these functional tests identify blocks in complement cascades, the levels of individual components may be measured by standard immunoassay methods. In some instances, nonfunctional immunoreactive protein may be present in serum. In these cases, the functional deficit may be demonstrated by measuring the ability of serum to restore function in an assay system in which a single complement component has been depleted by a monoclonal antibody.

NK Cells

NK cells usually represent approximately 5 to 25 percent of peripheral blood lymphocytes. Their function is the lysis of target cells after activation through poorly understood activating mechanisms in the absence of inhibitory signals through the killer inhibitory receptors (KIRs) (Bryceson & Long, 2008). While several PIDDs present with decreased peripheral NK-cell numbers, these disorders are usually dominated by severely disturbed functions of other components of the adaptive immune system (e.g., SCID, CID, subgroups of CVID patients). Isolated defects of NK-cell number and/or function are relatively rare (Orange, 2006). In contrast, disturbed NK-cell function is one of the hallmarks of hemophagocytic syndromes, including perforin deficiency (familial hemophagocytic lymphohistiocytosis type 2), MUNC13b deficiency, Rab27a deficiency (a form of Griscelli syndrome), Chediak-Higashi syndrome due to mutations in *LYST*, and X-linked lymphoproliferative syndrome due to mutations in *SH2D1A* (see Chapters 54 and 44, respectively). The assessment of NK-cell function will be discussed below in the section on cytotoxicity.

Toll-like Receptor Function

The Toll-like receptors (TLRs) are one group of pattern-recognition receptors that initiate innate cellular immune protective mechanisms and participate in and modulate adaptive immune mechanisms as well. TLRs and the PIDDs associated with their dysfunction are discussed in Chapter 36. TLR function may be assessed by measuring cytokine production by peripheral blood mononuclear cells (PBMCs) stimulated with various ligands for the individual TLRs. Figure 56.2 shows an example of defective interferon (IFN)-α production by PBMCs from a patient with interleukin (IL)-1 receptor-associated kinase 4 (IRAK-4) deficiency (McDonald et al., 2006). Commercially available tests of TLR function use similar ligands and may measure production of a variety of

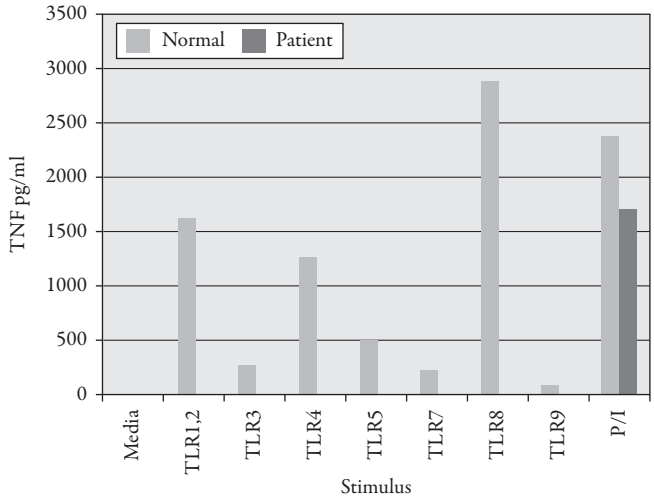

Figure 56.2 Cytokine production after stimulation of TLRs. PBMCs were stimulated with ligands specific for each of the TLRs listed, as well as a nonspecific activating stimulus, PMA and ionomycin (P/I). TNF production of cells from a healthy control was compared to a patient with IRAK4 deficiency. The patient has negligible TNF production with all TLR stimuli. (Reproduced from McDonald et al., 2006, with permission.)

cytokines, such as IFN-β, IL-6, and tumor necrosis factor (TNF) in culture supernatants using standard immunoassays.

Most TLRs signal through the adapter proteins MyD88 and IRAK4 (Barton & Kagan, 2009). Defects of either of these molecules lead to a global impairment of TLR signaling, with the possible exception of TLR3 (Fig. 56.2) (McDonald et al., 2006, von Bernuth et al., 2008). Defects of TLR3 itself and UNC93B lead to selective deficits of TLR3 signaling (Casrouge et al., 2006; Zhang et al., 2007).

ADAPTIVE IMMUNITY

Serological Assays

Serological assays are mainly used to determine total and specific immunoglobulin levels in the serum of patients with suspected immunodeficiency. The general availability and the low cost render the determination of IgG, IgA, and IgM serum levels an excellent screening parameter in patients with suspected humoral immunodeficiency. Immunoglobulins are produced by different subsets of B cells, usually after antigen-specific stimulation. While IgM serum levels are considered to represent a constantly produced, so-called "natural" response, as well as the early antigen-triggered response (Boes, 2000), antigen-specific IgG and IgA are mainly produced by plasma cells derived from class-switched memory B cells after their differentiation in germinal centers within secondary lymphoid tissues. Class-switching to IgG and IgA requires B-cell intrinsic machinery and is largely T-cell–dependent. Thus, patients with either a disturbed class-switch function or absent T-cell help present with severely reduced IgG and IgA, but normal or even elevated IgM (Durandy, 2009) (see Chapters 26 and 27). The assessment of serum immunoglobulins must use age-adjusted normal values, especially in children (Table 56.6). Due to possibly transient dysregulation, when abnormalities are relatively mild, determination of serum Ig levels should be repeated twice with an interval of at least 6 weeks in between, based on the half-life of IgG.

Hypogammaglobulinemia is found in several PIDDs (Table 56.7), of which CVID is the most common form (see Chapter 28). For the diagnosis of CVID, secondary hypogammaglobulinemia due to protein-losing enteropathy and severe proteinuria has to be excluded by clinical presentation and additional studies such as serum albumin levels and urinalysis. Other important elements of the differential diagnosis include lymphoma, especially in late-onset hypogammaglobulinemia and drug-induced hypogammaglobulinemia.

IgG consists of four subclasses (IgG1–4), which differ slightly in their functions (complement activation, Fc receptor binding), half-life, and antigen specificity. Determination of IgG subclasses should be reserved for specific subgroups of patients, including those with the clinical presentation of humoral deficiency with normal or only borderline reduction of IgG. Established clinically relevant PIDDs include combined IgG2/IgG4 deficiency and extreme reductions in IgG1 or IgG2; the relevance of an isolated IgG3 reduction and especially of an IgG4 reduction is less well demonstrated (Olinder-Nielsen et al., 2007).

Reductions or elevations of specific isotypes are important differential biomarkers in PIDDs. IgA-deficient patients (see Chapter 28) with increased susceptibility to infection should be evaluated for additional IgG subclass deficiency (see below). The selective reduction of IgM serum levels (<0.2 g/L) is reported in small cohort studies (Goldstein et al., 2008), but the pathogenesis is not understood. In contrast, the increase of serum IgM levels combined with severely reduced IgG and IgA levels is the hallmark of the immunoglobulin class-switch disorders due to either B-cell intrinsic defects affecting the necessary steps of DNA recombination (Durandy, 2009) or defects in B-cell costimulation by activated T cells as a result of mutations in CD40 or CD40L. B-cell intrinsic defects can be defined by in vitro class-switch assays (see below). CD40 deficiency may be assessed by flow-cytometric evaluation of surface expression on B cells; CD40L deficiency is analyzed on activated CD4 T cells using anti-CD40L monoclonal antibodies or a soluble CD40–Ig construct.

There is no significance of very low levels of IgE. However, elevated levels of IgE are associated with several forms of PIDD (see the section on atopy above and Chapter 38).

There is no established clinical utility of routine measurement of serum IgD levels in the evaluation of PIDDs. Low IgD may be seen in association with low levels of C2 (Calvo et al., 2000), although this has not been demonstrated to contribute to infection susceptibility in this setting or in any other. Elevated levels of IgD (>0.05 g/L) are seen in mevalonate kinase deficiency (hyper-IgD syndrome, Chapter 33) and other periodic fever syndromes (Haas & Hoffmann, 2006).

To evaluate the antibody-forming capacity in patients with the typical clinical presentation of humoral immunodeficiency with only a selective decrease in or normal levels of immunoglobulins, the analysis of specific antibody responses

Table 56.6 AGE-ADJUSTED REFERENCE RANGES FOR SERUM IMMUNOGLOBULINS (G/L)

AGE	IGG	IGA	IGM	
0–1 months	7.00–13.00	0.00–0.10	0.05–0.30	
1–4 months	2.80–7.50	0.06–0.50	0.15–0.70

10–12 years	4.56–9.52	1.47–4.93	0.12–1.79	0.01–1.53
12–14 years	3.47–9.93	1.40–4.40	0.23–1.17	0.1–1.43
Adult	4.22–12.92	1.17–7.47	0.41–1.29	0.10–0.67

These are normal ranges (5th–95th percentiles) from the laboratories of Boston, Children's Hospital, MA. Normal ranges are method-dependent and should be validated for each laboratory. These reference ranges are intended for educational purposes only.

Table 56.7 PIDDS ASSOCIATED WITH HYPOGAMMAGLOBULINEMIA

SCID (X-linked and autosomal recessive forms) including ADA deficiency
Agammaglobulinemia (X-linked and autosomal recessive forms)
Common variable immunodeficiency
Class-switch deficiency disorders (defects of CD40L, CD40, AID, UNG, PMS2, NEMO)
X-linked lymphoproliferative syndrome
Some forms of radiosensitive PIDD (Njimegen breakage syndrome, DNA ligase IV and Cernunnos deficiencies)
Facultative manifestation of other PIDD

is the next step. At initial evaluation, it is generally appropriate only to measure antibodies to antigens to which patients are exposed by vaccination or are prevalent in the population (e.g., EBV, cytomegalovirus). Two different qualities of the humoral response should be tested by assessing antiprotein and antipolysaccharide responses (Bonilla et al., 2005). The former usually include antitetanus or diphtheria toxoid responses, since a high prevalence of vaccination can be assumed in most countries.

In a few centers, responses to neoantigens like bacteriophage X174 (Ochs et al., 1992) or keyhole limpet hemocyanin (KLH) (Kondratenko et al., 1997) are available for testing. Rabies vaccine has also been used as a neoantigen in the assessment of humoral immunodeficiency (van Zelm et al., 2006). Since patients have no prior exposure to these antigens, primary as well as recall responses can be standardized. In addition, the use of neoantigens permits the evaluation of patients receiving IgG replacement therapy, since no preformed antibodies interfere with the response or the diagnostic detection. However, except for a few centers, neither advantage has yet led to a widespread use of neoantigen immunization in the routine clinical assessment of PIDD.

For the assessment of the antipolysaccharide response, the available 23-valent unconjugated (pure polysaccharide) pneumococcal vaccine (Pneumovax®, Pnu-Immune-23®) has been routinely used (Paris & Sorensen, 2007) in children above the age of 2 years and adults. The limitations of this approach are that not many laboratories perform serotype-specific assays, and there is not yet consensus on rigorously defined criteria of normal response (Jeurissen et al., 2007). Sanders et al. defined a normal response to polysaccharides as a twofold or greater increase in serum antibody titer and a postimmunization antibody concentration of at least 20 percent (20 U/L) of a hyperimmune plasma pool of healthy volunteers immunized with Pneumovax® (Sanders et al., 1993). Nonresponsiveness was defined as failure to generate antibody to five or more of the seven serotypes tested. Other authors recommend a fourfold rise in titer as one criterion (Bonilla et al., 2005; Paris & Sorensen, 2007). However, if

the initial level is relatively high, a fourfold rise may not occur, even in normal individuals. Furthermore, children older than 2 years should respond to 50 percent or more types, while all individuals older than 5 years should respond to 70 percent or more types (Bonilla et al., 2005; Paris & Sorensen, 2007). A level of 1.0 to 1.3 μg/mL is considered protective against invasive disease. Methods of measurement vary among laboratories, and it is not clear that these criteria can be applied in all cases.

As an alternative, a polysaccharide vaccine against *Salmonella typhi* (Typhum Vi) has become available, but the established assay (Ferry et al., 2004) is not available in most centers. These assays are used to detect patients with specific polysaccharide antibody deficiency (SPAD) and are indicated in the evaluation of patients with recurrent infection with encapsulated bacteria, usually *Haemophilus influenzae* or pneumococci.

Cellular Assays

After the evaluation of the differential blood count to determine the total lymphocyte number, a basic lymphocyte subset flow-cytometry profile is often applied in patients with suspected PIDD. This represents the essential assay in the differential diagnosis of SCID, separating patients according to the presence or absence of T cells, B cells, and NK cells and directing evaluation toward the respective underlying genetic defects (see Chapter 9). Flow cytometry is also important for the diagnosis of agammaglobulinemia (Chapter 25), which is characterized by extremely low (<1 percent of lymphocytes) or absent B cells.

The primary panel should consist of at least markers identifying $CD3^+CD4^+$ and $CD3^+CD8^+$ T cells, $CD19^+$ or $CD20^+$ B cells, and $CD16^+$ or $CD56^+$ NK cells. As is the case with serological assays, age-matched normal values need to be applied (Tables 56.8 and 56.9) (van Gent et al., 2009). A potential pitfall in the diagnosis of SCID is the presence of maternal T cells in the circulation, giving the false impression that host T-cell development is occurring. However, these cells may be identified by the memory T-cell marker CD45RO, which is not normally found on most peripheral blood T cells in newborns (see below). Hypomorphic SCID variants and a host of other PIDDs with abnormal T-cell number and function may have less severely diminished lymphocyte populations.

Some abnormalities of the basic flow-cytometry panel may suggest specific diagnoses in certain clinical contexts. For example, selective reduction in $CD8^+$ T cells should be analyzed for ZAP70 deficiency (see Chapter 14), CD8α deficiency (Chapter 18), or MHC class I expression defects (Chapter 16). In the latter case, $CD8^+$ T cells need to be carefully analyzed for αβTCR expression, since normal CD8 numbers may be detected due to the contribution of an expanded γδ $CD8^+$ T-cell population. HIV-negative T-cell lymphopenia mainly affecting $CD4^+$ T cells may be idiopathic CD4 lymphopenia (Zonios et al., 2008). In rare cases, a defect in the expression of the src family kinase lck has been described (Goldman et al., 1998). In MHC class II deficiency, $CD4^+$ T-cell counts are only mildly reduced.

More detailed T-cell phenotyping may include the separation of $CD4^+$ T cells into $CD45RA^+$ naïve and $CD45RO^+$ memory or activated T cells (Tables 56.8 and 56.9 and Fig. 56.3). This separation is especially helpful in the context of identifying engrafted maternal T cells in SCID patients, since these cells are almost exclusively $CD45RO^+$, while $CD4^+$ T cells of infants are usually 60 to 95 percent $CD45RA^+$ (naïve) T cells (van Gent et al., 2009). The small number of endogenous $CD4^+$ T cells of (S)CID patients often exhibit an activated phenotype expressing CD45RO and HLA-DR. In CVID, the absolute reduction of naïve $CD4^+CD45RA^+$ T cells has also been suggested as a means of classifying patients. Those with reduced $CD4^+CD45RA^+$ T-cell counts often present with a more complicated clinical course due to inflammatory and lymphoproliferative manifestations (Giovannetti et al., 2007).

Naïve T cells that have recently emigrated from the thymus express CD31 (platelet endothelial cell adhesion molecule 1 [PECAM-1]) (Kohler & Thiel, 2009). $CD4^+$ cells that express CD45RA and CD62L (L-selectin) are also enriched for recent thymic emigrants. The enumeration of these cells may be helpful in determining the level of thymic function in patients with DiGeorge syndrome or SCID with maternal T-cell engraftment, Omenn syndrome, or other "leaky" phenotypes with oligoclonal T-cell populations (Markert et al., 2004; Poulin et al., 1999).

Molecular methods to identify recent thymic emigrant T cells have also been developed. During the process of T-cell development in the thymus, T-cell receptor (TCR) gene segments rearrange to assemble mature TCR genes. The DNA between these segments is excised and ligated into a closed loop that remains as an episomal DNA fragment that is preserved within the nucleus. This circular fragment is known as a T-cell-receptor excision circle (TREC) (Dion et al., 2007). TRECs do not replicate as cells divide, so the content of TRECs within naïve cells that have just exited the thymus is much higher than in cells that have expanded in the periphery. TRECs can be expanded by PCR methods and serve as another measure of thymic function. Normal values have been established (Gent et al. 2009). The PCR methods for detecting TRECs can be also applied to the dried blood spots that are collected as part of newborn screening programs for genetic/metabolic diseases. Pilot programs of screening for SCID by the detection of TRECs in newborn dried blood spots have been initiated in several states in the United States (Baker et al., 2009) and have shown promising results (Verbsky et al., 2012). The level of TRECs in SCID infants is extremely low or absent due to the rudimentary nature of the thymus in the majority.

Additional analyses of T-cell subpopulations helpful in the differential diagnosis of PIDD include the increase in double-negative ($CD4^-CD8^-$) $\alpha\beta TCR^+$ T cells (DN T cells, Fig. 56.3) in ALPS patients (Chapter 30), the reduction of NK T cells ($CD3^+CD56^+$) in XLP (Chapter 44) (Pasquier et al., 2005; Rigaud et al., 2006), $CD4^+CD25^+FOXP3^+$ (or alternatively $CD4^+CD25^+CD127^-$) regulatory T cells in IPEX patients (Chapter 32) (Bennett et al., 2001), and reduction of TH17 T cells (producing IL-17) in STAT3-deficient hyper-IgE syndrome (see Chapter 38) (Ma et al., 2008). None of these changes is specific, and they need to be interpreted

Table 56. 8 REFERENCE VALUES OF LYMPHOCYTE SUBPOPULATIONS IN PERIPHERAL BLOOD OF HEALTHY PEDIATRIC CONTROLS

$CD27^{+}IgM^{-}IgD^{-}$ memory B cells	90	0 (0–2)	10 (6–19)	16 (2–42)	21 (16–34)	33 (19–53)	27 (6–113)	24 (7–98)	32 (7–65)	9 (3–34)	7 (3–39)	10 (2–40)

Absolute counts × 10^6 per liter blood. Values are presented as medians (5th–95th percentiles). No. = number of individuals. (Adapted from van Gent et al., 2009, with permission.)

Table 56.9 REFERENCE VALUES OF LYMPHOCYTE SUBPOPULATIONS IN PERIPHERAL BLOOD OF HEALTHY ADULT CONTROLS

T-CELL POPULATION		REFERENCE RANGE
$CD3^+$ of lymphocytes	$CD3^+$ T cells	55–83%
$CD4^+$ of lymphocytes	$CD4^+$ T cells	28–57%
$CD8^+$ of lymphocytes	$CD8^+$ T cells	10–39%
$CD4^-CD8^-$ of $CD3^+$alpha/beta TCR^+ T cells	Double-negative T cells (DNT)	0.4–2.2%
$CD4^+CD45RO^+$ of $CD4^+$ T cells	$CD4^+$ memory T cells	29–63%
$CD4^+CD45RA^+$ of $CD4^+$ T cells	$CD4^+$ naïve T cells	32–73%
$CD4^+CD45RA^+CD31^+$ of $CD4^+CD45RA^+$ T cells	Recent thymic emigrants T cells	41–79%
$CD8^+CD27^+CD28^+$ of $CD8^+$ T cells	$CD8^+$ naïve T cells	43–91%
$CD8^+CD27^+CD28^-$ of $CD8^+$ T cells	Early $CD8^+$ effector/memory T cells	3–18%
$CD8^+CD27^-CD28^-$ of $CD8^+$ T cells	Late $CD8^+$ effector/memory T cells	1–41%

B-CELL POPULATION		REFERENCE RANGE
$CD19^+$ in $CD45^+$ lymphocytes	B cells	4.9–18.4%
IgD^+ $CD27^-$ in $CD19^+$ B cells	Naïve B cells	42.6–82.3%
IgD^+ $CD27^+$ in $CD19^+$ B cells	IgM-memory B cells	7.4–32.5%
IgD^- $CD27^+$ in $CD19^+$ B cells	Class switched memory B cells and plasmablasts	6.5–29.1%
IgA^+ in $CD19^+$ B cells	IgA^+ B cells	2.7–13.8%
IgG^+ in $CD19^+$ B cells	IgG^+ B cells	3.6–13.4%
Kappa/lambda ratio	Light chain restriction	1.2–2.0
$CD21^{low}$ $CD38^-$ in $CD19^+$ B cells	$CD21^{low}$ subpopulation	0.9–7.6%
M^{++} D^{++} $CD24^{++}$ $CD38^{++}$ in $CD19^+$ B cells	Transitional B cells	0.6–3.4%
$CD24^-$ $CD38^{++}$ $CD27^+$ in $CD19^+$ B cells	Plasmablasts	0.4–3.6%

Fifth–95th percentiles. T cells: University Medical Centre Freiburg, Clinical Immunology Laboratory, unpublished data. B cells: based on 54 healthy donors (age range 19–61 years) (Wehr et al., 2008). Normal ranges are method-dependent and should be validated for each laboratory. These reference ranges are intended for educational purposes only.

in the context of clinical and other laboratory findings and, finally, confirmed by genetic diagnosis.

Detailed B-cell phenotyping has developed with the discovery of CD27 as a marker for memory B-cell formation (Klein et al., 1998). Agematsu et al. (1998) were the first to describe the reduction of $CD27^+$ B cells in X-linked hyper-IgM syndrome, and Warnatz et al. (2002) were the first to apply B-cell phenotyping in patients with CVID. B-cell phenotyping is now mainly applied in the classification of CVID (see Chapter 28) (Piqueras et al., 2003; Wehr et al., 2008). The current B-cell phenotyping uses mAbs to CD27, IgD, and IgM for the separation of naïve, IgM memory, and switched memory B cells, and mAbs to CD38, CD21, and IgM for the identification of transitional B cells, $CD21^{low}$ B cells, and plasmablasts (Tables 56.8 and 56.9 and Fig. 56.4) (van Gent et al., 2009). Low numbers of switched memory B cells in CVID are associated with autoimmunity, granulomatous disease, and lymphoproliferation. Low levels of switched memory B cells also occur in other immunodeficiencies such as WAS, XLP, STAT3-hyper-IgE syndrome, and so forth (Chaganti et al., 2008; Meyer-Bahlburg et al., 2012; Park et al., 2005). Reduction of IgM memory B cells has been associated with (functional) asplenia and a poor antipolysaccharide response, while the expansion of $CD21^{low}$ B cells is associated with a higher risk of inflammatory and lymphoproliferative manifestations (Rakhmanov et al., 2009). Expansion of transitional B cells is the hallmark of the rare B-cell–activating factor receptor (BAFFR) deficiency (Warnatz et al., 2009) and is frequently found in patients with X-linked lymphoproliferative syndrome (Cuss et al., 2006) as well as idiopathic CD4 lymphocytopenia (Malaspina et al., 2007).

Although not frequently applied in practice, analysis of the differentiation pattern of B-cell precursors in the bone marrow is valuable for the differential diagnosis of patients with severe peripheral B-cell reduction found in variants of SCID or agammaglobulinemia (Noordzij et al., 2002a, 2002b). Staining for immunoglobulin κ or λ light chain expression may be used as a screening parameter for prominent monoclonal B-cell populations.

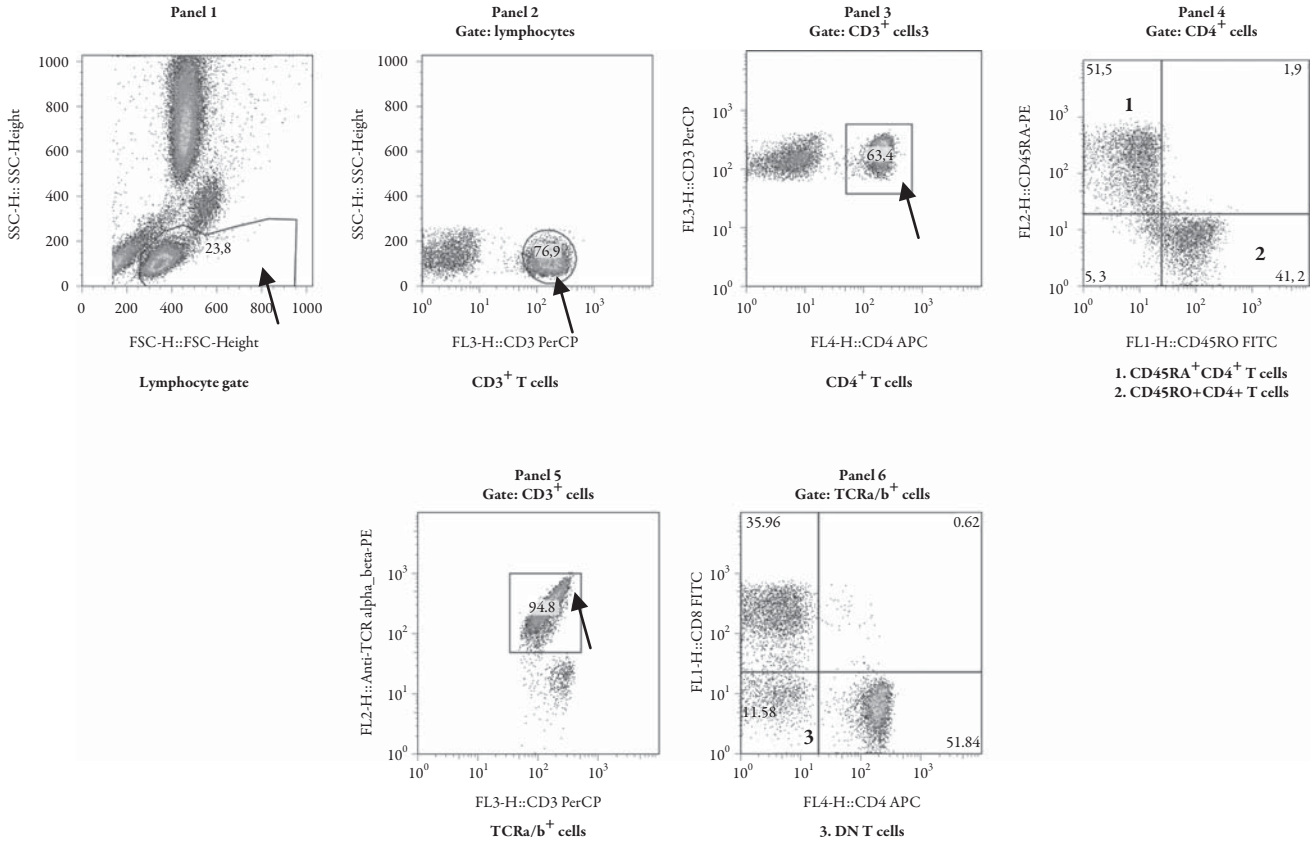

Figure 56.3 T-cell phenotyping. For flow-cytometric evaluation of T cells, lymphocytes gated by forward and side scatter (panel 1) are analyzed for CD3 expression (panel 2). $CD3^+$ T cells are then divided into $CD4^+$ (panel 3) and $CD8^+$ T cells (not shown). CD4 T cells can be further separated into $CD45RA^+$ naïve CD4 T cells (1) and $CD45RO^+$ memory CD4 T Cells (2) (panel 4). Alternatively, by gating on $TCR\alpha/\beta^+$ $CD3^+$ T cells (panel 5), $CD4^-CD8^-$ DN T cells can be determined (3) (panel 6).

FUNCTIONAL TESTS

B Cells: Immunoglobulin Production In Vitro

Human B cells cultured with lectins such as pokeweed mitogen or *S. aureus* Cowan strain will develop into plasma cells producing antibody in vitro. Although not widely applied in clinical practice, it can be a useful method to study the intrinsic capacity of B cells to undergo isotype class-switching and plasma cell differentiation (Livaditi et al., 2007). Other stimuli may be used to study class-switching in vitro. For example, stimulation with cross-linking antibody to CD40 in the presence of IL-4 will lead to production of IgE (Jabara et al., 1995), while stimulation in the presence of transforming growth factor-β leads to production of IgA (Briere et al., 1995).

T Cells

Delayed Hypersensitivity Skin Test

The classic example of this is the Mantoux test for tuberculosis performed by an intradermal injection of the purified protein derivative (PPD) of tuberculin. In individuals infected with *Mycobacterium tuberculosis,* antigen is taken up and presented by skin dendritic cells and antigen-specific T cells are activated and recruit inflammatory cells, leading to cellular infiltration with resulting induration and erythema. The reaction usually develops over 48 to 72 hours. For the purpose of assessing T-cell function diagnostically, the test may be performed with any antigen to which the patient has been exposed (Yates & deShazo, 2001). Examples include tetanus and diphtheria toxoids, streptococcus, *Candida*, *Trichophyton*, and *Proteus*. An area of induration of at least 5 mm is considered positive; in children, some accept 2 mm as a criterion of a positive test (Franz et al., 1976). Infants are able to respond, but the test is not considered generally reliable under age 1 year. Glucocorticosteroids and other immunosuppressive drugs may blunt the response; the reaction may also be suppressed during acute infectious illnesses. In these situations, or when the interpretation of a negative result is unclear, an in vitro method of measuring T-cell function should be used.

T-Cell Proliferation Tests

Peripheral blood T cells may be induced to undergo cell division (proliferate) in vitro by a variety of stimuli. These include nonspecific mitogenic agents such as plant lectins (phytohemagglutinin, concanavalin A, pokeweed mitogen) and antibodies against the CD3 complex, as well as antigens such as tetanus and diphtheria toxoids (Bonilla, 2008; Nisbet-Brown et al., 1987; Stone et al., 2009). Also, phorbol esters and calcium ionophores together induce T-cell activation and

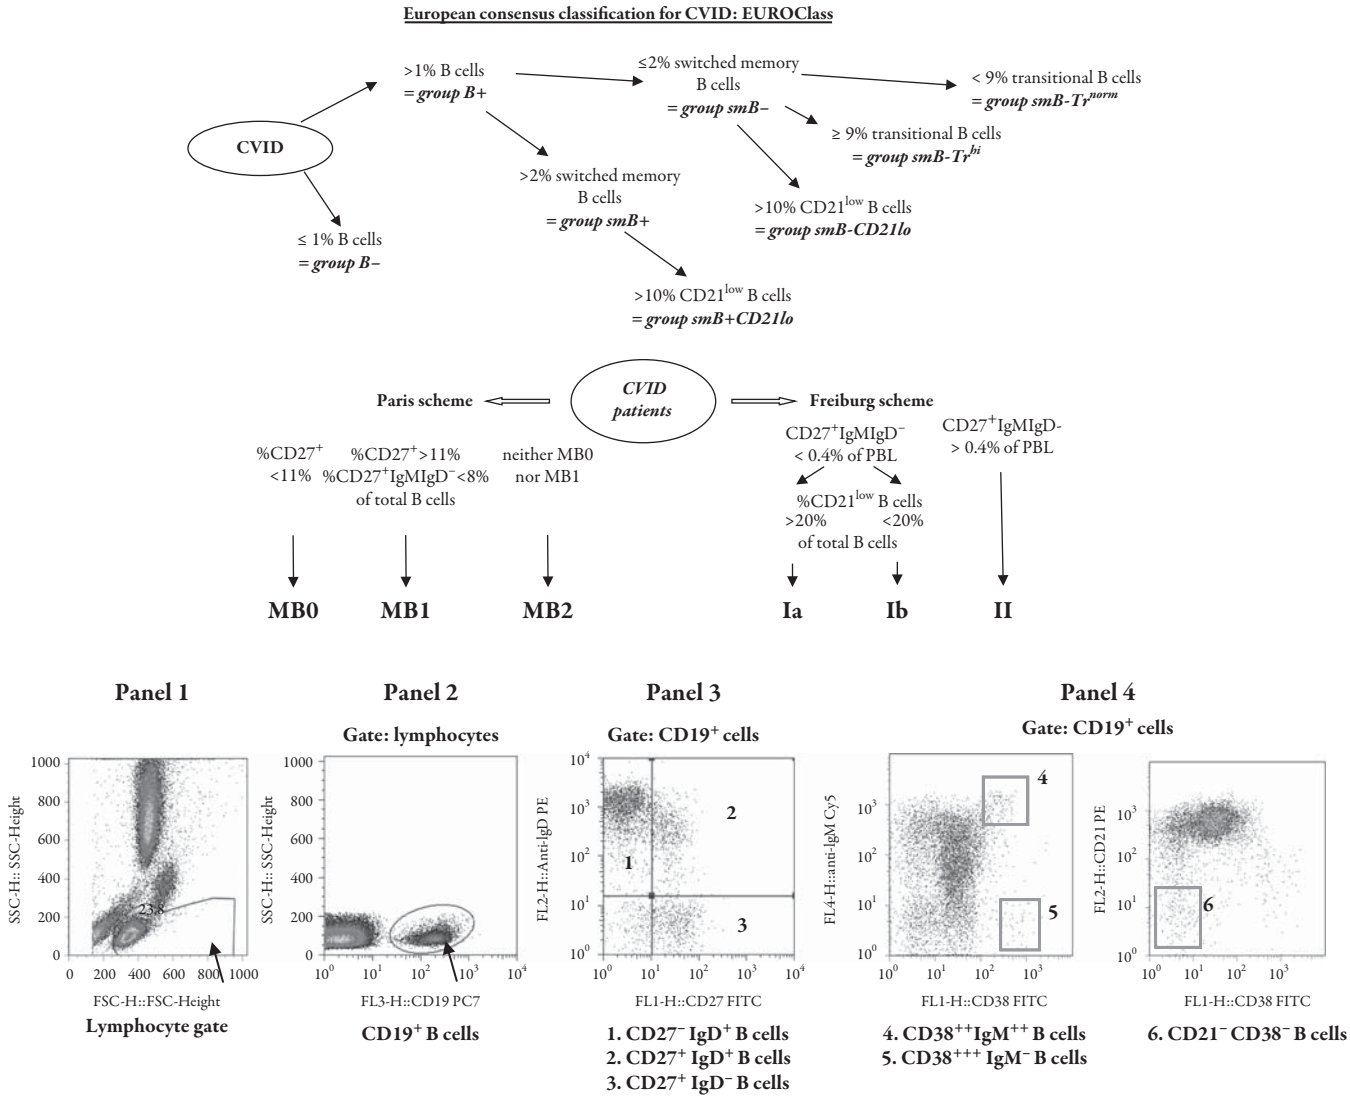

Figure 56.4 B-cell phenotyping. For flow-cytometric evaluation of B cells, lymphocytes gated by forward/side scatter (panel 1) are analyzed for CD19 expression (panel 2). $CD19^+$ B cells are then divided into $CD27^-IgM^+IgD^+$ naïve B cells (1), $CD27^+IgM^+IgD^+$ IgM memory B cells (2), and $CD27^+IgM^-IgD^-$ class-switched memory B cells (3) (panel 3). Additionally, $CD19^+$ B cells can be separated into $CD38^{++}IgM^{++}$ transitional B cells, $CD38^{+++}IgM^-$ plasmablasts, and $CD38^-CD21^{low}$ B cells (6) (panel 4). Classification schemes for CVID based on B-cell phenotyping. Freiburg classification (Warnatz et al., 2002), Paris classification (Piqueras et al., 2003), and EUROClass consensus classification (Wehr et al., 2008).

proliferation bypassing mechanisms of T-cell–receptor signaling (Weiss & Imboden, 1987). Irradiated allogeneic lymphocytes may also be used as a stimulus for proliferation (mixed lymphocyte culture) (Virella et al., 1993). Density gradient-purified PBMCs are incubated with one of these stimuli, and their activity is compared to healthy controls. Nonspecific mitogens will rapidly stimulate the majority of T cells (80 to 100 percent), and these assays can be performed in 3 days. Allogeneic cells induce response in approximately 10 percent of T cells. Specific antigens require processing and presentation and the recruitment of specific T cells that represent only about 1/1,000 T cells or fewer. These latter tests require about 5 to 7 days in culture. The most widely applied method of measuring proliferation uses tritiated thymidine added to the culture. Dividing cells incorporate the radioactive nucleotide into their DNA, and this can be measured in a radiation counter as a surrogate for proliferation.

The ability of T cells to divide in response to mitogens or antigens is affected to varying degrees by discrete lesions in pathways of cellular signaling during activation. This type of test is easily interpreted in an "all-or-none" manner, for example in the diagnosis of SCID. Part of the clinical definition of SCID is an in vitro mitogenic response that is less than 5 to 10 percent of normal (Fig. 56.5) (Railey et al., 2009). The predictive value of proliferation testing for less-severe defects of T-cell function or for the risk of infection is otherwise relatively poor; these tests lack both sensitivity and specificity as a screening tool in diverse patient populations (Stone et al., 2009). This is most likely due to the fact that many clinically important defects of T-cell interaction with other cell types lead to only partial impairment of their ability to divide in culture in response to these stimuli. Similarly, partial impairment of cell division does not necessarily indicate that the cells are incapable of generating effector responses that are sufficient for

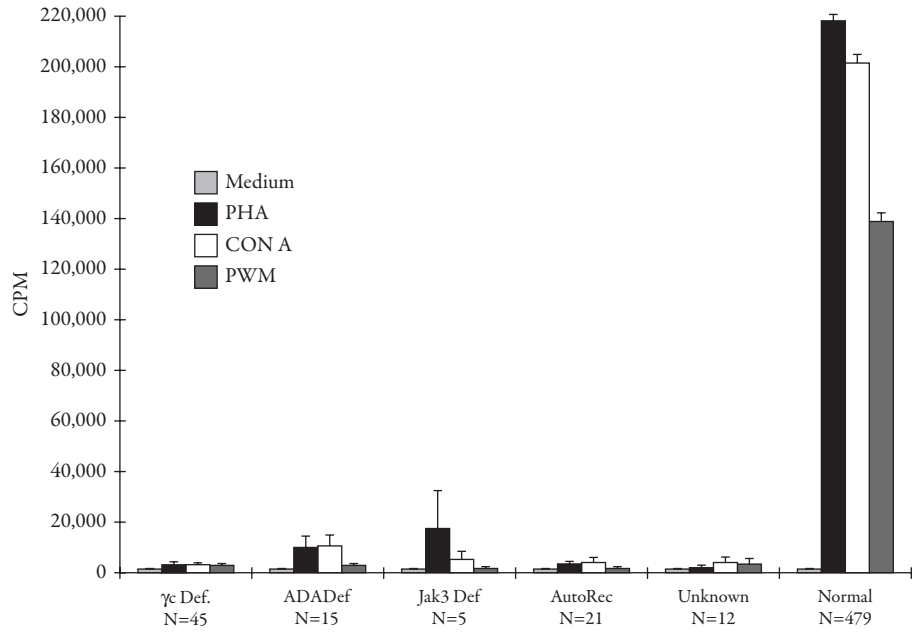

Figure 56.5 Lymphocyte proliferation testing by thymidine incorporation. PBMCs from infants with SCID and healthy adult controls were incubated with PHA, CONA, or PMA, and cell division was measured by incorporation of tritiated thymidine. The CPM of radioactivity incorporated into cells is shown on the y-axis. PBMCs from the infants with the forms of SCID listed failed to divide in response to the mitogens. (Reproduced from Sarzotti-Kelsoe et al., 2009, with permission.)

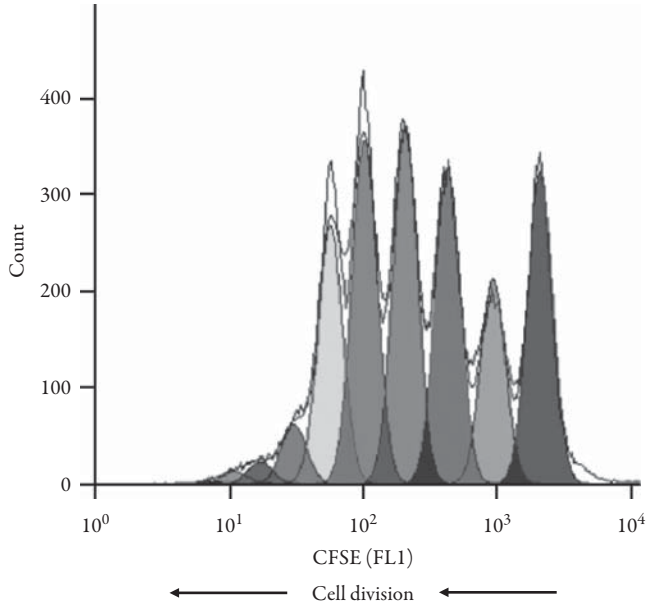

Figure 56.6 Lymphocyte proliferation by CFSE dilution. PBMCs from healthy adults were incubated with CONA. In this flow-cytometry histogram, the peak at the far right represents cells with the highest fluorescence intensity that have the highest internal concentration of CFSE because they have not divided. Each successive peak moving toward the left represents cells that have divided, diluting the CFSE by approximately half with each cycle. There are eight peaks in addition to the peak of undivided cells; thus, this culture contains cells that have undergone up to eight rounds of division. (Reproduced from Wallace & Muirhead, 2007, with permission.)

protection against many pathogens. All proliferative responses must be interpreted in the context of the $CD4^+$ and $CD8^+$ T-cell counts, since severely reduced proportions of $CD4^+$ T cells or preactivated or high numbers of $CD8^+$ T cells reduce the proliferative response in vitro without revealing the proliferative capacity on the cellular level.

A newer method of detecting cell division uses flow cytometry to measure the dilution of a fluorescent tracking dye. One that has been widely used is carboxyfluorescein diacetate succinimidyl ester (CFSE or CFDA-SE) (Lyons et al., 2001). This molecule will diffuse passively into cells where cytoplasmic esterases cleave the acetate moieties, making the molecule fluorescent and lipophobic so it cannot diffuse out. The amount of dye in each cell is reduced as cells divide in culture (Fig. 56.6) (Wallace & Muirhead, 2007). Several other fluorescent dyes with similar properties have also been used. This method may have some advantages over the traditional proliferation assay. With the use of reagents labeled with distinct fluorescent dyes, a multiparameter analysis may be used to track populations of responding cells, such as B cells, or $CD4^+$ or $CD8^+$ T-cell subsets, and so forth. Reagents may also be targeted to cytokines or surface molecules to provide additional functional readouts in addition to proliferation (Fig. 56.7) (Munier et al., 2009). These methods are not yet widely applied in clinical settings.

Although there is generally good correlation between proliferation assays using tritiated thymidine and methods using fluorescent dyes, the dye molecules may inhibit some processes of cellular activation and may cause cells with low proliferation in a tritiated thymidine assay to cease to divide altogether (Last'ovicka et al., 2009). The performance of this

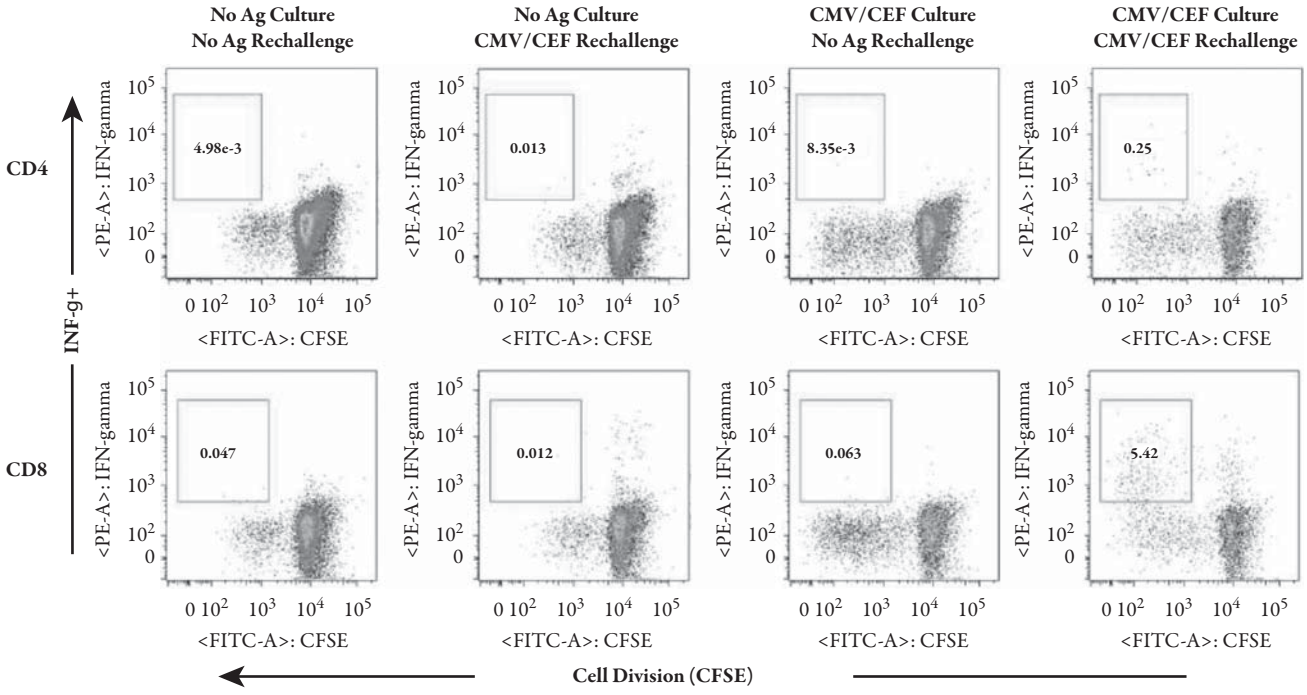

Figure 56.7 Multicolor (multiparameter) flow-cytometry analysis of cell division, surface-marker expression, and cytokine production. PBMCs from healthy cytomegalovirus (CMV)-immune adults were cultured under various conditions, with or without CMV, and with or without rechallenge with CMV at a later time point. These flow-cytometry dot plots show the fluorescence intensity of CFSE on the x-axis to measure cell division and staining with a monoclonal antibody against IFN-γ on the y-axis. In the upper panels, the analysis is restricted to ("gated on") cells expressing CD3 and CD4; in the lower panels, the plots are gated on cells expressing CD3 and CD8 (gating plots not shown). The dots inside each boxed region within each plot represent cells that have both undergone cell division and are expressing IFN-γ. This analysis shows that there are very few dividing and IFN-γ–expressing cells except under conditions where the cells are both incubated with CMV early and rechallenged later. Under these conditions, 0.25 percent of the CD4 cells and 5.42 percent of the CD8 cells divide and express IFN-γ. (Reproduced from Munier et al., 2009, with permission.)

type of assay in a clinical setting requires further study; it may not provide information that is equivalent to tritiated thymidine incorporation.

Apart from proliferation, there are many methods available to study distinct features of lymphocyte activation. Two broad categories include modulation of the expression of surface molecules and the production of cytokines. In general, the types of stimuli used are similar to those discussed above in the setting of the proliferation assay. Flow cytometry is well suited for both of these types of measurements. A variety of cell-surface markers have been used to monitor cellular activation, including CD69 (a C-type lectin rapidly upregulated in leukocytes after activation), CD25 (the α chain of the high-affinity IL-2 receptor), CD27 (a TNF receptor superfamily member expressed on activated and memory B lymphocytes), CD40 ligand (CD40L, expressed mainly only on $CD4^+$ cells), CD71 (transferrin receptor), and HLA-DR, among others (Fig. 56.8) (Last'ovicka et al., 2009; Pitsios et al., 2008). Any cytoplasmic cytokine of interest for which a suitable reagent is available may be studied by intracellular flow cytometry in fixed and permeabilized cells. Clearly, the multiparametric nature of flow cytometry is well suited to the simultaneous analysis of distinct lymphocyte subsets with respect to several surface markers and/or cytokines (Figs. 56.7 and 56.8).

Another type of T-cell–activation test is based on the production of ATP following stimulation with PHA (Hooper et al., 2005). This type of test is used widely in clinical organ transplantation and has defined predictive values with respect to the risk of infection and graft rejection. This test has not been widely applied for diagnosis of immunodeficiency.

As is the case with dye dilution methods, there are generally good correlations between surface marker or cytokine expression, and metabolic (ATP) measures of cellular activation with "traditional" testing based on tritiated thymidine incorporation. Although these different types of tests are intended to provide conceptually similar information regarding T-cell responsiveness to various stimuli, few have been subjected to a formal analysis of their predictive value in PIDD diagnosis. There may be clinically important differences in their interpretation as diagnostic tools. One small study indicates that CD69 expression may be a less-sensitive indicator of impaired T-cell function than tritiated thymidine incorporation (Hutchinson et al., 1999). Newer flow-cytometry–based methods require further additional evaluation in large patient cohorts to assess their performance as screening tools for diagnosis.

Cytotoxicity

Cytotoxicity describes the capacity of one cell to kill another cell by direct contact. $CD8^+$ T cells and NK cells are the two major, but not exclusive, cytotoxic cell populations. Therefore, tests concerning cytotoxicity focus on these populations. While cytotoxicity of $CD8^+$ T cells typically requires cognate interaction with the target cell, the license to kill of NK

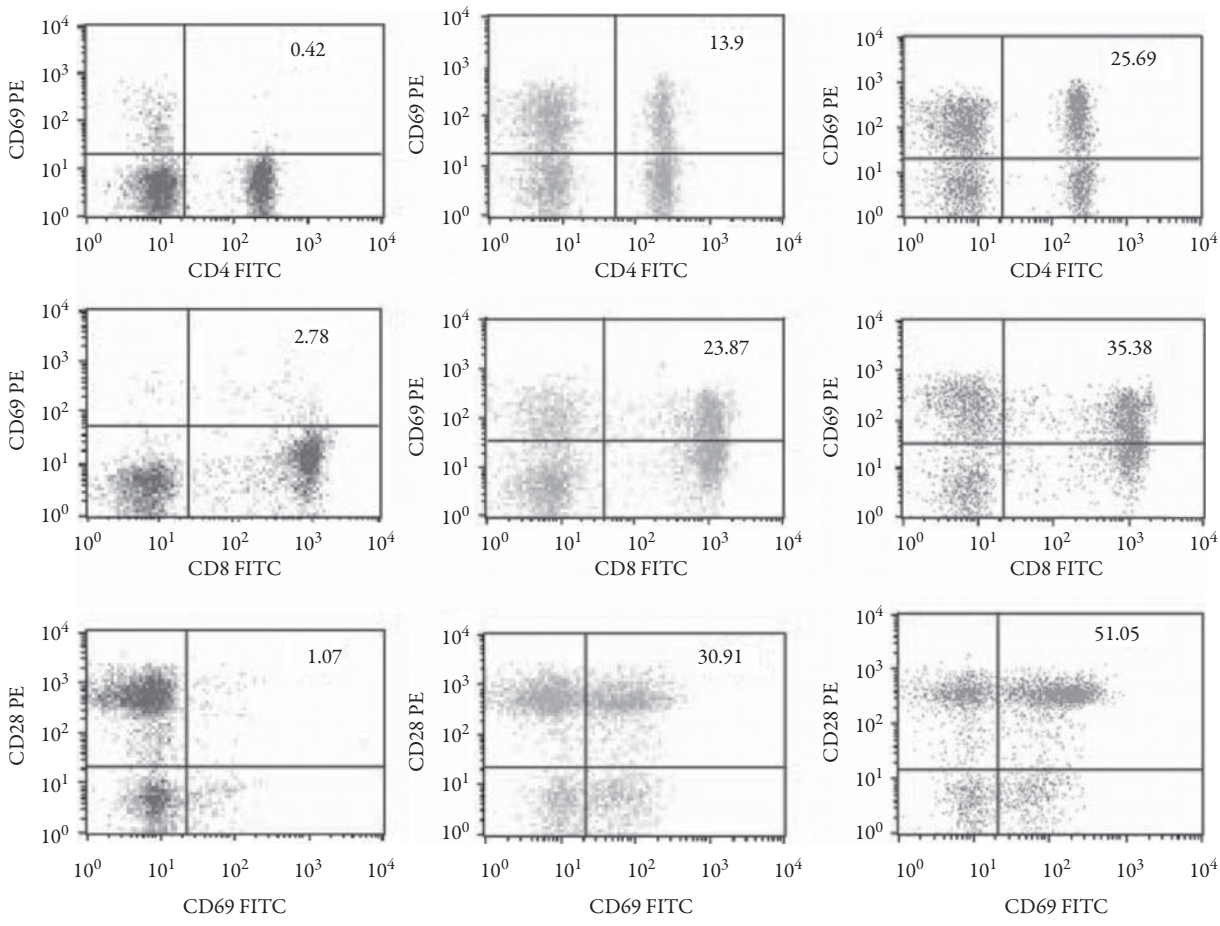

Figure 56.8 Multicolor (multiparameter) flow-cytometry analysis of lymphocyte activation by surface-marker expression. PBMCs from an HIV-infected adult were incubated without stimulation (left column of panels), with PHA (center column), or with a combination of monoclonal antibodies against CD3 and CD28 (right column). These dot plots represent the characteristics of T cells in the cultures. Plots are gated on cells that express CD3 (not shown). The top row of panels shows cells expressing both CD4 (x-axis) and the leukocyte activation surface marker CD69. The percentage of $CD4^+CD69^+$ cells is shown. The center row shows the results for $CD8^+$ cells; the bottom row shows expression of CD69 (x-axis) and CD28 (y-axis). (Reproduced from Pitsios et al., 2008, with permission.)

cells relies on less-specific activating and inhibitory signals. Cytotoxic cells kill through the release of cytotoxic granules (Fischer et al., 2007). Several disorders affecting the cytotoxic function present as hemophagocytic syndromes (Filipovich, 2008; see Chapter 54).

The standard assay for NK-cell function is the in vitro lysis of target cells. The target cell most often used is the erythroleukemia cell line K562. In the standard method, the K562 cells are loaded with ^{51}Cr. PBMCs of the patient, with or without activation with other agents such as PHA, are incubated with K562 tumor cells at various effector:target (E:T) ratios (von Zons et al., 1997). Cytotoxicity is measured after 4 hours of incubation by chromium release. While this radioactive assay is still the gold standard, several other nonradioactive assays for cytotoxicity have been developed (Allegra et al., 2006; Cholujova et al., 2008; Kim et al., 2007; Ozdemir et al., 2003). Their sensitivity and specificity in the context of immunodeficiency needs to be addressed in future studies.

In familial forms of hemophagocytic syndromes, NK-cell cytotoxicity is usually absent or markedly decreased in comparison to normal controls. The evaluation of the results needs to take into account whether NK cells are present and whether the function was tested during active disease or remission, since NK-cell function might normalize in secondary hemophagocytic syndromes and in X-linked lymphoproliferative syndromes (see Chapter 44). In the absence of NK cells in active hemophagocytic lymphohistiocytosis syndromes, CTL blasts can be generated in vitro and analyzed for cytotoxicity.

A flow-based assay to measure CD107 expression was suggested as a surrogate marker for the release of cytotoxic granules by $CD8^+$ T cells and NK cells (Betts et al., 2003). Further research needs to address whether this test can be used as a screening test for defects in cytotoxicity. In addition to functional assays, flow-cytometric evaluation of perforin might allow direct visualization before genetic or other molecular testing. Normal number but abnormal function of NK cells has also been reported in WAS (Orange et al., 2002) and Netherton syndrome (Renner et al., 2009).

Apoptosis

Disturbed apoptosis is the hallmark of ALPS (see Chapter 30). The majority of ALPS patients carry a mutation in the apoptosis-

inducing receptor FAS (CD95) (Su & Lenardo, 2008; Oliveira et al, 2010) and are designated ALPS-FAS. In addition to the increase of $CD4^-CD8^-$ double-negative $\alpha\beta$ TCR^+ T cells (DN T cells) to more than 2 percent, the essential diagnostic feature is the failure of induction of apoptosis of lymphocytes in vitro. Usually, PHA blasts are incubated with anti-FAS antibody or recombinant FAS ligand that is cross-linked to induce activation-induced cell death (AICD) (Rieux-Laucat et al., 1995). PBMCs are preferred to herpesvirus saimiri-transformed T cells or EBV-immortalized B-cell lines; even so, both are potential substitutes as targets (Broker et al., 1997). This assay will reveal about two thirds of the ALPS patients, including the FAS-deficient (ALPS-FAS) and caspase 10-deficient (ALPS-CASP10) patients (Su & Lenardo, 2008). The few Fas ligand (Fas-L)-deficient patients (ALPS-FASL) may be identified by the failure of their T-cell blasts to perform cytotoxicity in vitro (Del-Rey et al., 2006). In the subgroup of patients with somatic mutations of Fas (ALPS-sFAS), the decreased apoptosis and mutation can be seen only in sorted DN T cells (Holzelova et al., 2004) since the nonmutated T cells outgrow mutated T cells in culture and conceal the defective response of the DN T cells. The combination of DN T cells and elevated levels of soluble Fas-L, IL-10, and, surprisingly, vitamin B12 is a reliable marker of ALPS-FAS (Caminha et al., 2010; Magerus-Chatinet et al., 2009, Oliveira et al., 2010). Intrinsic defects of apoptosis can be tested by growth factor withdrawal; however, only a single patient has been described (Oliveira et al., 2007), and this is not part of routine diagnostic evaluation.

Signaling

Several PIDDs are characterized by disturbed leukocyte signaling. Defects can involve signaling via the B-cell receptor (e.g., XLA), T-cell receptor (ZAP70), TLR (IRAK4 or MyD88 deficiency), cytokine receptors (defects in STAT3, STAT1, or common γ chain, and others), or nuclear factor- κB (NF-κB) signaling (defects in NF-κB essential modulator [NEMO] or the inhibitor of κB kinase α chain). To date, mainly indirect functional assays have been performed to detect these deficiencies. With the increasing availability of phosphospecific antibodies, several of these immunodeficiencies can be analyzed by flow cytometry before the defect is confirmed by genetic analysis. Thus, recently Walshe et al. described the value of pSTAT5 detection by flow cytometry compared to Western blot and electrophoretic mobility shift assay (EMSA) in 32 SCID patients (Walshe et al., 2009). Absent STAT5 phosphorylation after IL-2 stimulation suggests defects in the common γ chain or in JAK3.

Bruton's tyrosine kinase (BTK) expression and phosphorylation can also be evaluated by flow cytometry. In patients without B cells, BTK expression can usually be determined in monocytes or platelets. This assay can also distinguish female carriers (Futatani et al., 1998). Defects in calcium signaling, as described in patients with mutations of Orai calcium release-activated calcium modulator 1 (ORAI1) (Feske et al., 2006) or stromal interaction molecule 1 (STIM1) (Picard et al., 2009), may be detected by the flow-cytometric measurement of the bound/unbound ratio of the calcium-sensitive dye Indo-1.

Mutations that permit protein expression but do not affect the phosphorylation site might not alter the flow-cytometric signal. Thus, pSTAT3-specific antibodies detect only STAT3-deficient hyper-IgE syndrome patients with mutations in the SH2 domain, but not in the DNA binding domain of STAT3 (Renner et al., 2008)

Radiosensitivity

Several PIDDs present with increased radiation sensitivity (Table 56.10). These are due to various DNA-repair defects (Chapters 46 to 49). To test for increased radiation sensitivity, usually cultured skin fibroblasts are irradiated with 1 to 4 Gy. Alternatively, EBV lines or immortalized T-cell lines of patients have been used. Sun et al. established normal ranges for a colony survival assay after radiation with 1 Gy (Sun et al., 2002). While only 13.1 ± 7.2 percent of the irradiated cells of patients with ataxia-telangiectasia (AT) survived after 24 hours, 50.1 ± 13.5 percent cells of healthy controls were still viable after the same treatment. The assay is time-consuming, since fibroblast or B- or T-cell lines need to be grown before the assay can be performed. Positive and negative control cultures have to be included in each experiment.

Recently, flow-cytometric assays have been developed using decreased phosphorylation of the histone γ-H2AX (Porcedda et al., 2009) or structural maintenance of chromosome 1 (SMC1) (Nahas et al., 2009), two phosphorylation targets of ATM that allow the identification of heterozygous carriers and homozygous AT patients. The great advantage of these assays is the rapid performance and the potential use of PBMCs. It remains controversial whether the count of γH2AX foci persisting after 24 hours is a reliable readout of increased radiation sensitivity (Markova et al., 2007).

Molecular Methods

Protein Detection

Where the clinical and screening laboratory phenotype is highly indicative of one or a few distinct possible genetic lesions, targeted molecular methods to analyze the gene product(s) may be employed. Labeled and unlabeled monoclonal antibodies for many molecules relevant for PIDDs are readily available from many commercial sources. Western blotting may be used to

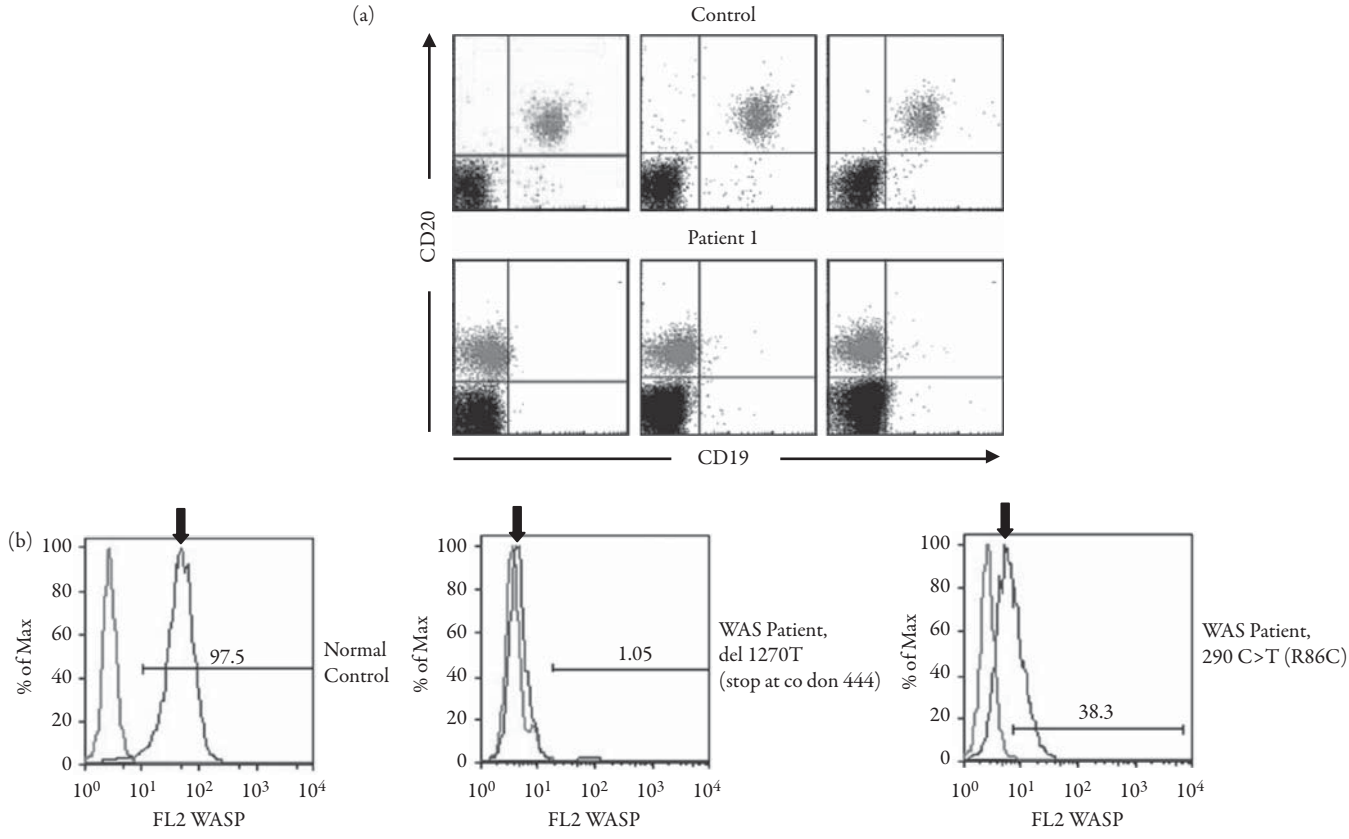

Figure 56.9 Flow-cytometric analysis of surface markers or cytoplasmic proteins for diagnosis of specific PIDDs. Part A: Peripheral blood lymphocytes are stained with monoclonal antibodies against CD20 (y-axis) and three different antibodies against CD19 (x-axis, three columns). A healthy adult control (top row) shows staining of B cells with all of the CD19 antibodies. A patient with CD19 deficiency has B cells (positive staining with anti-CD20), but these cells do not stain with any of the three anti-CD19 antibodies. (Reproduced from van Zelm et al., 2006, with permission.) Part B: PBMCs are permeabilized and stained with a monoclonal antibody against the Wiskott-Aldrich syndrome protein (WASP). The left panel shows the staining of a healthy adult control. The lymphocytes clearly show a shift in fluorescence with the anti-WASP antibody compared to the isotype control (left peak), indicating normal WASP expression. The middle and right panels show the staining patterns of two patients with WAS having two different WASP mutations. The middle panel shows a patient with a deletion leading to premature termination of translation and absence of WASP. The right panel shows a patient with a missense mutation that results in low-level expression of the mutant WASP. The low level of staining could be due to intrinsic instability of the mRNA and/or the protein, reduced binding of the staining antibody to the mutant WASP, or some combination of these factors. (Reproduced from Ochs & Thrasher, 2006, with permission.)

detect the presence, quantity, or size of any protein for which a suitable antibody is available (Becker-Catania et al., 2000; Holinski-Feder et al., 1998; Jirapongsananuruk et al., 2003; Lemahieu et al., 1999). Overall, this method is relatively cumbersome in comparison to methods based on flow cytometry but can be particularly useful for detecting altered structural forms, particularly those that are smaller or larger as a result of mutation. Flow cytometry may be used to study cell-surface, cytoplasmic, and nuclear molecules. The latter two require permeabilization of cells prior to addition of labeled antibodies. Examples include CD3ε (on T cells), CD19 (on B cells), CD25 (on T cells or B-cell lines), CD40 (on B cells), CD40L (on activated T cells), inducible T-cell co-stimulator (ICOS) (on activated T cells), BTK (in monocytes or platelets), WASP (in lymphocytes or monocytes) (Nakajima et al., 2009), SLAM-associated protein (SAP) by activated T cells (Shinozaki et al., 2002), and BAFFR on B cells (Warnatz et al., 2009). Some examples are shown in Figure 56.9. Point mutations may lead to dysfunction but may not alter expression, and therefore normal flow-cytometric detection of the suspected molecule may be misleading.

RNA Detection

A variety of molecular methods are available for the study of single gene mRNA expression and structure for diagnostic purposes (see Chapters 2 and 57). These include Northern blots, dot blots, and PCR methods (including quantitative RT-PCR), alone or in conjunction with single-strand conformation polymorphism analysis. (Holinski-Feder et al., 1998; Lemahieu et al., 1999)

Gene Structure

Methods for the study of gene structure are increasingly applied for the diagnosis of PIDDs. These include methods such as Southern blotting to detect large-scale changes (deletions), as well as genomic sequencing to identify smaller mutations. Demonstration of altered genetic structure is necessary but not sufficient for establishing a definitive PIDD diagnosis. Particularly in the case of new missense mutations, there must be plausible or clearly demonstrated functional alteration of the gene product as a result of the mutation, as well as absence of the mutation in the general population. Genetic aspects of PIDDs are discussed in Chapters 2 and 57.

GENETIC ASPECTS OF PRIMARY IMMUNODEFICIENCIES

Jennifer M. Puck

There are three reasons why evaluation of an immunological disorder in any patient should include consideration of potential underlying genetic determinants. First, genetic studies can confirm a suspected diagnosis of immunodeficiency and indicate the best treatment; they can also help to pinpoint a specific primary etiology even when other available data are unusual, incomplete, or inconclusive. Second, new understanding of the immunological basis and pathogenesis of immunodeficiencies can be gleaned as more disease genes are identified through the partnership between researchers in molecular genetics, clinicians, and affected patients. Finally, diagnosing a genetic disorder in an index patient, or proband, has profound implications for the patient's family members, both affected and unaffected, living and as yet unborn.

Disorders of the immune system may be due to defects in single genes, either already known or currently unidentified, that encode gene products essential for development or function of immune pathways. Because we have now recognized newly arising mutations and variant phenotypes for many immunodeficiency genes, we know that even immunodeficient patients who lack a positive family history may have genetic mutations underlying their condition that pose a risk of recurrence in their offspring or other family members.

More common on a population basis than single gene disorders causing immunodeficiency are many as yet incompletely understood immune dysfunctions with a complex etiology with one or more genetic factors that may act in conjunction with environmental influences. As the fields of genetics and genomics advance, genetic contributions to all categories of human disease, including immunodeficiencies, become increasingly apparent. While this chapter emphasizes the available genetic tests for single gene diseases, the field is changing rapidly and promises to be radically different when whole genome sequencing becomes widely available. Not only are additional disease genes being discovered, but technologies are improving to understand the significance of observed gene variants. The immense increases in technical ability to determine an individual's genetic constitution present a formidable challenge to our medical and social systems to help individuals understand their risks, and to develop new therapies based on genetic advances.

The reader is referred to Chapter 2 for a summary of genetic principles and technologies. This chapter will present an overview of genetic tests used to diagnose inherited immunodeficiencies, but these tests should be viewed in a broad context of evolving basic knowledge, technological advances, and social and regulatory issues. The physician specializing in the diagnosis and treatment of immunodeficiencies should stay in contact with patients and their families to be able to pass on relevant new information. Much can be gained through enlisting the involvement of clinical geneticists and genetic counselors, who specialize in helping individuals and families grasp and manage their personal genetic risks.

ESTABLISHING A GENETIC ETIOLOGY

POSITIVE FAMILY HISTORY

The first diagnostic measure when considering any heritable disorder is to obtain a full pedigree and family health history; heritable immunodeficiencies are no exception. Although most of the immunodeficiencies in this book have been identified at the gene level recently, families can often provide details about potentially affected members in past generations whose presentation and course might be compatible with the disorder (see agammaglobulinemia pedigree and discussion in

Table 57.1 X-LINKED IMMUNODEFICIENCIES AND THEIR DISEASE GENES

IMMUNODEFICIENCY DISEASE	GENE NAME	PROTEIN	LOCATION	FEMALE SKEWED X INACTIVATION	AUTOSOMAL GENOCOPY	SEE CH
X-linked chronic granulomatous disease (CGD)	*CYBB*	Cytochrome oxidase gp91^{phox} that generates reactive oxygen species	Xp21.1	No	Yes	51
Properdin deficiency	*PFC*	Properdin activator of complement	Xp11.23	No	Yes	54
Immunodysregulation polyendocrinopathy enteropathy sundrome (IPEX)	*FOXP3*	Forkhead/winged-helix transcriptional regulator critical for regulatory T cells	Xp11.23	No	Not known	31
Wiskott-Aldrich syndrome (WAS)	*WAS*	WAS protein (WASP) activator of actin polymerization and signal transduction	Xp11.22	Yes: all hematopoietic cells	Yes	42
X-linked severe combined immunodeficiency (XSCID) Immunodeficiency X-linked with magnesium transport defect (XMEN)	*IL2RG* *MAGT1*	Common γ chain of cytokine receptors Magnesium transport protein; defect leads to severe Epstein-Barr virus infections, lymphoma	Xq13.1 Xq21.1	Yes: T, B, NK cells (not phagocytes) Yes: T cells	Yes Not known	10 (Li et al., 2011)
X-linked agammaglobulinemia (XLA)	*BTK*	B cell tyrosine kinase	Xq21.3-q22	Yes: B cells (not T cells, phagocytes)	Yes	24
X-linked lymphoproliferative syndrome type 2 (XLP2) X-linked lymphoproliferative syndrome type 1 (XLP1)	*XIAP* *SAP, SH2D1A*	Inhibitor of apoptosis XIAP Lymphocyte signaling activation molecule	Xq25 Xp25	Unknown Yes: NKT cells (not T, B cells)	Yes Yes	43 43
X-linked hyper-IgM syndrome	*CD40L*	CD40 ligand	Xq26.3-q27.1	No	Yes	25
G6PD deficiency	*G6PD*	Glucose-6-phosphate dehydrogenase	Xq28	No	No	49
X-linked ectodermal dysplasia with immunodeficiency (NEMO) Dyskeratosis congenita X-linked hypogammaglobulinemia with growth hormone deficiency	*NEMO, IKBKG* *DKC1* *[ELF4?]*	Inhibitor of κ light polypeptide gene enhancer in B-cells, kinase γ Component of telomerase; defect causes premature aging, myelodysplasia (Myeloid ELF-like factor [MEF])	Xq28 Xq28 [Xq26? Not proven]	Sometimes; females may have incontinentia pigmenti Yes (in all cells in a mouse model) Yes: B cells	Not known Yes Not known	35 (He et al., 1998) 24

Chapter 1). Assembly and recall of complete information often requires more than one session and interviews with more individuals than just the nuclear family of the index case. Retrieval and review of medical records from relatives can provide critical data, so they are well worth seeking. Ethnic and geographical ancestry should be recorded as part of every family history because they may suggest consanguinity or increased risks associated with particular populations.

The X chromosome harbors a large number of recognized immunodeficiency genes, and the X-linked immunodeficiency diseases occur in disproportionately high frequency (Table 57.1). This is because in males, mutations in genes on the sole copy of the X chromosome are uncompensated, and therefore a single mutation causes overt disease, while females with one mutated and one normal gene copy generally remain healthy. The X-linked inheritance pattern of multiple

affected males related through maternal lines, as discussed in Chapter 2, should be sought in all families with a male presenting with immunodeficiency.

Autosomal recessive diseases, in contrast, require defects in both alleles of a gene for a disease phenotype to be manifest. One way in which this occurs is through consanguineous marriages. Another risk factor for homozygous recessive diseases is belonging to a genetically isolated population, in which the same mutation may be transmitted through both maternal and paternal lines to the patient from a common ancestor. A rare cause of homozygous recessive inheritance is isodisomy, in which an affected individual has inherited both copies of a chromosome from one parent, rather than one copy from each parent. However, in most recessive immunodeficiencies, such as adenosine deaminase (ADA)-deficient severe combined immunodeficiency (SCID) (Chapter 14), patients are predominantly compound heterozygotes, having a different mutation in each of their two alleles.

There are relatively few dominant immunodeficiency phenotypes. As a rule they are characterized by incomplete penetrance (skipping generations in family pedigrees) and/or variable expressivity (a large spectrum of severity among relatives with the same genetic mutation). Examples include DiGeorge syndrome (Chapter 45); autoimmune lymphoproliferative syndrome due to Fas deficiency (Chapter 30); some instances of hyper IgE-recurrent infection syndrome or Job syndrome (Chapter 38); and, importantly, some instances of common variable immunodeficiency and IgA deficiency (Chapter 28) and even atopy and allergic disorders (Holgate, 1997). These conditions may turn out to be diseases in which a dominant gene mutation has a predisposing or contributory effect, but in which genetic or environmental factors act as modifiers of the phenotype.

Several immunodeficiency syndromes, such as SCID or chronic granulomatous disease (CGD), can be caused by defects in any of several different genes; the existence of autosomal phenocopies of the X-linked immune disorders is indicated in Table 57.1. Family history can be critical in differentiating the X-linked from autosomal forms.

IMPORTANCE OF FAMILY HISTORY, EVEN IF NEGATIVE

Documentation of a complete family pedigree is helpful even if it fails to reveal any sign of disease comparable to that of a proband affected with immunodeficiency. First, the structure of the pedigree determines the quantity of genetic information. A large kindred with many siblings of both sexes has had more opportunities to have affected relatives, whereas at the other extreme, there may be no information whatsoever about an adopted proband's heredity. Second, the absence of disease in many relatives who could potentially be at risk is useful. For example, if a male with SCID has many healthy maternal uncles, either a new occurrence of an *IL2RG* gene mutation (Table 57.1) or recessive disease is more likely than an X-linked mutation inherited from the patient's grandmother. A third benefit of obtaining a family history is the insight it can provide into the way in which family members will approach a serious immunodeficiency disease. We can provide optimal care for patients and their families only if we understand what the disease means to them. In previous generations or when the initial diagnosis has been delayed and treatment was ineffective, children born with immunodeficiencies are likely to have died, leading to parental feelings of guilt, secrecy, and other family stresses. Important family events or beliefs unrelated to immunodeficiency also strongly influence the outlook of family members. Finally, the family history may bring to light facts that influence the type of genetic testing that may be indicated, such as multiple miscarriages (a risk factor for chromosomal rearrangements) or misattributed paternity.

GENETIC TESTING FOR ABNORMALITIES IN IMMUNE SYSTEM GENES

Inherited immunodeficiencies are sufficiently rare that population-based screening would be required to make the diagnosis prior to the onset of infectious or autoimmune complications; screening has become possible for SCID (see below). Genetic testing is otherwise used to establish the diagnosis in an affected individual or to determine the status of relatives of a person already suspected to have a primary immunodeficiency. Individuals in a family with recognized immunodeficiency for whom genetic testing may be indicated include affected patients who are ill; individuals who may have inherited an defective immune system gene but as yet show no symptoms (presymptomatic testing); and healthy relatives who are not at risk for becoming immunodeficient themselves but who may be carriers of a defective copy of a gene and are concerned about their reproductive risks. In addition, prenatal testing has been performed for many immunodeficiencies in pregnancies that occur subsequent to the diagnosis of an affected proband. No single testing modality is appropriate for all situations. The reader is referred to specific chapters for discussions of the options for each disease.

TECHNIQUES THAT DO NOT RELY ON ISOLATION OF PATIENT DNA OR RNA

BIOCHEMICAL TESTS

The immunodeficiencies associated with enzyme abnormalities such as ADA and purine nucleoside phosphorylase (PNP) deficiency can be diagnosed by detecting increased amounts of physiological precursors, dATP or dGTP, respectively, or by direct measurement of enzyme activity in vitro (see Chapter 14). Similarly, glucose-6-phosphate dehydrogenase (G6PD) deficiency, associated with impaired intracellular killing by neutrophils, is best detected by enzyme assay (Beutler et al., 1979; Luzzatto & Mehta, 1995). The advantage of biochemical testing is that the functional consequences of the underlying gene mutation can be immediately demonstrated without the need for DNA sequencing. Moreover, gene defects that permit production of inactive or partially active protein will be distinguished from DNA sequence variants

of no physiological significance (genetic polymorphisms). A disadvantage, however, is that carrier testing, which relies on demonstrating enzyme activity intermediate between the normal and deficient ranges, may be imprecise due to overlap with the partial activity of some mutant proteins in affected individuals. Careful assay standards with positive and negative controls in every run are essential.

IMMUNOLOGICAL TESTS

Enumeration of leukocyte populations; measurement of their secreted products, such as immunoglobulins; and functional tests involving in vitro activation are necessary for the definitive diagnosis of virtually all immunodeficiencies. Their use in diagnosis is discussed in Chapter 56. In only a few circumstances, however, have these immunological tests been made specific for a particular gene product so that they can be used to establish a specific gene diagnosis. One example is X-linked hyper-IgM syndrome due to CD40 ligand (CD40L) deficiency (Table 57.1 and Chapter 26). Stimulated T cells from healthy individuals express CD40L, which can be detected by binding to immunofluorescent-tagged soluble CD40 or to an anti-CD40L monoclonal antibody (Conley et al., 1994). However, mutations that permit production and expression of defective protein at the cell surface may not be detected by this test, and it may be unreliable for the testing of female heterozygous carriers and cannot be used for prenatal testing early in pregnancy.

Another example of an immunodeficiency with a useful immunological test is CGD (Chapter 52). Formerly diagnosed by counting cells able to reduce nitroblue tetrazolium dye, the inability of CGD granulocytes to produce superoxide is now most accurately measured by flow-cytometric determination of neutrophil NADP oxidase activity (Jirapongsananuruk et al., 2002). Not only are patient cells readily shown to be defective in this test, but the results can be quantified to yield predictive information about disease severity. Moreover, female carriers of the X-linked form of CGD can be identified because the Lyonization, or random X inactivation, of their neutrophils results in two distinct populations when their cells are analyzed (see below). Cells whose active X chromosome has an intact *CYBB* gene have normal NADP oxidase, while those with an active X chromosome bearing mutated *CYBB* demonstrate the same lack of activity as the affected proband.

A special use of immunological tests is in the prenatal evaluation of fetal blood samples. By the middle of the second trimester of pregnancy it is possible to obtain blood from the fetal umbilical vein to determine whether functional T cells, B cells, or granulocytes are present in normal numbers (Lau & Levinski, 1988). Fetal blood sampling involves greater risk to the fetus than does either amniocentesis or chorionic villus biopsy, and it should be performed only in a center with extensive experience in the technique. It is possible for the sample to be contaminated with maternal blood. Only a small volume of fetal blood is collected, and it must be analyzed without delay by an immunology laboratory that has established normal fetal blood ranges. Despite these caveats, fetal blood sampling is undertaken by certain pregnant couples who have had a previous affected child with immunodeficiency but who lack a gene-specific diagnosis. For example, cell-surface staining for T cells and lymphocyte mitogen responses can be tested in a fetal blood sample to rule in or rule out a diagnosis of SCID in a pregnancy at risk, even if the gene mutation causing SCID in the proband is not known.

CYTOGENETIC STUDIES

Cytogenetic studies involve the microscopic analysis of chromosomes, usually when they are condensed during metaphase of mitosis. Giemsa banded karyotypes can reveal abnormal numbers of chromosomes or large structural changes, such as translocations, deletions, or duplications. The most common cytogenetic abnormality, trisomy 21 or Down syndrome, is associated with many qualitative immune defects but is almost always diagnosed because of its physical stigmata before immune dysfunction is recognized. While chromosomal abnormalities should be suspected when immune dysfunction is accompanied by additional congenital anomalies, there are instances in which a cytogenetic abnormality has only an immune phenotype, such as in males with X-linked lymphoproliferative disease due to deletions within Xq25 (Chapter 44). Pursuit of cytogenetic abnormalities has led directly to the identification of at least one immunodeficiency gene, *CYBB* in X-linked CGD (Orkin, 1989). A small minority of CGD patients have deletions of *CYBB* large enough to be detected cytogenetically. Patients with these deletions often have deletion of multiple contiguous genes, leading to a phenotype of CGD plus other abnormalities (Chapter 52). Balanced translocations can be clinically silent except for the disruption of particular genes at the chromosomal breakpoints, but a family history of multiple miscarriages should prompt cytogenetic investigation because offspring undergoing fetal demise may have received an unbalanced parental chromosomal complement. Thus, while the yield of karyotype analysis may be rather low in immunodeficiencies, this simple test is at times extraordinarily helpful in uncovering a genetic basis for a puzzling clinical syndrome and pinpointing the region of the genome involved. One caveat is that cytogenetic analysis is generally done on phytohemagglutinin-stimulated peripheral blood samples; if lymphocytes are present in low numbers and have impaired function, they may fail to respond to mitogen activation, leading to inadequate mitoses for scoring.

The power of cytogenetics was extended by fluorescent in situ hybridization (FISH). In this technique, a cloned unique human DNA fragment is tagged with a fluorescent label and allowed to hybridize to its corresponding sequence within chromosomes spread on a microscope slide. Viewed with a fluorescence microscope, the two homologous chromosomes are marked with the fluorescent DNA probe. FISH can be used to diagnose interstitial deletions on one copy of chromosome 22q11 associated with DiGeorge syndrome (thymic hypoplasia, hypoparathyroidism, and conotruncal heart malformations; Chapter 45). Although some deletions are large enough to be detected by karyotype analysis, especially with high-resolution technique, FISH with fluorescent probes

from 22q11 reveals only one signal in 90 percent of DiGeorge syndrome patients (Color Plate 45.I or 45.II).

A copy number array is a new DNA-based technique (see below) that many now prefer over karyotype or FISH because it provides information about deletions and insertions throughout the genome, although it does not reveal balanced translocations.

DNA- AND RNA-BASED TECHNIQUES

Molecular methods for mutation diagnosis are being applied to thousands of genetic conditions today, and many more genetic tests, including whole genome sequencing, will be common in the future. Certain generalizations distinguish mutations underlying immunodeficiency genes from those causing many other well-studied diseases. In some disorders, such as sickle cell disease, a single mutation predominates (Kan, 1992). Even in the cystic fibrosis disease gene CFTR, about two thirds of mutated chromosomes in Caucasians have the same Δ508 mutation (Zelenski & Tsui, 1995), and testing for a panel of mutations can effectively diagnose the great majority of cases (Richards et al., 2002). In contrast, immunodeficiency gene mutations tend to be extremely diverse, with half or more of the mutations unique to a single family. Unlike the dystrophin gene, defective in Duchene muscular dystrophy, in which large deletions and duplications account for 66 percent of mutations (Worton, 1992), by far the most common immunodeficiency gene mutations are small changes on the order of one to a few nucleotides, occurring in both coding sequences and their adjoining splice regions. An important new class of mutations described in human neurological and muscular diseases is the expansion of triplet repeats either in coding regions or in regions near a gene that are subject to silencing by methylation (Everett & Wood, 2004). However, to date no immunodeficiency-causing gene mutation of this type has been described.

In other respects, gene mutations that cause inherited immune disorders are similar to those in other genetic diseases (discussed in Chapter 2). These include a high proportion, approximately one third, of newly arising mutations for X-linked disorders (Haldane, 1935). As previously noted for the hemoglobin locus, factor IX locus, and many other genes (Cooper & Krawczak, 1995), the occurrence of C-to-T mutations at CpG dinucleotides in immunodeficiency genes is greatly increased above the number that would be expected if all nucleotide changes were completely random.

LINKAGE TO PCR-BASED POLYMORPHIC MARKERS

Linkage analysis is discussed in some detail in Chapter 2. For immunodeficiency diseases mapped to a unique genomic region but not yet identified, linkage analysis can define which chromosome segments in a family carry mutated disease gene alleles, provided there are both affected and unaffected relatives available for testing. Linkage analysis can also be useful when the gene that is defective in a family is known, but the specific mutation has not been determined. Linkage diagnosis can be used for carrier testing and for prenatal diagnosis. One should select tightly linked markers that flank the disease locus and are polymorphic in the required members of the family being tested. A haplotype of flanking marker loci is determined for disease-bearing and normal chromosomes in the parents of the individual at risk. If the flanking alleles on both sides of the disease locus match parental alleles from an unaffected chromosome, the person is likely to have inherited the entire haplotype block of DNA, including the normal copy of the disease gene. Similarly, flanking alleles co-inherited from a disease-bearing chromosome predict that a mutated copy of the disease gene has been inherited (see Chapter 2).

The first linkage markers to be used were restriction fragment length polymorphisms (RFLPs), nucleotide variations resulting in the presence or absence of a restriction enzyme site at a defined genomic DNA position (Botstein et al., 1980; Drayna & White, 1985). Digestion of genomic DNA with the relevant restriction endonuclease will demonstrate allelic variants with either shorter or longer DNA fragment sizes depending on whether the polymorphic restriction site is present or absent. Fragment lengths are assayed by Southern blotting.

The discovery of PCR revolutionized linkage analysis. PCR depends on designing short synthetic oligonucleotides flanking a DNA segment to be amplified. These oligonucleotides, called primers, are added in excess to genomic DNA along with free nucleotides, magnesium salts, pH buffer, and a heat-stable DNA polymerase enzyme, such as Taq polymerase. First, the reaction mixture is denatured by heating to 95°C so that the DNA helices unwind and the DNA becomes single-stranded. Next, the mixture is cooled to a moderate temperature, typically between 50° and 65°C, enabling the oligonucleotides to bind by complementary base pairing to the particular regions of template DNA that they exactly match. Finally, warming the mixture to 72°C allows the polymerase to synthesize new DNA using the oligonucleotides as primers and adding free nucleotides to form new complementary strands. Each repetition of this sequence of denaturation, annealing, and extension produces a doubling of the quantity of each template strand. This succession of temperatures constitutes one cycle of PCR. In successive cycles the segment of DNA between the primers is exponentially amplified. Eventually the amount of product becomes large enough to detect by direct visualization after gel electrophoresis.

Segments of DNA that are polymorphic can be readily detected by PCR. If the primers flank a polymorphic restriction site, the product can be digested to assign the restriction site allele. Another type of polymorphism is called a microsatellite or short tandem repeat polymorphism (STRP). The most common repeated unit, occurring on average once every 50,000 nucleotides throughout the genome, is CA on one DNA strand, GT on the opposite strand (Litt & Luty, 1989; Weber & May, 1989). Other repeats of units of two to five nucleotides also occur frequently. Very often, assorted numbers of repeated units are found in chromosomes from different individuals, and a stable number of repeats is inherited from parents to offspring. PCR amplification of the DNA segment

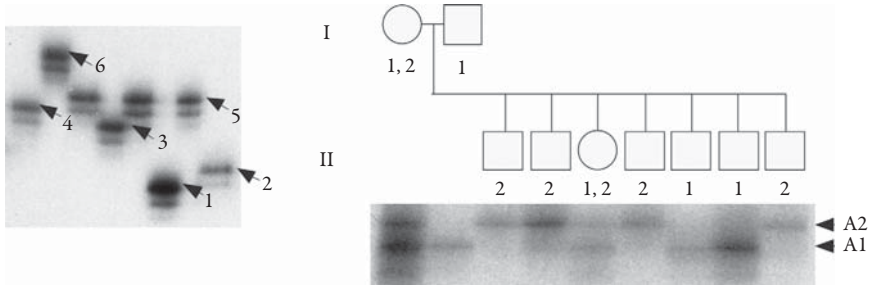

Figure 57.1 Short tandem repeat polymorphism (STRP). Right, DNA from eight unrelated males amplified with primers defining STRP locus DXS441 in Xq13 (Ram et al., 1992). Six alleles, numbered according to their increasing numbers of CA repeat units, were amplified using flanking PCR primers. Darker bands are the primary signal; lighter "shadow" bands seen below each primary band are typical artifacts in CA repeat STRPs. Left, DNA from family members amplified with primers defining the STRP GATA182e04 at Xq28.

containing a series of simple repeated units, followed by size separation by gel electrophoresis, reveals the length differences between the polymorphic alleles. Each lane of the gel on the left of Figure 57.1 shows DNA from an unrelated male amplified with appropriate primers surrounding the CA repeat present at the STRP marker DXS441 in Xq13, close to the X-linked SCID locus (Ram et al., 1992). Alleles of six distinct sizes are seen, indicating that the number of CA units can vary considerably between individual X chromosomes. The right side of the figure shows inheritance of a different X-linked STRP, GATA182e04, in a kindred. The parents share allele A1 and the mother is heterozygous for this allele and A2. The allele content of offspring is shown below their symbols: the sons are each hemizygous for one of the maternal alleles while the daughter is heterozygous, carrying paternally derived A1 and maternally derived A2.

STRPs have several advantages compared to RFLPs, reflecting the power of PCR as a tool for molecular genetic analysis. Foremost is the high frequency of STRPs throughout the genome. For linkage studies, STRPs can be found near any immunodeficiency gene. STRPs are also easily assayed by PCR. Miniscule amounts of input DNA template can be successfully amplified, including DNA recovered from newborn screening dried blood spots, formalin-fixed tissues, or histological slides. Thus, genetic information may be derived even if an affected patient has died without having donated samples for molecular analysis. Finally, the multiplicity of commonly observed alleles means that it is likely that a child's alleles can be unambiguously traced to one or the other parent.

Even more common than STRPs are single nucleotide polymorphisms, or SNPs, which occur at a rate of around one per 1,000 nucleotides of genomic DNA sequence. Unlike highly informative STRPs, SNPs have only two alleles, but their huge numbers make up for this inconvenience; the database dbSNP at the National Center for Biotechnology Information (NCBI: http://www.ncbi.nlm.nih.gov) contains over 50 million SNPs with a minor allele frequency of at least 5 percent. Clusters of neighboring SNPs tend to be inherited together in haplotype blocks that have been maintained with little crossing over since ancestral origins of humans (Gabriel et al., 2002), so that SNP signatures can identify ancestral haplotype blocks to streamline linkage analysis.

COPY NUMBER ARRAYS

Copy number array testing is a high-throughput method for detecting both the presence and the intensity of signals hybridizing to a large number of specific oligonucleotides throughout the genome, including polymorphic SNPs. SNP content (for example A/A, A/C, or C/C at a given position) and intensity of the signal relative to neighboring and distant signals is detected, making possible identification of haplotypes and revealing interstitial deletions or duplications (copy number variations [CNVs]). Many CNVs are recurrent while others are unique and of unknown significance. However, in the context of clinical findings or additional genetic information, CNVs can explain phenotypes. For example, Figure 57.2 shows a copy number analysis of proximal chromosome 16p11.2 in DNA from a patient with

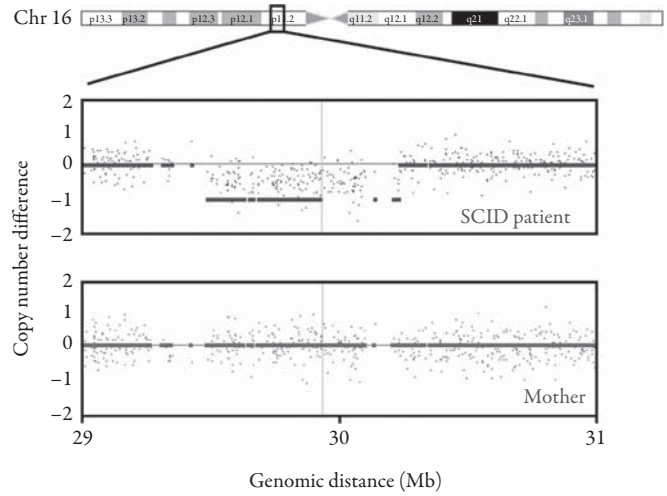

Figure 57.2 Copy number array analysis in a SCID patient and her mother across a 2 MB region of chromosome 16p11.2. Patient hybridization intensity is approximately half of normal (copy number -1) over a 600 bp region, diagnosing an interstitial deletion of one of her two copies of chromosome 16. The mother does not have a deletion in this region.

SCID (top) and her mother (bottom). The patient has a 600 kb interstitial deletion, indicated as "-1" copy number compared to her adjacent regions of diploid signal strength. The patient is hemizygous for over 24 genes in the deleted region. One of the deleted genes, CORO1A, encoding Coronin-1A, a lymphocyte protein involved in actin polymerization and cell motility, was also mutated in her paternally derived allele, resulting in an atypical SCID phenotype (Chapter 23, Shiow et al., 2008). Moreover, the region is now appreciated to be a recurrent CNV, prone to deletions and duplications because of crossing over of the direct repeats at each end; in fact, the patient's deletion was de novo, occurring on her maternally derived allele, but not found in her mother's blood cells. Other genes in the region currently under study are associated with infantile seizures (PRRT2), attention-deficit/hyperactivity disorder, and autism spectrum disorder when present in abnormal copy number (deVries et al., 2012; Luo et al., 2012; Weiss et al., 2008).

SOUTHERN BLOTTING, EVALUATION OF GENOMIC DNA

Southern blotting, named for its inventor, E.M. Southern (1975), is the prototypic technique for specific gene detection. A cloned segment of DNA is synthesized to incorporate labeled nucleotides, such as radioactive ^{32}P, and this labeled DNA is used as a probe to hybridize to a complex mixture of DNA, such as restriction enzyme digested genomic DNA prepared from the cells of a particular person. Now considered too labor-intensive for most clinical applications, this was the method historically used for the evaluation of RFLP markers and changes in genomic DNA before the development of PCR. Southern blotting can detect disease-causing mutations due to either large DNA deletions or rearrangements affecting the disease gene or due to single nucleotide changes that alter restriction enzyme sites. Southern blot variations have often provided the first clue that a candidate gene in fact harbors deleterious mutations in individuals with inherited immunodeficiencies. For example, they were used to find some of the first BTK mutations in patients with XLA (Vetrie et al., 1993). However, because the great majority of immunodeficiency gene mutations are small changes of one to a few nucleotides, Southern blot analysis is insensitive for finding suspected mutations in new patients. Moreover, finding altered Southern blot band patterns does not directly indicate the location or specific nature of a mutation. However, in families with a previously documented disease-associated Southern blot abnormality, this method can be successfully applied for carrier and prenatal diagnosis in relatives at risk of having inherited the same defect.

NORTHERN BLOTTING AND REVERSE TRANSCRIPTASE-PCR

Many mutations within or adjacent to exons of genes affect the quantity or size of the mRNA produced. These changes can be detected by Northern blot analysis, which is carried out in a manner similar to that of Southern blots. RNA is isolated from cells and electrophoresed through a gel to achieve separation by size. After transferring the RNA to a membrane, a labeled nucleic acid probe is allowed to hybridize to it, identifying a band of RNA containing the specific nucleotide sequence of interest. Mutations can produce differences in expected size or amount of RNA detected by Northern analysis.

As with DNA analysis, PCR has greatly enhanced our ability to analyze RNA through a process called reverse transcriptase PCR (rt-PCR). First, a complementary DNA (cDNA) strand is created by incubating mRNA with the enzyme reverse transcriptase and a DNA oligonucleotide primer. Even the nanogram quantities of RNA that can be purified from small numbers of cells can yield enough cDNA for successful amplification by PCR. Amplified cDNA can be sequenced, sized by gel electrophoresis, and quantitated to reflect the amount of cellular mRNA originally present (provided carefully monitored conditions and appropriate controls are used).

Mutations that disrupt the 3′ and 5′ splice motifs that flank exons prevent normal processing of newly made mRNA. These mutations are generally associated with low or undetectable levels of correctly spliced mRNA in the cytoplasm of cells. Aberrantly spliced mRNA species may be detected, such as RNA retaining an intron that would normally be excised. Missense or frameshift mutations that generate termination codons within the 5′ portions of coding sequences also usually cause mRNA to be degraded (known as nonsense-mediated decay). Thus, studies of mRNA are important in assessing the actual consequences of any mutation observed in DNA sequence. However, investigation of mRNA quantity or sequence is often complex and therefore not well suited to clinical diagnostic testing.

X-CHROMOSOME INACTIVATION PATTERN INPOTENTIAL FEMALE CARRIERS

The special property of inactivation of one of the two X chromosome in females has been exploited for identification of carriers of X-linked immunodeficiency diseases (Table 57.1). A unique feature of the sex chromosomes is that males have one X and one Y, while females have two X chromosomes. As first hypothesized by Mary Lyon (1955), the problem of expression of double doses of genes from the female's X chromosomes is solved in mammals by inactivation of one X chromosome in all somatic tissues. A random inactivation of either the maternally or the paternally derived X chromosome occurs before differentiation of specialized tissues in the early female embryo (but, interestingly, not in the placenta, where the paternal X is preferentially inactivated). The random X inactivation imprint of each embryonic cell is maintained throughout subsequent cellular proliferation and differentiation, so that the contribution of maternal and paternal active X chromosomes in all tissues statistically follows a normal distribution. Thus the blood cells of normal women are chimeric for maternally and paternally derived active X chromosomes.

The ratio is usually around 50/50 but can vary substantially (Puck et al., 1992).

Carriers of certain X-linked immunodeficiencies have negative selection superimposed on the underlying inactivation pattern in the hematopoietic cell lineages affected by the gene defect they carry. If one of the X chromosomes bears a mutation in a gene that confers an intrinsic survival advantage upon cells of a particular lineage, then cells of that lineage will have skewed X inactivation. As indicated in Table 57.1, this is the case for B cells of carriers of XLA (Allen et al., 1994; Fearon et al., 1987); T, B, and NK cells of carriers of X-linked SCID (Conley et al., 1992; Puck et al., 1987; Wengler et al., 1993), and all hematopoietic cells of carriers of Wiskott-Aldrich syndrome (Prchal et al., 1980; Puck et al., 1990a). In contrast, there is no selective pressure on X inactivation in female carriers of X-linked CGD. Thus, as discussed above under immunological assays for CGD, two populations of granulocytes can be detected in female carriers, one with the mutated and one with the normal copy of the disease gene *CYBB*. In the unusual circumstance of extreme, constitutional unbalanced X inactivation, a female carrier of a *CYBB* mutation whose normal X chromosome is predominantly inactive can be clinically affected with CGD (Anderson-Cohen et al., 2003).

Assays of X inactivation have been used to identify female carriers in pedigrees for the purpose of gene mapping and positional cloning, first for X-linked SCID (Puck et al., 1987, 1990b) and recently for the *MAGT1* gene encoding a magnesium transporter defect that leads to T-cell impairment, severe Epstein-Barr virus infections, and lymphoma (Li et al., 2011) (Table 57.1). Methods to assay X inactivation based on methylation of the inactive X chromosome have been developed (Allen et al., 1994). However, X-inactivation analysis is an indirect test that can be misleading in women with constitutional unbalanced Lyonization, and it is no longer recommended for clinical carrier testing because specific mutation detection by DNA sequencing is more accurate.

MUTATION DETECTION

Several mutation detection techniques have been developed based on PCR amplification of genomic DNA or cDNA of individuals affected with immunodeficiencies or at-risk relatives, including single-strand conformation polymorphism (SSCP) (Hyashi et al. 1993; Orita et al., 1989; Puck et al., 1997a; Sheffield et al., 1993) and dideoxy fingerprinting (ddF) (Puck et al., 1997a; Sarkar et al., 1992). In these methods amplified DNA segments or dideoxy sequencing reactions, respectively, of up to 300 nucleotides in length are denatured by heating and then quickly chilled so that they assume a single-stranded conformation depending on their primary nucleotide sequence. The single-stranded segments are separated on nondenaturing acrylamide gels to preserve the secondary structure. Even single base changes alter the mobility of one or both of the single strands, as in Figure 57.3. In a study of 87 unrelated patients with X-linked (XSCID),

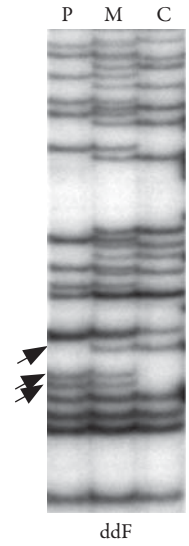

Figure 57.3 Dideoxy fingerprinting (ddF). Dideoxy T sequencing reactions of exon 5 of *IL2RG* in DNA from an XSCID patient, P; his carrier mother, M; and an unrelated control, C. Multiple bands with altered mobility are seen in the patient's lane, starting with two extra bands and a missing band marked by arrows. The band pattern in the lane of the heterozygous carrier mother is a composite of the patient's hemizygous mutated pattern and the control pattern.

IL2RG mutations were detected in all cases by ddF (Puck et al., 1997b).

However, determination of the nucleotide sequence of mutant DNA is now the gold standard for mutation detection as the costs of sequencing have fallen and fluorescence-based methods have become routine. Nucleotide changes detected by any DNA-based evaluation must be interpreted in light of expression studies and functional data before concluding that they are pathogenic mutations. Figure 57.4 shows detection by fluorescent sequencing of a two-base deletion in *IL2RG*. The wild-type or reference sequence and reading frame (upper tracing) and frame-shifted, deleted sequence of a patient with XSCID (lower tracing) can be observed to be superimposed in the central tracing from the patient's heterozygous mother. Sequence analysis of another XSCID kindred, shown in Figure 57.4, reveals the origin of the premature termination mutation in exon 3, V105X. The tracing of blood-derived DNA from the grandmother, whose son died of infections in infancy, shows only a minor admixture of an A base at the position that is a T in the wild type, indicating somatic mosaicism for this mutation in blood cells. The grandmother must also have had the new mutation in some of her egg cells, accounting for her affected son (not shown) and daughter, whose tracing in Figure 57.4 with equal amounts of mutant T and wild-type A is diagnostic of a heterozygous carrier state. Amniocyte DNA from the male fetus of this carrier demonstrates the presence of the mutant allele, in which a TAT tyrosine codon has become an immediate TAA termination codon. This fetus was therefore predicted to be affected with XSCID.

Detection of specific gene mutations has in some cases been scaled up and further automated (Lebet et al., 2007).

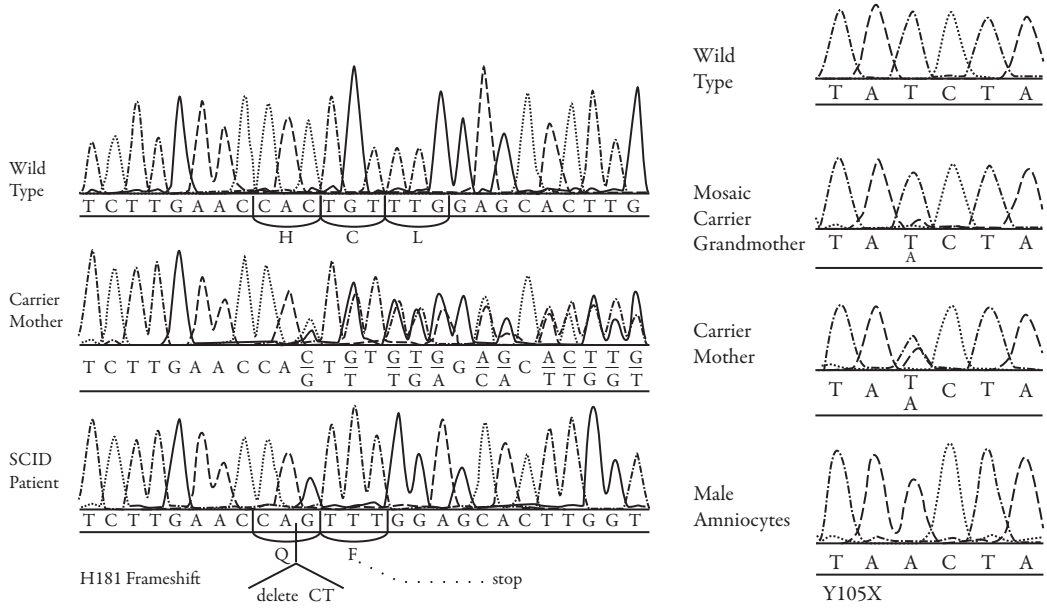

Figure 57.4 Fluorescence-based sequence determination. Right, wild type (upper), carrier (middle), and XSCID patient (lower) sequences from exon 3 of the *IL2RG* gene. The patient's deletion of two nucleotides in codon 181, normally specifying histidine (H), results in a frameshift specifying glutamine (Q) followed several further missense codons and a premature termination. The mother's genomic sequence is a composite of wild type and mutant, reflecting the two *IL2RG* alleles on her two X chromosomes. Left, *IL2RG* gene sequence in exon 3 showing wild type and three generations of a kindred with XSCID. The second tracing shows minor mosaicism in the grandmother for the mutant TAA allele, encoding a termination signal instead of the wild-type tyrosine (Y) residue. Her daughter, the mother of the patient, is a carrier of this mutation with roughly equal wild-type and mutant signals, while her male fetus is hemizygous for the mutant allele.

Detection of mutations in any of several SCID genes has used hybridization of PCR-enriched DNA to chips containing microarrays of partially overlapping oligonucleotides that span the gene's normal coding sequence.

HIGH-THROUGHPUT NEXT-GENERATION SEQUENCING

New massively parallel methods, referred to as next-generation sequencing (NGS), are now available to perform sequencing of several genes at once. Genomic DNA is sheared and fragments corresponding to the desired gene exons and surrounding nucleotides are captured by hybridization to beads or arrays of "bait" oligonucleotides. The captured DNA undergoes amplification and sequence determination, for example with bidirectional reads from the ends of each fragment, and sequence data are compiled by matching to the reference genome sequence using software programs. Arrays to capture DNA corresponding to many candidate disease genes are being used as an alternative to sequencing genes one at a time. On a somewhat larger scale, whole exome capture and sequencing, targeting about 2 percent of the human genome containing coding regions of genes, has become a very important tool for mutation detection in primary immunodeficiency diseases, particularly when the phenotype under study has been found in a population with consanguinity so that homozygous recessive mutations can be selected. While methods to capture, sequence, and analyze variants in DNA are still evolving, this technology has already led to many disease gene discoveries. Examples include defects in the signal transduction and activator of transcription protein STAT1 in chronic mucocutaneous candidiasis with impairment of IL-17 T cells (Liu et al., 2011); the Fas-associated death domain protein FADD in dominant immunodeficiency, immune dysregulation and cardiac disease (Bolze et al., 2010); and the p85α subunit of PI3 kinase in B-cell deficiency with agammaglobulinemia and colitis (Conley et al., 2012). In addition, known primary immunodeficiency genes have been associated with previously unappreciated phenotypes by whole exome sequencing, such as in discovery of susceptibility to papillomavirus-associated epidermodysplasia verruciformis caused by defects in the MST1 gene, already associated with defective T-cell production and survival (Crequer et al., 2021); Kaposi sarcoma in STIM1 deficiency (Byun et al., 2010); and ataxia-telangiectasia as a cause of T lymphocytopenia in otherwise healthy infants identified by newborn screening (see below) (Mallott et al., 2012).

The ultimate NGS for primary immunodeficiencies is whole genome sequencing, covering 50-fold more DNA than exome sequencing. Whole genome sequencing is not subject to bias introduced by capture methods, above, and is anticipated to become more widespread as methodology improves, costs decrease, and algorithms for analysis of the vast amounts of data improve. There are undoubtedly genomic loci that lie outside of exons and their immediate neighboring nucleotides but that control expression of genes. However, our abilities are still primitive when it comes to finding these amid the high level of variation that occurs outside of gene-coding regions.

GENETIC COUNSELING

Genetic testing has received increasing public attention because of the rapidly growing number of tests that can be performed for gene mutations associated with a wide variety of conditions. Testing is becoming publicly available in some cases before research has established its true ability to predict significant risk for development of a disease, such as breast cancer (Struewing et al., 1997). Our society is in the process of adjusting to increasing genetic information, but many issues, such as population screening, testing of minor children, protection of confidentiality, and insurability of persons carrying genetic mutations, remain to be resolved (American Society of Human Genetics Board of Directors and The American College of Medical Genetics Board of Directors, 1995; Clarke et al., 1994; Rowley et al., 1997). Unlike most other forms of medical evaluation, molecular genetic testing has implications not just for the proband, but also for relatives who share the same DNA. For all of these reasons, genetic counseling should precede genetic testing. Counseling should preferably be done by a geneticist or genetic counselor rather than the medical team primarily involved with treating an affected child, who may be critically ill. A genetic diagnosis that becomes available while a child is in the hospital should be reviewed with the family at a later time when the information can be processed more fully, questions can be answered, and implications for each family member can be sorted out.

Molecular diagnostic testing is usually undertaken to establish a diagnosis in an affected individual. Parents of an affected child are likely to be concerned about the risk of recurrence in a future pregnancy. For autosomal recessive diseases it is assumed that the parents are both likely to be carriers and the recurrence rate is one in four for pregnancies of either sex. For X-linked diseases in which the mother of an affected child is demonstrated to be a carrier, there is a 50 percent chance that each subsequent male pregnancy will be affected and a 50 percent chance that each female pregnancy will carry the mutation but not be affected with immunodeficiency.

Risks for being affected with the disease in question or for having affected children of one's own can be calculated for other family members. For example, a sibling of a proband affected with an autosomal recessive disease may be a carrier, but unless his or her mate is also a carrier of a mutation in the same gene (very unlikely unless the members of the couple share ancestry), the risk of having affected offspring is exceedingly low. On the other hand, sisters of males with X-linked diseases are at 50 percent risk of being carriers, in which case their male offspring will be at risk of being affected with the disease.

Now that many males with X-linked immunodeficiency diseases have been successfully treated and are reaching adulthood, it is important to help them understand that their reproductive risks have not changed, even if the disease in their blood cells has been permanently treated, such as by bone marrow transplantation. Affected males will pass on their mutation-bearing X chromosome to all of their daughters, who will be carriers; however, none of their sons will be affected because they will inherit the Y chromosome and not the X chromosome from their father.

Prenatal testing is possible for a large number of immunodeficiencies, and the chapters in Part II of this volume outline specific considerations for prenatal evaluation of each disorder. However, bringing the findings and techniques of research laboratories into a clinical setting has lagged. Because of high costs and low numbers of DNA-based diagnostic tests for each immunodeficiency gene, many tests have not yet been offered by clinical laboratories certified by the Clinical Laboratory Improvement Amendments of 1988 (CIA) Act Regulations (Regulations for implementing the Clinical Laboratory Improvement Amendments of 1988, MMWR, 1992). Fetal cells can be sampled by chorionic villus biopsy as early as the ninth week of pregnancy, or amniotic fluid can be obtained some weeks later as a source of fetal DNA for molecular testing. Fetal blood sampling between 16 and 20 weeks of pregnancy has also been used to evaluate the number and function of leukocytes in pregnancies at risk for well-defined abnormalities.

Preimplantation diagnosis is another procedure for families in which the specific mutations for the pregnancy at risk are known. This was first performed successfully in humans in the setting of cystic fibrosis in which the parents were both carriers of the common ΔF508 mutation in the *CFTR* gene (Ao et al., 1996). In vitro fertilization was carried out with superovulated eggs and sperm from the parents, embryos were grown to the eight-cell stage, and a single cell from each embryo was removed and genotyped by PCR. Embryos with an unaffected genotype were reimplanted into the mother. Of 22 couples in one early study, 5 had singleton pregnancies carried to term with the birth of healthy, unaffected infants.

Only limited information is available to indicate how parents with an at-risk pregnancy weigh the difficult choices that confront them. When a fetus is diagnosed as affected, the pregnancy may be terminated, but neonatal and even prenatal treatment options are increasingly available. The parents' perceptions of the burden of the disease are undoubtedly distinct for each immunodeficiency and are colored by the particular experience each person has shared with his or her affected relatives. A series of families followed with pregnancies at risk for XSCID indicated that most couples wanted to have prenatal testing, but few affected pregnancies were terminated (Puck et al., 1997a). In SCID, the improving outlook over the past three decades of bone marrow transplantation therapy has given families hope. Couples anticipating delivery of affected infants took advantage of the information gained through counseling and prenatal testing to learn about options for treatments. Pediatric centers performing bone marrow transplantation for immunodeficiency were contacted and financial and care arrangements were made. In some cases, the prenatal sample was HLA typed to identify potential matched bone marrow donors, either among the parents' healthy children or in an unrelated donor registry. Rare families have undergone experimental in utero bone marrow transplant; this treatment may become success-

ful with a variety of immune disorders (Flake et al., 1996; Flake & Zanjani, 1997).

A further development is the harvesting of cord blood at delivery as a source of autologous hematopoietic stem cells in which the gene defect could be corrected by gene therapy. Retroviral gene transfer has proven effective for XSCID and ADA-deficient SCID and has been undertaken for Wiskott-Aldrich syndrome, X-linked CGD, and other conditions (Chapter 61 and individual chapters). The development of leukemic clonal expansions of transduced cells due to retroviral insertional mutagenesis in recipients of gene therapy for XSCID and other diseases has identified a major hurdle, retroviral insertional mutagenesis. This complication has delayed widespread adoption of gene therapy, but vectors with improved safety are already in clinical trials.

POPULATION-BASED NEWBORN SCREENING FOR IMMUNODEFICIENCIES

Primary immunodeficiencies are underdiagnosed and frequently diagnosed late because of their low incidence and variable presentation, and because of insufficient awareness on the part of physicians and the public (Chan et al., 2011; Lindegren et al., 2004; Meyers et al., 2002). Screening of newborns for treatable genetic conditions has been a successful public-health measure to facilitate diagnosis and prompt intervention. As discussed in Chapter 10 and recently reviewed (Buckley, 2012; Puck, 2012; Verbsky et al., 2012; Kwan et al., 2013), newborn screening for SCID has become a practical reality in many states in the United States and is spreading to other countries.

Criteria to establish whether newborn screening is indicated for a given disease include that the disease be serious, treatable, and not detectable by physical examination in the nursery. Also, early treatment must be available and offer a better outcome, and incidence and test characteristics (cost, sensitivity, specificity) must make screening cost-effective (Wilson & Jungner, 1968). Several inherited immunodeficiencies meet several of these criteria, but to date only SCID has a screening test that has proven clinical utility (Chan & Puck, 2005; Routes et al., 2009; Kwan et al., 2013). The test, an assay of T-cell–receptor excision circles (TRECs) by PCR of DNA isolated from dried blood spots, reliably detects SCID. TRECs are formed as byproducts of T cell receptor rearrangement in the thymus, and a single PCR reaction across the joining point of the TREC is an indicator of thymic production of new, naïve T cells (Douek et al., 1998). TRECs are an excellent biomarker for newly produced naïve T cells. Low or absent T cells are characteristic of other conditions as well. Table 57.2 lists disease categories of T-cell lymphocytopenia detectable by TREC testing. The primary public health targets of TREC screening (Category I) are disorders that are life-threatening without prompt, definitive treatment by immune system restoring therapy: hematopoietic cell transplantation (Chapter 60), gene therapy (Chapter 61), enzyme therapy for ADA deficiency (Chapter 14), or thymus transplantation for complete DiGeorge syndrome (Chapter 45; Markert et al., 2009). Various genotypes of SCID and leaky SCID, discussed in Chapters 9 through 15, must be newly defined by minimal laboratory criteria (Table 57.1), because family history is usually negative and infectious complications will generally not have occurred at the time of diagnosis.

The remaining categories of T lymphocytopenia detected by TREC screening are considered secondary targets for which positive interventions can be made, such as avoiding live vaccinations, limiting exposure to infections, and in some instances administering immunoglobulin therapy or prophylactic antibiotics (Chapter 59). As experience is gained, unbiased data on the incidence, spectrum, and outcomes of infants with T lymphocytopenia detected by TREC screening are becoming available for the first time. In California, a state with a very diverse population and the largest number of births per year in the U.S., 993,724 newborns were screened in the first 2 years (Kwan et al., 2013). Of these, 50 (1/19,900; 0.005%) had significant T cell lymphocytopenia, as categorized in Table 57.2. Fifteen (1/66,250) required hematopoietic cell or thymus transplantation or gene therapy, including 11 infants with typical SCID, 3 with leaky SCID or Omenn syndrome, and 1 with complete DiGeorge syndrome. Survival to date in this group is 93%, higher than any published series of non-screened SCID patients. Other infants with low T cell numbers identified by screening included 6 with variant SCID or combined immunodeficiency, 12 with genetic syndromes associated with variable T cell impairment, 9 with secondary T lymphocytopenia, and 8 with preterm birth. All T lymphocytopenic infants avoided live vaccines and received appropriate interventions to prevent infections. The TREC test specificity was excellent, with only 0.08% of infants requiring a second test and 0.016% requiring lymphocyte phenotyping by flow cytometry.

Although low T-cell number is a common feature of many primary immunodeficiency disorders, the TREC test fails to identify several serious disorders characterized by impairment of T-cell function after the VDJ recombination step in T cell development that generates TRECs. Examples of non-detected disorders include ZAP70 deficiency, MHC class II deficiency, NEMO deficiency, and CD40 ligand deficiency, in which TRECs and T cells are present, but T cells are functionally compromised. In addition, antibody or neutrophil deficiencies, such as agammaglobulinemia or CGD, will not be detected. Identification of these disorders by newborn screening would be beneficial, and indeed B-cell immunoglobulin kappa chain gene recombination products can be assayed by DNA PCR in a manner similar to TRECs (Borte et al., 2012; Nakagawa et al., 2011). Even if additional tests are developed, newborn screening is unlikely to expand to diagnose all primary immunodeficiencies in a timely manner, even if whole exome or whole genome sequencing becomes routine. Thus, it is important for physicians to maintain awareness of the clinical presentations of immunodeficiency and to be vigilant for risk factors, including family history of early deaths, poor growth, recurrent or severe infections, or physical features, and to investigate accordingly.

Table 57.2 **CATEGORIES OF T LYMPHOCYTOPENIA DETECTABLE BY NEWBORN SCREENING WITH TRECS**

I. Conditions requiring immune system restoring therapy to establish T-lymphocyte production and maturation from hematopoietic stem cells

A. Typical SCID

T^- B^+ NK^+ or NK^- SCID with defects in IL-2 receptor common γ chain, IL-7 receptor α chain, JAK3 signaling kinase

T^- B^- NK^+ SCID with RAG1/2 or Artemis defects

T^- B^- NK^- SCID with ADA deficiency

Any other SCID genotypes that produce the phenotype of both <300 autologous T cells/uL and insufficient T-cell function revealed by maternal T-cell engraftment and/or PHA proliferation <10% of normal

B. Leaky SCID or Omenn syndrome, **due to incomplete (hypomorphic) defects in genes that when completely knocked out cause typical SCID**

300–1,500 T cells/uL, or higher numbers of autologous T cells that are oligoclonal and/or display memory phenotype (such as by expression of CD45RO)

No maternally engrafted cells

Defective lymphocyte function and/or lymphocyte dysregulation

C. "Complete" DiGeorge syndrome with profound thymic insufficiency, requiring definitive therapy by thymus transplantation

Absent production of autologous naïve T cells, not improving over several months of life

Usually associated with chromosome 22q11 deletion

Accompanied by other congenital anomalies (see Chapter 45)

II. Variant SCID or CID, **requiring immunological monitoring and possibly definitive transplantation therapy**

No identified gene defect

No maternal engraftment

300–1,500 T cells/uL, or higher numbers of autologous T cells that are oligoclonal and/or display memory phenotype (such as by expression of CD45RO)

Often, defective lymphocyte function or increased lymphocyte apoptosis

III. Syndromes with variably affected cellular immunity (that may be severe)

Partial DiGeorge syndrome with low T lymphocytes

CHARGE syndrome

Jacobsen syndrome

Trisomy 21

Ataxia-telangiectasia

DOCK8-deficient hyper-IgE syndrome

Cartilage-hair hypoplasia

RAC2 dominant interfering mutation

Additional rare multisystem genetic syndromes

IV. Secondary T lymphocytopenia

Neonatal cardiac surgery, with or without thymectomy

Neonatal leukemia

Gastroschisis

Third-spacing

Possibly severe prenatal HIV disease (hypothesized, but not observed to date)

V. Preterm birth alone

Generally resolves over time

IMMUNODEFICIENCY INFORMATION RESOURCES

Crina Samarghitean, Jouni Väliaho, and Mauno Vihinen

Lots of information is available from the Internet for more than 200 primary immunodeficiencies (PIDs), but it is scattered and often difficult to find. As the Internet is the primary source for most people looking for medical information, a navigation starting point and knowledge service are very much needed. We have compiled all the major data on immunodeficiencies into the ImmunoDeficiency Resource (IDR), a service that contains thousands of useful and interesting links in addition to our own pages. There are also many other kinds of resources available (e.g., for the diagnosis of PIDs) as well as patient and variation registries.

GENERAL PID INFORMATION

Some general PID information resources have been developed in recent years (Table 58.1). IDR and INFO4PI focus on PIDs and are tailored for different types of user groups, ranging from patients and their families to researchers and healthcare professionals. Other services, such as ORPHANET, are focused on rare diseases in general and include some PIDs.

IMMUNODEFICIENCY RESOURCE (IDR)

The IDR is a knowledge base whose goal is to provide a comprehensive integration of relevant clinical, biochemical, genetic, genomic, proteomic, structural, and computational data for PIDs (Samarghitean et al., 2007). The IDR provides structured and systematic information about PIDs and enables doctors, researchers, students, nurses, and patients to find validated information (Fig. 58.1A and B).

The IDR knowledge base was first released in 1999 (Väliaho et al., 2000, 2002, 2005). Currently, it contains information for 167 PIDs, including clinical as well as molecular data. IDR provides the most complete and up-to-date dataset available (Fig. 58.1A) and has been integrated with several internal and external databases and services. The contents of the IDR are validated and selected for different types of users. The search engine allows either a detailed or a broad search from a simple user interface. Also, multiple strings can be searched using Boolean logic. A PubMed search is possible directly by disease or gene name.

The service contains several introductory texts and has classification and diagnostic criteria, protocols, and guidelines for PIDs (Bonilla et al., 2005; Conley et al., 1999; de Vries & Clinical Working Party of the European Society for Immunodeficiencies [ESID], 2006). Recently, we have made a new classification for all PIDs based on data from the IDR and elsewhere by utilizing clustering and network methods (Samarghitean et al., 2009). PIDs were grouped based on clinical, pathological, and laboratory characteristics. Consensus of at least five methods provided a statistically supported novel classification that revealed previously unknown features and relationships of PIDs. Many independent properties of the diseases and related proteins had a homogeneous distribution when the severity and therapy of the diseases, functional classification of the proteins, and protein interaction network properties were analysed (Samarghitean et al., 2009).

The IDR has plenty of genome- and gene-related information available, such as genes and their loci, reference sequences, and markers. Links to genomic DNA and amino acid sequences, as well as three-dimensional structures of proteins, are available.

The IDR also contains instructional resources and analysis tools as well as advanced search routines. It has extensive cross-referencing and links to other services. The IDR pages are extensively hyperlinked to an integrated immunology glossary that contains descriptions for over 1,000 immunological terms.

The IDR lists collections of immunology-related data sources, including lectures on immunology and immunodeficiencies, animal models, and knockouts of immunodeficiency-related genes. Immunology and immunodeficiency societies, nursing societies, and patient organizations, as well as a number of patient pages, are listed.

Fact files, which form the core of the IDR, integrate biomedical knowledge from several heterogeneous sources and include information for disorders, genes, variations, protein sequences, online resources, organizations, and associations (Fig. 58.1C). Inherited Disease Markup Language (IDML), developed for the fact files, provides a standard method for exchanging genetic and clinical data, general disease descriptions, diagnostic information, and links to other related resources (Väliaho et al., 2005). The fact files make use of the following specifications, standards, and databases: HGNC gene nomenclature (Seal et al., 2011), UniProt (UniProt Consortium, 2012), GeneCard (Rebhan et al., 1998), and SOURCE (Diehn et al., 2003).

Although the IDR contains a huge amount of data, its logical organization and user-friendly interface allow easy access even to complex information. The IDR is continuously updated.

OTHER GENERAL KNOWLEDGE SERVICES

INFO4PI is a general PID information resource designed for diverse user groups. It is the official webpage of the Jeffrey Modell Foundation and contains useful information for doctors and patients and the lists of 10 warning signs for PIDs and four stages for immunological testing adopted in many countries.

ORPHANET provides information on rare diseases to health-care professionals, patients, and their relatives to contribute to the diagnosis, care, and treatment of these diseases. ORPHANET includes an encyclopaedia for professionals, with expert-authored and peer-reviewed information for rare, mostly genetic, diseases and an Encyclopedia for patients. ORPHANET includes information on clinics, clinical laboratories, research activities, and patient organizations. PID-related information is cross-linked within IDR fact files. ORPHANET provides validated and up-to-date information about rare diseases in different languages and also contains information about initiatives of the EU Commission on Rare Diseases Task Force (RDTF, http://www.rdtf.org) and International Rare Diseases Research Consortium (IRDiRC, http://www.irdirc.org/).

A list of other useful websites, which contains information about PIDs, is provided in Table 58.1.

DIAGNOSIS TOOLS

Internet-distributed diagnosis tools for PIDs can be grouped between databases, which archive gene and clinical test laboratories; medical expert systems, which use different reasoning mechanisms to aid in diagnosis; and other tools helpful for diagnostic procedures.

IMMUNODEFICIENCY DIAGNOSTIC REGISTRY (IDDIAGNOSTICS)

The diagnosis of immunodeficiencies can be difficult because symptoms may be similar in several disorders. As many PIDs are rare, often there is no statistical information about signs and symptoms available. Early and reliable diagnosis is often crucial for efficient treatment of these diseases since delayed diagnosis and management of PIDs can lead to severe and irreversible complications, even resulting in the death of the patient.

The definitive diagnosis of PIDs in many cases depends both on genetic and clinical tests, since the physical signs may be nonspecific, very discreet, or absent. Due to the rareness of PIDs there are generally not many laboratories analyzing a particular disease. IDdiagnostics contains one registry for laboratories performing genetic tests and one registry for clinical testing for patients with a suspected PID (Samarghitean et al., 2004).

In IDdiagnostics, contact addresses for laboratories performing genetic diagnoses are provided, along with information about the assay method(s) used. There are also details on the turnaround time, how often the samples are run, and how many samples are studied annually. Laboratories can have special requirements for samples and their handling, data for which are also available from the IDdiagnostics service. Physicians planning to send samples should first consult the laboratories to learn about conditions, shipping details, and the expected time for the test and price (if any).

The IDdiagnostics database has multiple search facilities. Further information and submission pages (Fig. 58.1D) for both genetic and clinical testing can be found at http://bioinf.uta.fi/IDdiagnostics/. Laboratories carrying out testing are asked to provide their information, as inclusion in the registries is on a voluntary basis.

OTHER DIAGNOSTIC INFORMATION RESOURCES

The GeneTests service includes an international directory of genetic testing laboratories and genetics and prenatal diagnosis clinics. GeneTests will probably be continued at University of Washington since summer 2013. GeneReviews are expert-authored, peer-reviewed disease descriptions. IDR fact files and IDdiagnostics are linked to PID-related information in GeneTest.

The European Directory of DNA Diagnostic Laboratories (EDDNAL) disseminates information about DNA-based diagnostic services for rare genetic conditions in Europe. Information about PID gene test laboratories from EDDNAL is cross-linked in IDR fact files and in IDdiagnostics.

Some diagnostic protocols have been implemented on the Internet. The multistage diagnostic protocol designed for nonimmunologists (de Vries & Clinical Working Party of the European Society for Immunodeficiencies [ESID], 2006) has been reinterpreted as linked web pages on the UKPIN site. However, there is a new version of the protocol published (deVries & European Society for Immunodeficiencies

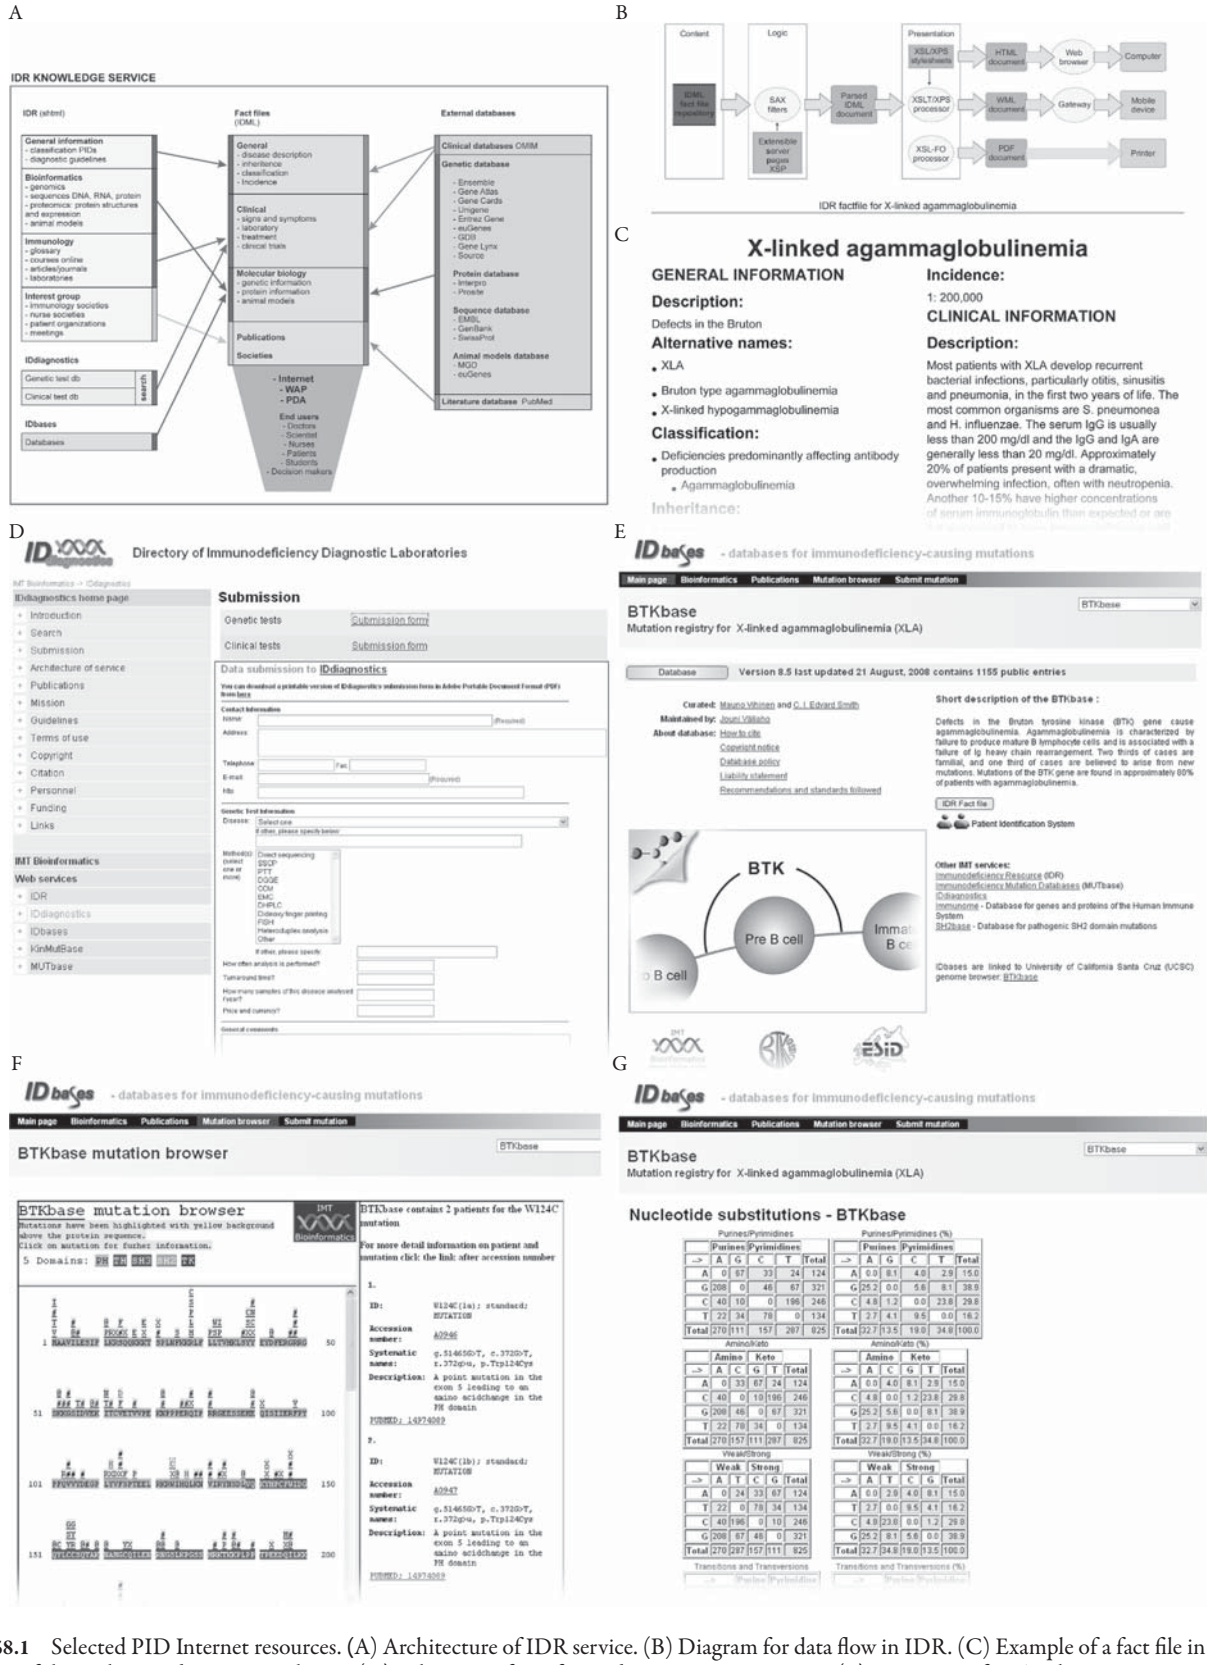

Figure 58.1 Selected PID Internet resources. (A) Architecture of IDR service. (B) Diagram for data flow in IDR. (C) Example of a fact file in IDR; only part of the multipage document is shown. Members, 2011). Recommendations for diagnosis and treatment of some PIDs, both in English and in Italian, can be found on IPINET, the Italian Primary Immunodeficiency Network. CEREDIH, the French National Immunodeficiency Center, distributes information about French centers and laboratories performing PID diagnosis. The 10 warning signs list for children and 12 warning signs for adults are also available. There are also articles and a diagnostic protocol. This service is written only in French.

PIDEXPERT

Medical expert systems (MESs) are computer software systems that use a set of rules applied to knowledge extracted from human experts and generated by computational analyses. MESs can help in diagnosis and report generation, improve consistency in decisions, and increase timeliness in decision-making and productivity (Samarghitean & Vihinen, 2008). MESs produce patient-specific and situation-specific recommendations. MESs can be integrated with other applications, such as electronic patient records, systems for prescribing and dispensing medicines, and other information systems used in health-care settings.

PIDexpert is an MES to help with the diagnosis and management of PIDs (Samarghitean et al., in preparation). PIDexpert generates a differential diagnosis from clinical symptoms and suggests any potentially useful further clinical and laboratory information required. The main components of the shell are a knowledge base, a query base, an inference engine, and a graphical user interface. The query base and knowledge base include data and facts from the IDR, IDdiagnostics, IDbases (Piirilä et al., 2006), ESID registry (Guzman et al., 2007), from different national registries such as IPINET, CEREDIH, UKPIN, USIDnet, and from the literature (Ochs et al., 2007; Rezaei et al., 2008; Spickett, 2006; Stiehm et al., 2004). The data are mainly informal and heuristic. The ESID/PAGID diagnostic guidelines (Conley et al., 1999) and practice parameters for the diagnosis and management of PIDs established by the American Academy of Allergy, Asthma and Immunology (AAAAI), the American College of Allergy, Asthma and Immunology (ACAAI), and the Joint Council of Allergy, Asthma and Immunology (JCAAI) (Bonilla et al., 2005) were coded into the system. These guidelines provide heuristics for possible/probable/definitive diagnosis for some of the most common PIDs.

The inference engine searches for best-fitting patterns instead of the nearest neighbor. The system also identifies other conditions that might be associated with the disorder and suggests how the diagnosis could be confirmed.

PATIENT REGISTRIES

Several PID patient registries have been developed in different countries during the past two decades. The information in them can help in making a diagnosis for a patient.

ESID has collected information about immunodeficiency patients into a large European registry (Guzman et al., 2007). In April 2013, the database counted16,547 patient datasets from 96 centers. There are individual databases for each PID with a common core dataset containing information about diagnosis, therapy, quality of life, and important laboratory data. There are also disease-specific data models for the most prevalent PIDs. A dedicated tool allows submission of variation data to the IDbases. Access to the data is carefully controlled and the resource is protected behind secure firewalls.

The United States Immunodeficiency Network (USIDnet) runs an identical registry for U.S. patients. Results from the national registry of U.S. residents with X-linked agammaglobulinemia provided an updated clinical view of the disorder in a large cohort of patients (Winkelstein et al., 2006).

A resource of Asian Primary Immunodeficiency Diseases (RAPID) hosts information on sequence variations and expression at the mRNA and protein levels for all PIDs. There is also information about protein–protein interactions, mouse studies, and gene-expression profiles in various organs and cell types. RAPID also has a tool to visualize mutations on PID protein 3D structures (Keerthikumar et al., 2009).

The Latin American Group for Primary Immunodeficiency Diseases (LAGID) collects epidemiological information about PIDs in Latin America using a uniform questionnaire and a computerized database (Leiva et al., 2007; Zelazko et al., 1998). The ESID online system has been adopted by LAGID. ASCIA PID Register of Australia and New Zealand has already been used to describe the prevalence of PIDs in Australia and the need for specific therapies (Baumgart et al., 1997).

There are also a number of other national PID registries that, like the ones described above, are not publicly accessible. Italian IPINET (Luzi et al., 1983, 1991; Plebani et al., 2002, 2004; Soresina et al., 2008) collects patient information including the pedigree, date of diagnosis, immunological data and clinical manifestations, laboratory data, and information about replacement therapy. The Spanish Registry for Primary Immunodeficiencies (REDIP) contains demographic information, data about diagnosis, age at diagnosis, family history, and treatment (Matamoros Flori et al., 1997). The Iranian PID Registry has followed 930 patients over a period of 30 years using a four-page questionnaire. The registry includes personal and demographic data, family history, clinical manifestations, laboratory findings, treatment, and follow-up data. The diagnosis of patients has been confirmed by the scientific committee of the registry using standard criteria (Rezaei et al., 2006).

IMMUNODEFICIENCY VARIATION DATABASES (IDBASES)

Information about PID-related genetic variations has been collected in the ImmunoDeficiency variation databases (IDbases) since the mid-1990s. Currently, 131 freely available IDbases are available (Table 58.2). Scientists analyzing variations are requested to submit their data either by contacting the curators or by using the Web submission available on the homepages of the databases. Many of the IDbases contain plenty of information in addition to details of the actual variation. The variation entries are linked to other data sources, such as sequence databanks (Benson et al., 2013), PubMed, OMIM (http://omim.org/), and UniProt (UniProt Consortium, 2009). The other standards and recommendations followed include the HUGO Gene Nomenclature Committee (HGNC) gene names (Seal et al., 2011) and Human Genome Variation Society (HGVS) recommendations for mutation nomenclature (den Dunnen & Antonarakis, 2000), database content, and submission for recommendations.

The MUTbase program suite (Riikonen & Vihinen, 1999) provides interactive and quality-controlled submission of information to IDbases and generates the pages for Internet distribution (Fig. 58.1E). There are several web pages to show the types of variations and their distribution within protein domains as well as in the exons and introns of the gene (Fig. 58.1F). The user can click the interactive pages to obtain more information. Interactive graphic pages show the number of disorder-related families having different variation types at each residue.

IDbases contains variation information for 9.950 patients from 8,623 families having a total of 3,627 different variation events. Figure 58.2 shows the distribution of PID

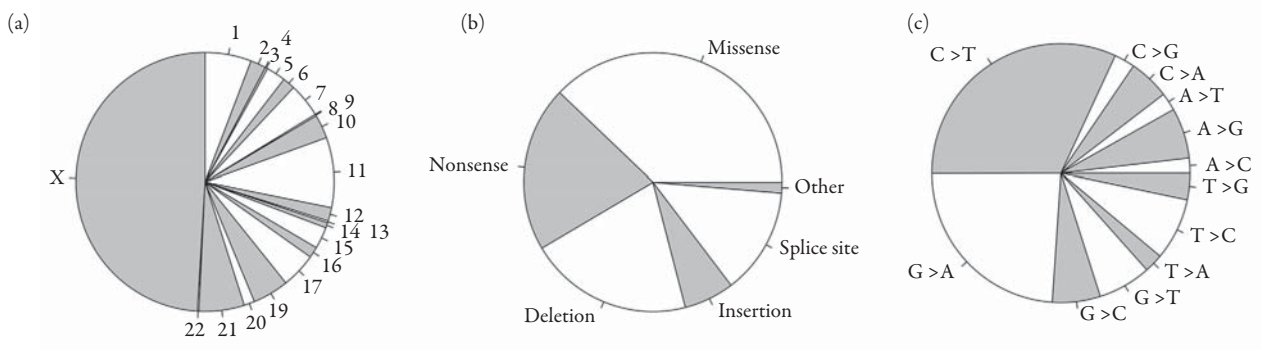

Figure 58.2 Distribution of variations in IDbases summed over all the registries at the Bioinformatics group. (A) Distribution of variations in chromosomes. (B) Distribution of variation types. (C) Distribution of nucleotide changes in PID-causing variations.

causing mutations in chromosomes and the mutation types and nucleotide changes. C>T and G>A substitutions are overrepresented due to their appearance in mutation-prone CpG dinucleotides.

We collaborate with the RefSeqGene (http://www.ncbi.nlm.nih.gov/RefSeq/) and LRG projects (http://www.lrg-sequence.org) in replacing our IDRefSeqs with updated and stable reference sequences describing the genes in three levels: genomic, RNA, and protein sequence. These will provide a stable genomic framework for reporting variations with a permanent and core content that will never change. In IDbases, in addition to the disease-causing variations, polymorphisms or benign variations are also included in separate files. A lot of statistical data is provided for each gene about amino acid substitutions, codon changes, and nucleotide substitutions (Fig. 58.1G).

IDbases can provide new insights into both genotype–phenotype correlations in patients as well as protein structure–function relationships for the encoded proteins. The information may be essential in developing new treatments, including in drug design. The IDbases are linked to the University of California Santa Cruz (UCSC) genome browser (Giardine et al., 2007; Karolchik et al., 2008). The mutation data can be easily viewed with PhenCode (Giardine et al., 2007), along with other genetic and variation information. The IDbases are developed along with recommendations jointly produced with the GEN2PHEN consortium (http://www.gen2phen.org/).

Several PID mutation databases are maintained in other laboratories (Table 58.3). The coverage and depth of detail vary in these registries. Currently, there exists a locus-specific mutation database for almost all PIDs in which gene defects are known.

OTHER IMMUNODEFICIENCY-RELATED SERVICES

Gene defects are relatively easy to identify; however, the interpretation of the effects of sequence variations and elucidation of the detailed molecular mechanisms of genetic diseases are much more difficult. Amino acid substitutions may have diverse effects on protein structure and function (Thusberg & Vihinen, 2009). Numerous methods can be used for predicting the effects of amino acid substitutions and are collected in the Pathogenic-Or-Not Pipeline (PON-P) website, which is freely available at http://bioinf.uta.fi/PON-P.

A bioinformatics approach has been applied to predict novel PID candidate genes (Ortutay & Vihinen, 2009a). A total of 26 putative PID genes were prioritized. The method combines information about protein interaction network properties and Gene Ontology terms. The analysis was based on a dataset for the immunome—that is, the entirety of genes and proteins essential for mounting immune responses (Ortutay & Vihinen, 2006). The approach utilizes protein interaction network information available from the Immunome Knowledge Base (Ortutay & Vihinen, 2009b). The identified disease gene candidates are mainly involved in cellular signaling, including receptors, protein kinases and adaptors, and binding proteins as well as enzymes (Ortutay & Vihinen, 2009a).

CONCLUSIONS

Many bioinformatics tools and information resources such as IDR, IDbases, and IDdiagnostics are freely available on the Internet. These services are clearly needed, as shown, for example, by the user statistics for IDR for the year 2012: 145,207 downloads from 114 countries. Constantly updated PID information resources are valuable for everybody working with, suffering from, or interested in these disorders.

PID patient registries, due to their nature, are not publicly accessible. In the future we can expect electronic information resources and computational tools to further help health-care professionals in diagnosis, in keeping up with the deluge of new data, and by providing reliable information and analyses, diagnosis, and prediction tools.

ACKNOWLEDGMENTS

This work was supported by the Finnish Academy, Tampere City Hall, Sigrid Juselius Foundation, and the Medical Research Fund of Tampere University Hospital. We thank Jukka Lehtiniemi for help in figure drawing.

59.

CONVENTIONAL THERAPY OF PRIMARY IMMUNODEFICIENCY DISEASES

E. Richard Stiehm and Helen M. Chapel

Long-term care of patients with primary immunodeficiencies is aimed at preventing infections and their long-term sequelae as well as treating breakthrough infections. The extent of appropriate infection prevention, as well as treatment for the complications, depends on the nature of the immune deficiency. For this reason, this chapter is divided into two sections: the first describes general measures applicable to all forms of immune deficiency, and the second details specific measures for patients with the most common individual disorders.

The management of all forms of immunodeficiency diseases requires interaction between generalists and specialists with experience and expertise in primary immune deficiencies. This usually requires a team of a primary care pediatrician or internist and an immunologist, with assistance and advice from other specialists (e.g., dermatologists, pulmonologists, gastroenterologists, rheumatologists, and radiologists) as necessary, since it is important that patients continue to have the benefit of optimal diagnostic procedures and new drugs for all organ-based complications that they may develop.

For example, patients with bronchiectasis following recurrent pneumonia (Chapel et al., 2008) need not only regular monitoring with pulmonary function tests and computed tomography (CT) scans but also access to chest physiotherapists. Those with asthma require the latest and most effective bronchodilators. In the same way that the immune system is multiorgan, the failure of this system manifests diverse complications requiring organ-based specialist medical care.

PART I: GENERAL CONSIDERATIONS

PREVENTION

Prevention of primary immunodeficiency is limited and is applicable only to those situations with a previous affected infant or a positive family history. These considerations are of particular importance in countries where consanguineous marriages are common. Preventive measures include providing genetic counseling to a family at risk, arranging for prenatal diagnosis, and, in certain circumstances, preimplantation diagnosis or termination of pregnancy.

Prevention of infections is not always possible, but several precautions are offered in Table 59.1 to minimize exposure to contagious illness and environmental sources of infection wherever possible.

TREATMENT

Because many patients with immunodeficiency will have a normal lifespan on immunoglobulin (IG) (Chapel et al., 2008), stem cell transplants, or other therapies, they and their parents and relatives must avoid making the patient an emotional cripple through overprotection. A child should be encouraged to venture outdoors, play with other children in small groups, attend nursery and regular school, and participate in sports and other extracurricular activities that involve pulmonary exercise. The aim is to teach patients to live in a near-normal fashion with their disease, much like a diabetic patient on insulin therapy.

Adolescents, and even adults, need advice about the importance of regular exercise (especially to improve bronchiectasis). They should not smoke, inhale secondhand smoke, or use illegal drugs. Like tobacco, marijuana is a pulmonary irritant and should be avoided. Sniffing drugs can result in inhaled nasal bacteria and pneumonia.

School health officials should be notified of the child's illness, so that exposure to infectious disease is minimized and prompt attention to injuries is provided.

Patients with immunodeficiency require extraordinary amounts of care to maintain general health and nutrition, prevent emotional problems related to their illness, and manage

Table 59.1 GENERAL MEASURES TO PREVENT INFECTIONS IN IMMUNODEFICIENCY

- Take precautions recommended by the physician for the particular immune deficiency.
- Keep indicated vaccines updated as recommended by the pediatrician for the particular immune defect (see text).
- Avoid people with an obvious infection.
- Avoid raw, undercooked, unwashed, unpasteurized foods/liquids.
- Avoid construction/excavation sites, mulch, hay stacks, compost turning.
- Wear gloves when gardening.
- Avoid well water and lake water.
- Avoid high-risk sexual activity.
- Avoid tattoos and piercing.
- Avoid tobacco, marijuana, illegal drugs.
- Consider avoiding farms, petting zoos, fare animals, puppies, kittens, stray animals, and exotic pets if rare infections are a particular risk.
- Take sick animals to vets right away.
- Ask someone else to clean fish tanks, litter boxes, animal feces, or bird cages.
- Wash hands regularly, especially after pet contact.

their numerous infectious episodes. This regimen applies equally to adults and children. Usually, no special dietary limitations are necessary; the aim is to provide a well-rounded, nutritious diet.

Patients with immunodeficiency should be protected from unnecessary exposure to infection, particularly to those types of infection to which they may be particularly susceptible due to their specific immune defect (e.g., Aspergillus and other fungi in patients with chronic granulomatous disease [CGD]). Children should sleep in their own beds, preferably with rooms of their own, and keep away from individuals with obvious serious respiratory or other infections.

NUTRITION AND GASTROINTESTINAL FUNCTION

The height and weight of children with immunodeficiency should be documented at 3- to 6-month intervals on a standard growth chart. Adults should be weighed regularly as well. A falling off of growth or an absolute weight loss is an ominous feature of immunodeficiency and suggests that infections are not under good control or that other medical complications (e.g., hyperthyroidism, chronic diarrhea, malignancy) are present. Chronic antibiotic therapy may decrease appetite or cause diarrhea. Febrile episodes with severe chronic infections will decrease appetite, increase metabolic demands and result in slow growth.

Nutritional assessment, including a calorie count, may be indicated, and a dietary supplement might be tried. A multivitamin and mineral supplement is also advisable but only if levels of essential vitamins or minerals are shown to be low.

If there is noninfectious chronic diarrhea, a search for malabsorption, food intolerance, coeliac disease or hypovitaminosis is indicated. Symptoms of night blindness, proximal weakness, ataxia, or tremor should raise suspicions of secondary deficiencies of fat-soluble vitamins that are reversible on treatment (Ardeniz et al., 2008; Aslam et al., 2003; Aukrust et al., 2000).

Celiac disease may not necessarily present with frank malabsorption or even diarrhea; weight loss alone should lead to investigation of the gastrointestinal tract. However, partial villous atrophy is common and not just due to celiac disease. There should be a careful search for microbial agents (e.g., Giardia, Crytosporidia), enteropathic viruses (Annick et al., 2012), inflammatory bowel disease, the unexplained enteropathy of common variable immunodeficiency disorder (CVID) or structural abnormalities of the gastrointestinal tract such as intestinal lymphangiectasia.

Many immunodeficiencies are associated with autoimmune illnesses (Lehman and Ballow, 2008) or hepatic nodular regenerative hyperplasia (Ward et al., 2008; Malamut, et al, 2008).). Since in the past, use of blood products, including intravenous immunoglobulin (IVIG), resulted in hepatitis C (Centers for Disease Control, 1994), liver function tests should be done at yearly intervals on all patients receiving Ig therapy, and more regularly (every 3–6 months) if there is a risk of hepatitis C, since early treatment has been shown to be effective (Chapel et al., 2001).

RESPIRATORY AND PULMONARY PROBLEMS

Sinusitis, bronchitis, and recurrent pneumonia are common in patients with most forms of immunodeficiency and are often the chief cause of morbidity and mortality (Quinti, et al., 2011; Lucas et al., 2010) Sinusitis must be suspected if the patient has any of the following: purulent nasal discharge, frontal headaches, chronic nasal obstruction, postnasal drip, a decreased gag reflex, or unexplained coughing or wheezing. A microbial diagnosis (including fungal cultures) should be sought. Waters-view sinus films are of value, particularly in youngsters, but a CT scan of the sinuses is used for definitive diagnosis in adults. Treatment consists of prolonged courses of antibiotics, nasal decongestants, and nasal steroids. Nasal polyps should be surgically removed; surgical sinus drainage may be indicated.

Many patients with a significant immunodeficiency have experienced pneumonia at one time or another prior to diagnosis and developed bronchiectasis. All breakthrough infections, particularly those in the chest, must be treated promptly. Vigorous exercise, including team sports, should be encouraged to facilitate expectoration of mucus and to prevent bronchial sepsis.

A chronic cough due to bronchiectasis or wheezing is cause for special concern; attempts to detect structural damage or reversible airways disease are essential. Under such circumstances pulmonary function tests are conducted, including the response to bronchodilator therapy.

If bronchiectasis is found on CT scan, regular physiotherapy and exercise should be instigated. If the patient has antibody deficiency, a trial of a higher-dose IVIG (600–800 mg/kg) might be used (Lucas et al., 2010) and has been shown

to improve pulmonary function (Bernatowska et al., 1987; Eijkhout et al., 2001; Roifman et al., 1987). For older patients, routine pulmonary function testing at 6-month or yearly intervals is recommended for all but the mildest immunodeficiency syndromes.

Patients who develop pulmonary infiltrations not responsive to antibiotics should undergo bronchoalveolar lavage or lung biopsy for an exact microbiological or tissue diagnosis. Lung biopsy may reveal nonmicrobial granulomatous disease (Mechanic et al., 1997; Viallard et al., 1998; Wislez et al., 2000), lymphoid interstitial pneumonitis (LIP) (Davies et al., 2000; Wheat et al., 2005, Chapel and Cunningham-Rundles 2009), or even frank lymphoma (Dhalla et al 2011).

Immunodeficient individuals with chronic lung disease should be started on a program of pulmonary therapy including postural drainage, the use of a flutter device or oscillatory vest to loosen secretions, and inhaled bronchodilators or other agents (Atrovent, cromolyn, antibiotics). It is particularly important to identify patients likely to develop chronic lung disease early, so that periodic assessment of pulmonary function, management of sinus disease, and vigorous treatment of early pulmonary infections can be undertaken. Lung abscesses must be treated surgically. Some patients with neutrophil dysfunction, partial antibody deficiencies, or selective IgA deficiency may also have IgE-mediated allergies and may benefit from inhaled corticosteroids and oral antihistamines.

SKIN PROBLEMS

Patients with immunodeficiency often have cutaneous abnormalities (telangiectasia, molluscum contagiosum, warts, eczema, etc.). The most common cutaneous complication is chronic skin infection, particularly in the hyper-IgE immunodeficiency syndromes and in certain T-cell deficiencies, infections such as mucocutaneous candidiasis. These patients require local and systemic antibiotics and/or antifungal therapies, usually prophylactically.

Chronic eczema is a common problem in the immunocompetent population, but this may be more severe or may become infected in the immunodeficient patient. It is a cardinal feature of Wiskott-Aldrich syndrome (WAS). Local steroids, tacrolimus or picrolimus ointments, and antipruritic medications are the mainstays of therapy. If there is cracking, weeping, or regional lymphadenopathy, antibiotics, either local or systemic, should be used. Clarithromycin is particularly well tolerated in chronic eczema.

Severe warts are not uncommon (Barnett et al., 1983) and often refractory to usual methods of control. Subcutaneous IG therapy was reported to be of benefit in one child with common variable immunodeficiency disorder (CVID) and warts (Lin et al., 2009). The presence of extensive warts may indicate the presence of a rare syndrome, warts, hypogammaglobulinemia, infection, myelokathexis (WHIM)

Alopecia or vitiligo are also relatively common in antibody-deficient adults with CVID; both of these distressing conditions are untreatable.

Subcutaneous granulomas (as well as pulmonary and gastrointestinal granulomas) are not uncommon in CVID. There are several reports suggesting that these granulomas respond to anti–tumor necrosis factor (TNF) therapy with etanercept (Lin et al., 2006; Smith and Skelton, 2001) or infliximab (Hatab and Ballas, 2005, Thatayatikom et al., 2005), though with disappointing results on granuloma in other sites (Thatayatikom et al., 2005).

VACCINES

A review of immunization strategies in special clinical circumstances is provided in the "Red Book" (American Academy of Pediatrics, 2012); each country has a similar source of advice depending on the level of risk for a particular infectious disease.

Live attenuated vaccines, including, poliomyelitis, rotavirus, measles, mumps, rubella, bacillus Calmette-Guérin (BCG), and varicella/herpes zoster, should be avoided in all patients with severe antibody or cellular immunodeficiencies because of the risk of vaccine-induced infection. The evidence from DiGeorge syndrome patients and those with HIV suggest that it is safe to give live-virus vaccines to those with CD4 counts above 400 cells/uL (Perez et al., 2003). These vaccines have also been given without sequelae to patients with selective IgA deficiency, mucocutaneous candidiasis with intact cellular immunity to other antigens, and phagocytic and complement immunodeficiencies and to children fully reconstituted following human stem cell transplantation (HSCT).

Paralytic poliomyelitis, chronic encephalitis, and prolonged poliovirus shedding from the gastrointestinal tract were recognized complications of attenuated live poliomyelitis vaccination (Sabin) in immunodeficiency (Wyatt, 1973), although this vaccine is rarely used now since the World Health Organization implemented its strategy to eliminate poliovirus. In countries where oral polio vaccine is used, parents, siblings, and other household members of an immunodeficient child should be given inactivated poliomyelitis vaccine because of the risk of spread to the patient of live vaccine-strain oral virus.

Other routine inactivated vaccines should be given to patients with adequate antibody immunity, including yearly influenza vaccine. We also administer killed vaccines to patients with partial antibody deficiencies (e.g., IgG subclass deficiency, ataxia-telangiectasia). The antibody response to these vaccines can also be used to assess their B-cell function. Many such patients have a short-lived antibody response that subsequently decreases over 6 to 12 months.

Vaccines (except for oral attenuated poliovirus and rotavirus) should also be given to family members of patients with immunodeficiency. Adult individuals with a propensity to lower or upper respiratory infection but some antibody function should be given pneumococcal polysaccharide vaccine, and conjugated pneumococcal vaccine to such children. For patients with intact cellular immunity, periodic tuberculin testing or an ELIspot test for mycobacteria-induced interferon (IFN)-γ production may be indicated, particularly if corticosteroid or anti-TNF therapy is anticipated.

ANTIBIOTICS AND ANTIVIRALS

Antibiotics are life-saving in the treatment of infectious episodes of patients with immunodeficiency. The choice and dosage of antibiotics for specific infections are identical to those used in normal subjects, but treatment must be started early and last longer. Culture specimens may be obtained prior to therapy; these will be especially important if the infection does not respond promptly to the initial antibiotic chosen.

Patients should be preemptively treated for infectious episodes pending cultures, even if this necessitates frequent or chronic use of antibiotics and occasional unnecessary hospitalizations. If the infection does not respond promptly to antibiotics, the physician should consider the possibility of fungal, mycobacterial, viral, or protozoal (*Pneumocystis jiroveci*) infection. Invasive procedures such as bronchoalveolar lavage or biopsy may be necessary.

Antiviral therapy can be used effectively in many immunodeficiencies. Exposure to influenza or early symptomatic influenza infection may be managed with amantadine or ramatidine or the neuraminidase inhibitor drugs zanamivir and oseltamivir. Severe herpes simplex infection, chickenpox, or herpes zoster should be treated with aciclovir. Ribavirin aerosols have been used in the treatment of respiratory syncytial virus (RSV) and parainfluenza viral infections occurring in severe immunodeficiencies but are not effective in enterovirus infections (McIntosh et al., 1984). Aciclovir can also be used in the incubation period to modify or prevent chickenpox after exposure or as soon as the first lesion appears (Asano et al., 1993). Topical cidofovir has been used successfully to treat severe molluscum contagiosum (Davies et al., 1999).

Antibiotics should be given prophylactically with each dental or surgical procedure. Amoxicillin and gentamicin can be given intravenously 1 hour before and 8 and 18 hours after major surgery, or 3 days of oral broad-spectrum antibiotics can be used for less serious procedures (e.g., dental procedures).

ANTIMICROBIAL PROPHYLAXIS

Continuous prophylactic antibiotics often are of benefit in immunodeficiencies and are essential in those who have been splenectomized. They are especially useful in disorders characterized by rapid, overwhelming infections (e.g., complement deficiencies or in WAS patients who are not receiving immunoglobulin therapy). They can also be used in patients with antibody deficiencies, especially in those with structural damage, when recurrent infections occur despite optimal Ig therapy, and in phagocytic disorders in which no other form of therapy is available.

If respiratory tract infections are the highest risk, penicillin, ampicillin, or dicloxacillin given orally, 0.5 to 1.0 g/day in divided doses, may be recommended. The use of prophylactic antibiotics in CVID is controversial and is usually reserved for those with severe bronchiectasis in whom the risk of progression due to recurrent pneumonia is substantial. Azithromycin once daily (5 mg/kg, maximum of 500 mg/day or on alternate days or two or three times weekly) is often effective; its longer half-life and its anti-inflammatory action make this a popular choice.

Table 59.2 **RECOMMENDATIONS FOR PROPHYLAXIS AGAINST *PNEUMOCYSTIS JIROVECII* IN HIV AND PRIMARY IMMUNODEFICIENCY ON THE BASIS OF CD4 LYMPHOCYTE COUNT**

Age	CD4 COUNT*
<12 months	<1,500 cells/μL
12–23 months	<750 cells/μL
2–5 years	<500 cells/μL
>5 years	<200 cells/μL
Adults	<200 cells/μL

* Level at which prophylaxis is indicated:

- CD4 count <25% of total lymphocytes
- Past history of Pneumocystis *jirovecii* infecion
- Children with X-linked hyper-IgM syndrome (CD40L mutations)
- All patients with severe combined immunodeficiency

Prophylactic antibiotics alone, without IG therapy, are often used in patients with less severe antibody deficiencies (e.g., selective IgA deficiency, IgG subclass deficiencies, partial antibody deficiencies, transient hypogammaglobulinemia of infancy) and recurrent respiratory infections.

P. jiroveci pneumonia (PCP) prophylaxis is recommended for children with significant primary and secondary cellular (T-cell) immunodeficiencies (Centers for Disease Control, 1991) (Table 59.2). Prophylaxis consists of trimethoprim-sulfamethoxazole (TMP-SMX), 160 mg/M2 of body surface per day of the TMP and 750 mg/M2 per day of SMX given orally in divided doses twice per day three times per week, with frequent checks of the leukocyte count. Alternative drugs for PCP prophylaxis include pentamidine, dapsone, and atovaquone.

IMMUNOGLOBULIN (IG) THERAPY

IG therapy is indicated only for those patients with proven antibody deficiency (Table 59.3). Ig is not of value in the treatment of cellular, phagocytic, or complement immunodeficiencies. It is of only limited value in combined antibody and cellular immunodeficiencies, although it is used routinely prior to hematopoietic stem cell transplantation (HSCT) for Severe Combined Immune Deficiences [SCID] and also in those HSCT recipients in whom only the T-cell system is reconstituted.

Three human IG formulations are available: intravenous immunologlobulin (IVIG), concentrated liquid products for intramuscular use (IMIG), and subcutaneous immunoglobulin (SCIG). The route selected depends on ease of venous access, the dose and interval needed to keep the patient free of infection and the patient's preference and therefore compliance.

IG is derived from plasma pooled from 10,000 to 50,000 donors; the individual donors are first screened for pathogens, including hepatitis B and C viruses and HIV. The pool is treated with cold ethanol (Cohn fractionation) that precipitates the gammaglobulin fraction (termed fraction II); this

Table 59.3 PRIMARY IMMUNODEFICIENCIES IN WHICH HUMAN INTRAVENOUS OR SUBCUTANEOUS IMMUNOGLOBULIN MAY BE BENEFICIAL

Antibody Deficiencies:
X-linked and autosomal agammaglobulinemias
Common variable immunodeficiency disorders
Hyper-IgM syndromes
Transient hypogammaglobulinemia of infancy (in selected cases)
IgG subclass deficiency, with or without IgA deficiency (in selected cases)
Antibody deficiency with normal serum immunoglobulins (in selected cases)
Combined Deficiencies:
Severe combined immunodeficiencies (all prior to BMT and after BMT, if reconstitution of B cell function has failed)
Wiskott-Aldrich syndrome (if associated with severe immunodeficiency)
Ataxia-telangiectasia (if antibody-deficient)
Short-limbed dwarfism or cartilage-hair hypoplasia
Bare lymphocyte syndromes
X-linked lymphoproliferative syndromes (possible benefit)
22q11 deletion syndromes (if severe antibody deficiency)
Hyper-IgE syndromes (if severe antibody deficiency)
NEMO

BMT, bone marrow transplantation.

Table 59.4 PREPARATION OF INTRAVENOUS IMMUNOGLOBULIN FROM COHN FRACTION II*

1. Physical removal of aggregates by ultracentrifugation or gel filtration
2. Treatment with proteolytic enzymes
3. Treatment with chemicals that reduce sulfhydryl bonds, followed by alkylation of the free SH bonds
4. Addition of disaccharides or other stabilizing agents (e.g., glycine, proline)
5. Incubation at low pH

*These methods are used to eliminate high-molecular-weight complexes and most viruses.

precipitate undergoes several additional steps to concentrate the IG, remove other serum proteins and high-molecular-weight complexes, and remove or inactive pathogens. It is then treated by solvent-detergent (or other chemicals), by pasteurization or by nanofiltration as additional steps to ensure viral inactivation or virus removal (Henin et al., 1988; Stiehm et al., 2008) (Table 59.4).

The final product is again tested for pathogens, pyrogens, concentration of IgG, IgA and IgM as well as selected antibody levels. It is then brought to a relevant concentration for subcutaneous or intramuscular use (15–25 percent) or intravenous use (5–10 percent).

IG contains a wide spectrum of antibodies to viral and bacterial antigens (Stiehm et al., 2008). In most IG preparations is more than 95 percent IgG, but trace quantities of IgM and IgA are present; there is currently one preparation that contains higher concentrations of IgM and IgA but this is in limited supply. The IgM and IgA globulins are usually therapeutically insignificant because of their short half-lives (<7 days) and their low concentrations. IG contains all IgG subclasses and multiple IgG allotypes (Gm and Km types).

IVIG THERAPY

IVIG is the most widely used treatment for the majority of primary and secondary immunodeficiency syndromes in N. America though the proportion in relation to SCIG is more even in other continents, particularly in Europe. Over 20 IVIG preparations from different manufacturers have been used worldwide; all are slightly different in terms of their formulation (due to patent law) and therefore may have minimally different risks. In practice, all of these preparations have acceptable serum half-lives (18–28 days), contain all IgG subclasses, have minimal anticomplementary activity, have a good and diverse antibody content, and are negative for hepatitis B surface antigen (HBsAg), hepatitis C virus (HCV), and HIV.

There are advantages and disadvantage to the administration of IG by the intravenous route compared to the subcutaneous or intramuscular route (Table 59.5). Dosage, methods of administration, and adverse reactions are discussed in the later section devoted to antibody deficiencies.

SCIG THERAPY

IG for subcutaneous use is also a sterile (15–25 percent, 150–200 mg/mL), solution without preservative and is now available in many countries. Its advantages and disadvantages are shown in Table 59.5. A slow subcutaneous infusion of 10 to 12 percent IVIG was given in the United States prior to the licensure of a 16 percent solution of SCIG in 2006 (Stiehm et al., 1998; Welch and Stiehm, 1983).

Dosage, methods of administration, and adverse reactions of SCIG are also discussed in the chapters on antibody deficiencies.

IGIM THERAPY

Whereas most IG preparations for intramuscular injection in the United States had thimerosal as a preservative and were therefore unsuitable for subcutaneous or higher-dose intramuscular use, products suitable for subcutaneous infusion have been available in Europe and elsewhere for decades, obviating the need for intramuscular preparations.

Intramuscular products contain high-molecular-weight complexes that are strongly anticomplementary; these may account for the occasional systemic reaction to IGIM that is inadvertently injected intravenously. These products should not be given intravenously.

Table 59.5 ADVANTAGES AND DISADVANTAGES OF INTRAVENOUS IMMUNOGLOBULIN OVER SUBCUTANEOUS IMMUNOGLOBULIN

Advantages:
Ease of administering large doses
Less frequent treatments
More rapid action
No loss in tissues from proteolysis
Avoidance of swelling at injection sites
Disadvantages:
Requires venous access
Requires more training for home or self-infusions
Longer duration of infusion
Higher risk of serious side effects

IGIM therapy was utilized regularly for antibody deficiencies until the early 1980s, when IVIG therapy was introduced. The initial recommended dose was 100 mg/kg per month, based on studies of the Medical Research Council of the UK (1969). Treatment was given weekly at a dose of 25 mg/kg because of the large volumes needed (50 mL/month for a 70-kg adult).

These injections are painful and have occasionally resulted in sterile abscesses at the site of injections (Haeney et al., 1979). One case of mercury toxicity was reported as a result of the mercury used as a preservative (Matheson et al., 1980). Adverse events were relatively uncommon, other than the local reactions, though occasional anaphylactoid reactions and even fatalities were reported. The amount of IG that can be administered intramuscularly is limited, and serious breakthrough infections may occur as a result. This route is rarely used today, since IVIG and SCIG are more widely available and are now included in the WHO Essential Medicines lists for adults and for children.

HEPATITIS C IN IVIG

Hepatitis C virus (HCV) was transmitted through a number of IVIG lots prior to 1995 (Bjorkander et al., 1988; Bjoro et al., 1994; Centers for Disease Control, 1994; Christie et al., 1997; Lever et al., 1984; Ochs et al., 1985; Razvi et al., 2001; Schiff, 1994; Williams et al., 1989; Yap et al., 1994; Yu et al., 1995). Once testing for HCV became available, such transmission has not been reported including no reports relating to subcutaneous use. IG now is only manufactured with units tested for HCV by polymerase chain reaction (PCR), and all batches undergo viral inactivation steps (Stiehm et al., 2008).

These HCV cases followed the exclusion of plasma containing antibodies to HCV prior to the PCR assay. Because HCV infection does not result in detectable antibodies for up to 6 months after exposure in immunocompetent individuals (the window period), unchallenged virus from a few viremic donors contaminated a few of the final batches (Yu et al., 1995). Over 200 patients worldwide became infected (Centers for Disease Control, 1994; Christie et al., 1997; Healey et al., 1996; Schiff, 1994; Yu et al., 1995). The Gammagard/Polygam preparations involved in the outbreak were replaced with Gammagard-SD and Polygam-SD, whose manufacture included a solvent-detergent treatment to inactivate HCV and other membrane-enveloped viruses.

In a previous outbreak, Bjoro et al., (1994) reported that immunocompromised patients had a severe and rapidly progressive course of HCV infection, and the responses to IFN were poor. However, this was a study of patients with chronic infection of undefined length and unknown or mixed genotypes of HCV. The 1994 HCV outbreak in the United Kingdom provided a unique opportunity to study the long-term rate of progression of HCV and responses to therapy in patients with known onset of infection and a single genotype, genotype 1a (Christie et al., 1997; Healey et al., 1996). With early (acute-phase) high-dose IFN-α therapy, over half the patients cleared the virus and remained clear at 5 years (Chapel et al., 2001). Furthermore Razvi et al., (2001) reported that 16 of 58 (27 percent) immunodeficient patients who developed HCV infection from IVIG resolved their infection; this rate of recovery was the same as that in IFN-α–treated patients and those receiving no therapy.

There have been no further reports of HCV infections transmitted by IVIG since 1994. Manufacturers of IVIG are now required to show that the virus inactivation processes eliminate HCV. These studies have substantiated the effectiveness of low pH, pepsin, solvent-detergent, caprylate precipitation, pasteurization, and nanofiltration to remove HCV. Nevertheless, they do not guarantee the complete absence of other known or unknown infectious viruses.

No cases of HIV transmission have been identified with the use of IVIG, and HIV is readily inactivated by cold ethanol fractionation or partitioned into fractions other than Cohn fraction II.

PRION DISEASE AND IVIG

Several IVIG lots derived from plasma obtained from donors subsequently found to be at risk for Creutzfeld-Jakob disease (CJD) were recalled, although no cases of CJD or variant CJD (vCDJ) associated with mad cow disease transmitted by IVIG have been reported. (Zou et al., 2008).

Vigilance is needed in this area as for other potential blood borne pathogens, and the International Union of Immunological Societies (IUIS) Committee for Primary Immunodeficiency Diseases encouraged early referral to the Edinburgh Surveillance Unit of immunoglobulin recipients, especially those on long-term, repeated therapy, if they develop unexplained neurological or psychiatric symptoms. Ziegner et al., (2002) have reported unexplained neurodegeneration in 14 immunodeficient patients treated with IVIG in the United States and Europe, although none of these patients had proven prion disease and several may have been vitamin A deficient (Aslam et al., 2004).

Currently, British plasma and that from individuals who have lived in Great Britain for more than 3 months between

1980 and 1996 or who have stayed in Europe for an accumulative time of more than 5 years since 1980 are excluded from donating blood for use in immunoglobulin production. Several countries, including the United States use only plasma collected nationally, in line with the WHO guidelines for self-sufficiency but this is increasingly difficult as larger amounts of plasma is needed to meet the increasing demand for IG therapies, including for immunomodulation.

HIGH-TITER IGs

Following chickenpox or herpes zoster exposure of the immunodeficient child, varicella-zoster immune globulin (VZIG) may be given to prevent chickenpox. Alternatively, or in combination, oral aciclovir can be used. For antibody-deficient children receiving regular IVIG infusions at monthly intervals, VZIG is not necessary, since IVIG contains antibody to varicella/zoster virus. Even if not prevented, varicella infections are markedly attenuated by IVIG (Stiehm and Keller, 2009).

RSV-IG (RespiGam), licensed in 1996 in the United States, was a high-titer human IVIG that prevented or modified RSV infections in high-risk infants, such as those born prematurely and infants with bronchopulmonary dysplasia (Groothuis et al., 1993), during the respiratory virus season (November–April). RespiGam was replaced in 2003 with monthly intramuscular injections of the RSV monoclonal antibody palivizumab (Synagis, 15 mg/kg) (American Academy of Pediatrics, 2012). Immunodeficient infants less than 2 years of age should also receive palivizumab, even if they are on IG replacement therapy, since IVIG or SCIG has negligible titers of RSV antibody.

The prophylactic use of other high-titer immunoglobulins such as tetanus immunoglobulin (TIG) or hepatitis B immunoglobulin (HBIG) following exposure to those agents is particularly important in the immunodeficient patient who is unable to make antibodies (Stiehm and Keller, 2009).

CORTICOSTEROIDS

Corticosteroids are occasionally necessary in patients with immunodeficiency for such problems as asthma, LIP, obstructive gastrointestinal or genitourinary tract granulomas, hemolytic anemia, immune thrombocytopenia, severe contact hypersensitivity reactions, or graft-versus-host disease. Short-term courses are well tolerated; if chronic or high-dose corticosteroid therapy is used, *P. jiroveci* prophylaxis should be considered, particularly in those patients with low CD4 counts or T-cell deficiency.

We have used inhaled corticosteroids in children with CGD and local steroids for eczema in WAS and other immunodeficiencies without complications. Prolonged high-dose corticosteroids will severely depress the lymphocyte count, including that of T- and B-cell subpopulations, and may cause hypogammaglobulinemia, even in normal children, although lymphoproliferative and antibody responses usually remain intact (Lack et al., 1996).

PRENATAL MANAGEMENT

Pre-implantation diagnosis is available in some countries for those women known to be carriers of a specific severe immunodeficiency. Prenatal or diagnosis by newborn screening is of value if early treatment, therapeutic abortion, or Cesarean section is a possibility. In utero tissue typing of the fetus is sometimes of value to identify a potential matched related or unrelated HSCT donor, or an umbilical cord transplant donor (Vowels et al., 1993). In utero haploidentical BMT has been accomplished but is not routinely available (Bartolome et al., 2002; Flake et al., 1996; Merianos et al., 2008).

If a previous sibling has had a severe T-cell immunodeficiency and the mother is pregnant again, a number of options must be considered and planning is imperative.

Prenatal diagnosis should be considered either by genetic testing or phenotyping of a fetal blood sample for lymphopenia or thrombocytopenia. Fetal sampling can be done as early as 18 to 20 weeks. If the molecular defect is known through gene analysis of affected family members, prenatal diagnosis can be performed by analyzing fetal DNA obtained by chorio-villous biopsy (CVS) or by collecting amniocytes.

Cesarean section may be performed if a difficult labor is anticipated, but it is not routinely indicated. Cesarean section prior to the onset of labor is recommended when neonatal thrombocytopenia is anticipated, such as in WAS, to prevent a cerebral bleed.

NEONATAL MANAGEMENT

The importance of early diagnosis and treatment of primary immune deficiency to prevent death or long-term complications cannot be overemphasized (Griffith et al., 2009). Thus newborn screening, as employed in many countries for SCID, will soon be extended throughout the developed countries.

Cord blood should be obtained at delivery from newborns suspected of having an immunodeficiency. For optimal collection, a trained person should be available to drain the placenta for maximal yield, collect the blood in a sterile fashion, and anticoagulate it in multiple aliquots. Cord blood should be tested immediately for blood count, immunoglobulin assays, B- and T-cell enumeration, phytohemagglutinin and/or allogeneic cell stimulation, and human leukocyte antigen (HLA) typing. The remaining cord blood can be cryopreserved for possible future gene therapy or, if the infant is unaffected, for possible use in a future affected sibling.

Newborns at risk for severe combined immunodeficiency (SCID) should remain in a protective environment with reverse isolation or in an isolator until their immunological status is clarified or definitive treatment completed. On no account should such an infant be immunized with live vaccines; BCGosis is an inevitable complication of BCG immunization and is not only difficult to treat but increases the risk of failure of a subsequent HSCT.

A chest X-ray for thymic size should be done as soon as possible; an absent thymic shadow in an unstressed newborn is highly suggestive of a T-cell immunodeficiency, although ill infants from any cause may have thymic involution. Gastrointestinal sterilization with nonabsorbable antibiotics may be considered.

Pneumocystis prophylaxis (with TMP-SMX) should be considered for all patients with severe T-cell deficiencies or a CD4 cell count below 1,500 cells/uL, which is less than the fifth percentile for their age group (Stiehm et al., 2004).

FAMILY STUDIES

Immunoglobulin and complement levels should be obtained in the immediate family of all patients with antibody or complement deficiencies to determine a familial pattern. If other family members have suggestive histories, they should also be studied. Newborn siblings of an affected patient are followed carefully from birth for manifestations of a similar disorder. In disorders in which procedures are available for heterozygosity testing, the parents, siblings, and children of the affected subject can be tested for future genetic counseling.

SUPPORT GROUPS

Participation in support groups (listed at end of this chapter) provides essential information and help for patients and their families with schooling, insurance, access to medical care, and so forth. Medical and nursing teams can provide only limited resources to help families cope with the social, economic, emotional, and psychological issues that these diseases impose on families. Other patients and families can offer a perspective and mutual support not obtainable from medical personnel.

PART II: SPECIFIC IMMUNODEFICIENCIES

ANTIBODY DEFICIENCIES

Since many antibody-deficient patients have a reasonable life expectancy with IG therapy (Chapel et al., 2008), other general measures as outlined in the first section are particularly important in ensuring a long and active life. This includes lifestyle counseling (no smoking, good diet, exercise), prompt treatment of infection, avoidance of contagious situations and sick contacts, and recognition and treatment of disease-related complications such as granulomas, autoimmunity and malignancy.

IG Replacement Therapy

In patients with severe symptomatic antibody deficiency (Table 59.3), such as X-linked agammaglobulinemia (XLA), CVID or one of the hyper-IgM syndromes, human IG replacement is the mainstay of therapy.

Like the well-controlled diabetic on insulin therapy, many patients on adequate regular IG replacement are able to live relatively symptom-free. However, some antibody deficient subjects given IG remain chronically ill or undergo a progressive downhill course. Those with XLA and pre-existing bronchiectasis have long-standing pulmonary difficulties, as do those CVID patients who suffered pneumonia before diagnosis (Quinti et al., 2007, Chapel et al., 2008). CVID patients may also have immunological or hematological deficits as well as antibody deficiency or chronic lung or gastrointestinal disease (Chapel et al., 2008, 2009, 2012)

Patients with IgA or IgG subclass deficiency, transient hypogammaglobulinemia of infancy, or selective Ig antibody deficiency need not be treated with IG unless there is chronic refractory infection and/or a documented inability to produce specific antibodies following immunization (Moschese et al., 2008; Stiehm, 2008).

The aim of IG therapy is to keep the patient free of bacterial infections by maintaining serum antibodies at protective levels. Serum trough IgG concentration is used as a surrogate and the IgG level kept within the normal range in addition to monitorin of any breakthrough infections. However, as found in healthy populations, each individual needs a different level of trough IgG to maintain prevention against bacterial infections (Lucas et al., 2010).

IG is a blood product and therefore used only in patients in whom the risk/benefit analysis is likely to be beneficial to the patient. Pooled plasma from 10,000 to 50,000 donors is fractionated, and the fraction containing IG is then purified and treated with antiviral steps to provide a final product at various concentrations, with a variety of stabilizing agents, depending on the manufacturer (Table 59.4).

IVIG Dosage

Several studies indicate that larger doses of IVIG (400–800 mg/kg) are superior to lower doses (100–300 mg/kg per month) in terms of subjective improvement, reduced hospitalization rates, improved chest X-rays or CT scans, normalization of pulmonary function, and decreased incidence of major or minor infections (Bernatowska et al., 1987; Garbett et al., 1989; Haeney, 1994; Liese et al., 1992; Montanaro & Pirofsky, 1984; Ochs et al., 1984; Roifman et al., 1987; Stiehm, 1997; Wood et al., 2007; Orange et al., 2010, Lucas et al., 2010).

A common practice is to start IVIG at 400 mg/kg at 2- to 4-week intervals but to give additional doses (loading) at the onset of therapy to raise the IgG level quickly. After initiation of IVIG, the IgG trough level increases over several months as the tissue spaces become saturated with IgG. After 3 months the clinical progress of the patient alongside the preinfusion IgG level is assessed and the dose adjusted (Lucas et al 2010; Orange et al., 2006; Stiehm, 1997).

Those antibody deficient patients with chronic lung disease, vasculitis, rheumatic complaints, chronic diarrhea, protein-losing enteropathy or failure to thrive may require a higher dose (e.g., 800–1,000 mg/kg per month) to control disease manifestations (Lucas et al., 2010; Eijkhout et al., 2001; Roifman et al., 1987).

Administration of IVIG

IVIG administration requires venous access, which is sometimes a problem in small children, obese or elderly patients. The local use of an analgesic cream or spray applied to the infusion site prior to venipuncture makes the infusions more acceptable.

Close monitoring is required, especially during the first few infusions, when the risk of adverse reactions is much higher.

These can be minimized or prevented by premedication (see below). Adverse reactions are infrequent when regular IVIG infusions are given and once the patient is stable, provided the correct rates for infusions are observed or the patient has not had a breakthrough infection, adverse reactions are uncommon and nearly always mild; no serious reactions were reported in the large UK audit. (Brennan et al., 1995).

In Europe and the United States, IVIG infusions have been shown to be sufficiently safe to enable selected patients (adults and children) to receive infusions at home with the help of either a home infusion service, a responsible adult family member or by self-infusion (Kobayashi et al., 1990). Self-infusion without another informed adult in the house is discouraged. In one study of patients selected to self-infuse at home, the number of adverse reactions was 0.1 percent; universally the few reactions that did occur were mild (Brennan et al., 1995). Parents, patients and nurses who perform home infusions must be taught to recognize and treat adverse reactions, and their competency must be documented before such schedules are put in place.

In patients who have received infusions without adverse events, self- or parent administration at home can be accomplished with great cost savings in some countries, depending on the health-care system (Ashida and Saxon, 1986; Kobayashi et al., 1990; Ochs et al., 1986; Sorensen et al., 1987). This type of therapy is used by many patients in the United Kingdom and in other parts of Europe. In the United States, most IVIG infusions are performed in a clinic or by home infusion personnel.

An IVIG infusion usually requires 2 to 4 hours. The initial rate is 0.5 mg/kg/min (0.01 mL/kg/min of the 5 percent products), and this can be doubled at 20- to 30-minute intervals if there are no side effects to a maximal rate of 2 to 3 mg/kg/minute (0.04–0.06 mL/kg/minute). Ten percent products have been introduced and even faster rates have been shown to be safe, although each product has an individual recommendation. Adverse events tend to be associated with rapid infusion rates in patients with concurrent acute infections or previously untreated patients, or when a significant time between infusions has transpired (>6 weeks) (Brennan et al., 1995).

Side Effects of IVIG

Typical reactions associated with IVIG infusions include headaches, nausea and vomiting, flushing, chills, myalgia, arthralgia, and abdominal pain (Duhem et al., 1994; Katz et al., 2007; Ochs et al., 1980; Orange et al., 2006; Stiehm, 1997). Less commonly chest tightness, hives or even anaphylactoid reactions can occur. Severe, life-threatening reactions are very rare.

Immediate minor reactions can be avoided or diminished by slowing the infusion rate. Patients with minor side effects such as headaches, shaking chills, nausea and vomiting, or myalgia/arthralgia can be treated (and for subsequent infusions pretreated) with oral acetaminophen or a nonsteroidal anti-inflammatory drug and antihistamines. Severe reactions are treated with antihistamines and corticosteroids. The need for parenteral epinephrine is very rare and is no longer recommended for self-infusion patients who are well established on IG therapy, due to the risk of misuse.

If a severe reaction is anticipated (on a first infusion in a patient with marked bronchiectasis, for example), hydrocortisone (6 mg/kg, maximum 150 mg) can be given intravenously 1 hour before infusion in addition to oral acetaminophen and antihistamines. These drugs can be repeated after 3 or 4 hours if the infusion is not finished. Occasionally switching to a different IVIG product may alleviate recurrent reactions.

Serious late but very rare adverse reactions are almost always confined to high-dose usage of IVIG in immunomodulating doses (Duhem et al., 1994). These include aseptic meningitis (Kato et al., 1988; Vera-Ramirez et al., 1992), thrombosis or disseminated intravascular coagulation (Comenzo et al., 1992; Woodruff et al., 1986), renal (Miller et al., 1992) or pulmonary (Rault et al., 1991) insufficiency or hemolytic anemia (Brox et al., 1987). Sucrose-containing IVIGs are particularly likely to result in renal complications (Katz et al., 2007), so this is largely avoided now. Some IG product were reported to contain higher concentrations clotting factor XI, in one case in association with an increased risk of thrombosis even at replacement levels; this has not been a problem since the manufacturing processes have been changed (Funk et al 2013).

IVIG is contraindicated in patients who have had an anaphylactic reaction to IVIG or other blood products. IVIG is initially given with caution in patients who have high-titer or increasing amounts of anti-IgA antibodies (Burks et al., 1986; Rachid et al., 2011), as these patients may be at higher risk of a serious reaction (Rachid and Bonilla 2012).

Patients with an IgA deficiency in association with a profound IgG deficiency are not at increased risk for the development of anti-IgA antibodies or reactions to IVIG.

In the past there was some evidence that certain brands of IVIG may be more reactogenic. In one study of Kawasaki disease, the two IVIG brands used were at equivalence therapeutically, but one had a 12-fold (2 percent vs. 25 percent) increase in side effects (Rosenfeld et al., 1995). Such a discrepancy, however, has not held up in clinical practice.

A few investigators gave high concentrations of IVIG infused rapidly over 20 to 40 minutes; this rapid rate was tolerated by some but not all patients (Schiff et al., 1991) and is not recommended.

SCIG

Products for SCIG have been developed as an alternative to IVIG (Table 59.5). The monthly dose is the same as that for IVIG, starting typically at 400 mg/kg per month, in divided doses (Thepot et al., 2010). This can be given every 10 days, once or twice a week, or even daily, once the patient has been loaded; loading can be done intravenously or subcutaneously (Borte M, Quinti, I., Soresina, A., Fernández-Cruz, E., Ritchie, B., Schmidt, DS., McCusker, C. Efficacy and safety of subcutaneous vivaglobin® replacement therapy in previously untreated patients with primary immunodeficiency: a prospective, multicenter study. J Clin Immunol. 2011; 31:952–961.)

Initially, SCIG was given as a 16 percent formulation by slow subcutaneous infusion at a rate of 0.05 to 0.2 mL/kg/hour or 3 to 12 mL/hour, using a syringe driver as a pump (Abrahamsen et al., 1996; Berger et al., 1980) but this was not only inconvenient

but resulted in sterile abscesses; rapid infusion (up to 40 mL/hr) is now used worldwide (Gardulf et al., 1995, 2001; Hansen et al., 2002).

The SCIG injections are usually given into the abdominal wall and/or lateral thighs with the use of a battery-operated pump, though a gentle continuous push is fine too (Shapiro R. Subcutaneous immunoglobulin: rapid push vs. infusion pump in pediatrics. Pediatric Allergy and Immunology 2013; 24:49–53.) Multiple sites can be used simultaneously, particularly in older children and adults. More recently it was shown that using a new infusion area (e.g. changing from abdomen to thighs) increases the risk of local tissue reactions (Gardulf A,. Nicolay, U. Replacement IgG therapy and self therapy at home improve the health-related quality of life in patients with primary antibody deficiencies. Curr Opin Allergy Clin Immunol. 2006; 6:434–442.) These injections are well tolerated and enable the patient to receive the same or increased amounts of IG as given intravenously (Berger, 2004; Gardulf et al., 1991, 1995). They are especially valuable for self-administration at home in children and adults who cannot manage IVIG due to difficulty with venepuncture (poor venous access, fragile veins, etc.) (Gardulf et al., 1991, 2004, 2006; Nicolay et al., 2006; Ochs et al., 2006).

A multicenter study of the efficacy and safety of IVIG versus SCIG therapy showed no significant differences in rates of breakthrough infections or adverse reactions (Chapel et al., 2000). The IgG trough levels achieved subcutaneously were equivalent to that of a similar intravenous dose. These injections are particularly suitable for children and are well accepted by the parents (Berger et al., 2010; Abrahamsen et al., 1996).

A 20% preparation has been approved by the FDA in 2010 and by the European Commission in 2011 for subcutaneous use.

In countries or situations where no preservative-free 16 or 20 percent SCIG is available, 10 or 12 percent IVIG can be given subcutaneously (Stiehm et al., 1998).

SCIG is particularly suitable for individuals with poor venous access, those who have had severe immediate reactions or aseptic meningitis to IVIG, and those who have protein-losing illnesses in which IVIG is lost rapidly in the gastrointestinal tract or the kidneys (Rezaei et al., 2011).

IVIG for Enterovirus Encephalitis and Polymyositis

Chronic meningoencephalitis, polymyositis, or fasciitis due to disseminated enterovirus infection (usually ECHO virus) occurs in patients with XLA and, less commonly, in patients with CVID or CD40 ligand deficiency (Crennan et al., 1986; Cunningham et al., 1999; Erlendsson et al., 1985; Johnson et al., 1985; Lederman and Winklestein, 1985; McKinney et al., 1987; Mease et al., 1981; Prentice et al., 1985; Quartier et al., 2000; Schmugge et al., 1999; Wilfert et al., 1977).

PCR is required for establishing a viral diagnosis on the cerebrospinal fluid (Chesky et al., 2000). Since the introduction of higher doses of IVIG, the incidence of these infections has dropped dramatically, but they still may occur, even if patients receive adequate doses of IVIG (Misbah et al., 1992; Rotbart, 1990) or prior to a diagnosis of immunodeficiency.

Treatment of these patients with high-dose IVIG modifies the severity of infection and improves survival (Erlendsson et al., 1985; Mease et al., 1981; Prentice et al., 1985; Quartier et al., 2000), but failures have been reported (Crennan et al., 1986; Johnson et al., 1985). The response to IVIG may depend on the titer of neutralizing antibodies against the specific enterovirus in the preparation (Mease et al., 1981).

A review of published reports indicates that more affected patients treated with IVIG survived than those given IMIG or immune plasma; of those who did not receive IVIG, none survived (Stiehm and Keller, 2004). Intraventricular infusion of IVIG contributed to the eradication of the virus in some patients but not in others. Patients originally responding appropriately to high-dose IVIG may relapse after the high doses are discontinued (Mease et al., 1985)

An open trial of the antiviral drug pleconaril was only partially successful (Rotbart and Webster, 2001). With the advent of enteroviral PCR (Chesky et al., 2000) a definitive diagnosis is now possible, which should make future trials of new antivirals more robust.

IVIG for Other Viral Infections

IVIG has been advocated for the treatment of chronic Epstein-Barr virus (EBV) infection. In uncontrolled studies, selected patients have shown clinical improvement (Finberg, 1988; Tobi and Straus, 1985). It has been suggested that IVIG be used prophylactically in EBV seronegative infants and children with an X-linked lymphoproliferative syndrome (XLP) to prevent EBV infection. One EBV-sero-negative college student with XLP died from overwhelming EBV infection despite monthly IVIG infusions (Okano et al., 1991). It is particularly important to ascertain the underlying molecular diagnosis and to differentiate XLP from CVID (Morra et al., 2001).

High-dose IVIG (500 mg/kg/daily) may be of value in the treatment of immunodeficient patients with other viral diseases, including cytomegalovirus (CMV) infection, parvovirus-induced pure red cell aplasia (Kurtzman et al., 1989; Seyama et al., 1998), and respiratory virus infections such as parainfluenza or adenovirus (Stiehm et al., 1986).

Therapeutic immunoglobulin (150–300 mg/kg body weight) has been used orally in a few patients with antibody deficiency to stop enteroviral shedding following inadvertent live poliomyelitis immunization (Losonsky et al., 1985) or to treat rotavirus infections (Barnes et al., 1982).

Monoclonal Antibodies and Etanercept

Anti-TNF cytokine therapies have been used in a few CVID patients with life-threatening or serious disabling granulomas (Boursiquot et al. 2013, Bates et al., 2004; Chua, 2007; Hatab, 2005; Lin et al., 2006; Smith and Skelton, 2001; Thatayatikom et al., 2005). However corticosteroids remain the initial treatment of choice (Boursiquot et al, 2013) until the various immunopathogeneses of granuloma and lymphoid interstitial pneumonitis are unraveled.

There is limited experience with Rituximab and azathioprine in those CVID patients with lymphoid interstitial pneumonitis

and B cell follicles in the lung biopsy (Chase et al., 2013). Since the experience is limited and the outcomes are variable, an international register would be helpful (Chapel, 2009).

The successful use of rituximab (anti-CD20 monoclonal antibody) in CVID for immune cytopenias has been reported (Gobert et al., 2011, Cunningham-Rundles, 2008), but the long-term safety is not yet clear; there is an increased risk of infection in patients receiving more than one course, particularly if not on IG replacement therapy (Gobert et al 2011). The apparent efficacy and safety in immunocompetent patients are only partially reassuring.

Other Therapies

IG therapy alone is insufficient to maintain good health in antibody-deficient patients and other measures are needed, including prompt and longer courses of antibiotic therapy for any breakthrough infections and education of patients to seek help and therapies without delay for noninfective complications (Wood et al., 2007).

Continuous antibiotic therapy may be necessary to keep some antibody-deficient patients free of infection. In particular, adult patients with severe bronchiectasis or adults and children with bacterial overgrowth in the gastrointestinal tract may benefit from antibiotics. Some providers use full therapeutic doses of a cephalosporin, penicillin, clarithromycin, or TMP-SMX and usually change antibiotics at 2- or 3-month intervals. Others prefer alternate-day azithromycin on a continuous basis.

Some patients with antibody deficiencies have concomitant and usually transient neutropenia (e.g., XLA, immunodeficiency with hyper-IgM). High-dose IVIG (2 g/kg) may reverse persistent and clinically significant neutropenia and should be tried first. If this is ineffective, granulocyte colony-stimulating factor (G-CSF) can be given.

Attempts to stimulate antibody synthesis by immunological enhancing agents have been made with minimal success. Of particular interest was the use of PEG-IL-2, a preparation of IL-2 conjugated to polyethylene glycol (PEG). PEG-IL-2 was given to 15 CVID patients (Cunningham-Rundles et al., 1994, 2001). After 6 to 12 months of therapy, in vitro proliferative responses improved and antibody responses to a neoantigen developed (in 4 of 8 patients tested), but clinical benefit was minimal.

Isolated successes have been reported with cimetidine (White and Ballow, 1985) and retinoic acid (Saxon et al., 1993). Blys (BAFF), an agent that activates B cells, looked promising in animal experiments, but robust clinical trials have not materialised yet.

The management of complications is an important consideration, particularly for patients with CVID (Chapel and Cunningham-Rundles, 2009). Lymphoproliferative and serious autoimmune complications are usually treated with corticosteroids (with or without steroid-sparing drugs, including azathioprine, 6-mercaptopurine, ciclosporin, mycophenolate mofetil, or methotrexate) (Boursiquot et al 2013; Bates, 2004; Davies et al., 2000; Meyer et al., 2005; Misbah et al., 1992; Park et al., 2005). There are reports of anti-TNF therapies and hydroxychloroquine for granuloma or LIP in patients with severe clinical phenotypes of CVID (Thatayatikom et al., 2005; Yong et al., 2008), though successful mainly in skin granuloma.

Gluten-insensitive enteropathy is usually treated with the nonabsorbable corticosteroid budesonide or low-dose 6-mercaptopurine. New therapies are desperately needed, once the immunopathology is understood; it is encouraging that one such patient with documented enteropathic virus has responded well to Interferon-α (D.S.Kumararatne – personal communication) and another patient to bismuth therapy. It is most important to correct avitaminosis with replacement vitamins, especially the fat-soluble vitamins A, D, and E by injection if they are not absorbed orally (Ardiniz et al., 2008; Aslam et al., 2004; Aukrust et al., 2000).

Splenectomy for antibody-deficient patients with idiopathic thrombocytopenic purpura (ITP) or autoimmune hemolytic anemia poses a theoretical risk of overwhelming infection in patients who are noncompliant with prophylactic penicillin therapy. However a recent survey in Europe has shown that splenectomy does not worsen mortality in CVID and adequate immunoglobulin replacement therapy appears to play a protective role in overwhelming post-splenectomy infections (Wong et al., 2013).

Treatment of malignancies is the same as in immunocompetent patients except for patients with defective DNA repair (see Chapters 46,47,48).

In antibody deficiencies associated with drug treatment (e.g. IgA deficiency following phenytoin administration or hypogammaglobulinemia following gold therapy), discontinuing the drug may result in reversal of the disease, although in some cases the antibody deficiency persists indefinitely (Cunningham-Rundles, 2004; Snowden et al., 1996) and the patient may need IG therapy.

Prognosis

The prognosis has improved significantly for antibody-deficient patients (Chapel et al 2008; Chapel and Cunningham-Rundles, 2009). Early diagnosis, optimal IG therapy, prompt attention to infection, and management of complications are crucial. Factors leading to a more guarded outlook in general include coexisting T-cell deficiency (as in WAS, CVID with low CD4 cell numbers known as late-onset combined immune deficiency-LOCID (Malphettes et al., 2009), CD40 ligand deficiency, etc.), structural tissue damage (notably bronchiectasis), unexplained enteropathy, polyclonal lymphoid hyperplasia, malignancy, or poor compliance with treatment regimens.

CELLULAR IMMUNODEFICIENCIES

The cellular immunodeficiencies vary markedly as to their immunological severity and associated manifestations. Many are syndromic immunodeficiencies such as WAS and ataxia-telangiectasia. These patients need continuous attention to prevent infection and treat coexisting problems.

The increasing use of HSCT to treat SCID and other T-cell deficiencies has provided a cure for many of these patients (see Chapter 60) (Filipovich, 2008; Gennery and Cant, 2008).

Gene therapy has cured patients with X-linked SCID, adenosine deaminase (ADA) deficiency, and WAS (Chapter 61), but it remains experimental and is available in only a few research centers (Thrasher, 2008).

Precautions

Patients with a significant T-cell deficiency need preventive measures to avoid infective complications before attempting curative immunotherapy.

Vaccines: Immunization with live attenuated vaccines against mycobacteria or viruses is contraindicated in patients with a T-cell deficiency. In particular BCG and oral rotavirus vaccine must be avoided. Progressive enterovirus encephalitis, measles encephalitis, and mumps encephalitis have been recorded in undiagnosed T-cell–immunodeficient patients following routine childhood immunization. Additionally, siblings and other close contacts, such as house-mates or tutorial groups, should be immunized with inactivated polio vaccine (Salk vaccine) since live virus vaccine may be transmitted to the patient.

Blood products: Special care must be taken in administering blood products. Blood or blood-cell components given to patients with primary (and secondary) T-cell immunodeficiencies should be CMV-negative and must be irradiated with 27 Gy to prevent graft-versus-host reactions. Radiation of blood products is a simple procedure and can be accomplished rapidly in most blood banks. It is often done routinely for all premature infants and, in some centers, for all newborns.

Surgery: Tonsillectomy and adenoidectomy are rarely indicated. Splenectomy is contraindicated, except in unusual circumstances such as severe unresponsive immune thrombocytopenia or autoimmune hemolytic anemia, though recent data suggests that with modern management and IG therapy this can be a safe procedure (Wong et al., 2013). It has been used to treat the thrombocytopenia in WAS (Litzman et al., 1996) or X-linked thrombocytopenia. The addition of a phagocytic defect (absence of a spleen) to the already existing immunodeficiency increases the risk of sudden, overwhelming sepsis without affecting levels of memory B cells (Sanchez-Ramon et al., 2008).

Antimicrobials: Splenectomized and T-cell–deficient patients may benefit from the administration of broad-spectrum prophylactic antibiotics, as well as prompt treatment of every febrile illness with antimicrobials.

Patients with a significant T-cell deficiency are at risk for *P. jirovecii* infections. Those over age 5 years with CD4 counts below 200/uL are candidates for PCP prophylaxis, and for patients less than age 5, PCP prophylaxis should be considered at higher CD4 count levels (Stiehm et al., 2004) (Table 59.3).

Prophylactic antifungal medications, such as oral nystatin, ketoconazole, fluconazole, itraconazole, and caspofungin (Cancidas), are used to prevent or treat chronic candidiasis and other fungal infections.

Continuous antiviral therapy is sometimes needed for patients with symptomatic chronic CMV or other herpes infections, including herpes simplex or varicella. RSV infection prophylaxis with the monoclonal antibody palivizumab (Synagis) is indicated for all T-cell–deficient infants for the first several years of life (American Academy of Pediatrics, 2012) in the US. During influenza epidemics, anti-influenza medications should be considered, using one of the four licensed anti-influenza virus drugs (amantidine, rimantidine, oseltamivir, or zanamivir, the latter requiring inhalation and recommended only for children 5 years or older) (American Academy of Pediatrics, 2012b).

Immunoglobulin Therapy: All patients with SCID require prophylactic treatment with IVIG prior to stem cell transplantation because their B cells, if present, will either be nonfunctional or lack costimulation by T cells. Even if the T-cell defect is relatively mild (as in some patients with X-linked hyper-IgM syndrome), the patient may have severely impaired B-cell function and should be evaluated for abnormal antibody production. IVIG therapy is indicated for all patients in whom antibody function is deficient (Table 59.3). The dose of IVIG is similar to that discussed earlier for antibody deficiency.

VZIG and/or acyclovir following chickenpox exposure is indicated to prevent generalized chickenpox.

IL-2 cytokines: Patients with T-cell defects have been treated with IL-2 and appear to have achieved some improvement of in vitro T-cell function (Flomenberg et al., 1983).

A few patients with phenotypic SCID were reported to have a defect of IL-2 synthesis with intact IL-2 receptors. IL-2 therapy resulted in temporary restoration of some cellular immunity in a patient with defective IL-2 synthesis (Pahwa et al., 1989).

Cunningham-Rundles et al., (1999a) used PEG-IL-2 in a single patient with idiopathic CD4 lymphopenia and attained a transient favorable clinical and laboratory response.

Other cellular immunodeficiencies in which IL-2 has been used include NEMO syndrome, WAS, DiGeorge syndrome, ataxia-telangiectasia, combined immunodeficiency, and idiopathic CD4 lymphopenia (Roy-Ghanta and Orange, 2010).

G-CSF: G-CSF is of value in T-cell deficiencies when there is an associated neutropenia (e.g., X-linked hyper-IgM syndrome). It is also used in patients who have recently undergone stem cell transplantation to hasten granulocyte recovery. Finally, G-CSF is used to mobilize CD34+ hematopoietic stem cells in donors of peripheral blood stem cells prior to cell harvesting, when used for cellular reconstitution.

Interferons: IFN-γ is of unproven efficacy in most T-cell immunodeficiencies. It has some theoretical value in the treatment of Griscelli syndrome, natural killer (NK) cell deficiency, and bare lymphocyte major histocompatibility complex (MHC) class I deficiency in that it may replace deficient production, enhance NK cytotoxicity, and increase expression of HLA class I antigens.

High-dose IFN-γ therapy is of benefit in the treatment of patients with a partial IFN-γ receptor deficiency or in patients with IL-12 or IL-12 receptor defects (Holland, 2000; Jouanguy et al., 1997).

IFN-α and IFN-γ have been used to treat refractory viral infections such as hepatitis C and IFN-α is also used with success in acute HCV infection (Chapel et al., 2001). Recently IFN-alpha was successful in clearing norovirus in one of two patients with CVID enteropathy (personal communication from Dr. D. Kumararatne).

Other Medical Therapies: Medium-chain triglycerides: In patients with lymphopenia due to gastrointestinal lymphocyte

loss as part of severe protein-losing enteropathy, or in lymphangiectasia of the gut not amenable to medical or surgical treatment, oral medium-chain triglycerides may be of value.

Hormones: Endocrine abnormalities may be associated with T-cell deficiency, notably hypoparathyroidism and hypothyroidism in DiGeorge anomaly and chronic mucocutaneous candidiasis, and hypothyroidism and hypoadrenalism in ataxia-telangiectasia and chronic mucocutaneous candidiasis. These should be treated appropriately, although correction of the endocrinopathies will not affect the T-cell deficiency. Hypothyroidism is also common in CVID patients.

Biotin: In the rare condition of multiple carboxylase deficiency, often associated with candidiasis and severe viral and bacterial infections, the coenzyme biotin given orally at a dose of 1 to 40 mg/day has been curative (Kien et al., 1981)

Folate: Recent description of reversible folate deficiency secondary to a mutation of the proton-coupled folate transporter in a patient with a SCID-like phenotype is encouraging that similar patients may be found in specific transporter proteins (Borzutzky et al., 2009).

Immune lymphocyte infusions: Cytotoxic T lymphocytes specific for CMV from an unrelated donor have been used to combat CMV infection (Horn et al., 2009).

Immune Reconstitution: Restoration of immunity, short of transplantation, is rarely feasible in T-cell immunodeficiencies. Immunomodulating agents such as thymic hormones, levamisole, and transfer factor have not been of proven benefit.

Thymic transplants: Cultured postnatal thymic transplants have been used successfully in infants with DiGeorge syndrome by Markert et al. (2007). Thymic tissue is removed during cardiac surgery from healthy infants, cultured ex vivo to remove mature T cells, and then implanted in the quadriceps muscle. This tissue provides factors that allow maturation of the patient's own T-cell system An alternative procedure for complete DiGeorge syndrome patients with an HLA-matched sibling is stem cell transplantation, which provides mature, long-lasting memory T cells (Land et al., 2007)

PEG-ADA: Hershfield et al. (1995, 1998) reported that 108 patients with the ADA deficiency form of SCID received PEG-ADA, including many of those who have undergone gene therapy (Blaese et al., 1995; Bordignon et al., 1995). Among these patients, 71 remain on therapy. Among those started on PEG-ADA before age 12 months, survival is 74 percent (Hershfield et al., 2003).

The usual dose of PEG-ADA is 30 U/kg given once or twice weekly, with monitoring of plasma ADA levels and erythrocyte adenosine deoxyribonucleotides (dAXP) to assess their response. A few patients have developed an antibody to PEG-ADA with enzyme resistance; this was reversed by increasing the dose of enzyme and treating with corticosteroids and high-dose IVIG (Chaffee et al., 1992).

Clinical improvement is striking in many patients, some of whom have been observed for over 8.5 years, with restoration of protective antibody responses, enhanced proliferative response to injected antigens, and discontinuation of IVIG infusion. PEG-ADA is of particular value for patients too sick to undergo transplantation or those who have no HLA-identical bone marrow donor. Long-term follow-up of these patients shows a gradual decrease in lymphocytes and their proliferative responses, but they are still sufficient to provide protective immunity (Chan et al., 2005) Unfortunately the cost is extremely high (over US $100,000/year).

Attempts to treat purine nucleoside phosphorylase (PNP) and ADA deficiency with various chemicals to block the formation of toxic metabolites or circumvent the biochemical defect have not been successful.

Stem cell transplantation and gene therapy: The treatment of choice, since it may be curative, is HSCT from a matched or partially matched donor using bone marrow, peripheral blood, or cord blood as the source of stem cells. More recently, gene therapy has been successfully performed in a few patients. These procedures are discussed in Chapters 60 and 61.

PHAGOCYTIC IMMUNODEFICIENCIES

General Care

Hygienic precautions: Patients with phagocytic immunodeficiencies, including severe neutropenia (Chapter 51), CGD (Chapter 52), leukocyte adhesion defects (LAD I, II, and III) (Chapter 53), and hyper-IgE syndromes (Chapter 38), are particularly susceptible to cutaneous soft-tissue infections. Thus special care is indicated to avoid cuts, trauma, and environmental situations that lead to exposure to pathogenic organisms (Table 59.1).

Antimicrobials: Most patients require prophylactic antimicrobial therapy. TMP-SMX is usually used, unless neutropenia is present, in which case clarithromycin or ciprofloxacin can be used. Most patients with hyper-IgE syndromes need chronic anti-staphylococcal treatment, such as oral cloxacillin or dicloxacillin, and antifungal therapy, such as fluconazole or itraconazole. Those with an associated antibody deficiency improve on IG therapy. Severe cutaneous infections in these patients are treated with intravenous and/or local antibiotics, often in combination with local steroid therapy.

Neutropenic Syndromes

Patients with neutropenia or defects of cell adhesion and movement are particularly susceptible to periodontitis and oral ulcerations. Good oral hygiene must be stressed, and an antibacterial mouthwash (chlorhexidene) should be used on a regular basis. Prophylactic antifungal drugs should be given if thrush or esophageal candidiasis has occurred.

Congenital neutropenias or neutropenias associated with other immunodeficiency syndromes are usually treated with G-CSF. A persistent absolute neutrophil count less than 200 cells/uL is an indication for its use, particularly if there is an associated infection.

G-CSF and GM-CSF: G-CSF is indicted and approved for severe congenital neutropenia (Dale et al., 1993) (Chapter 51). It has also been used in cyclic neutropenia (Hammond, 1989) WHIM syndrome (Hord et al., 1997) (Chapter 40), and the neutropenias of the hyper-IgM syndrome (Ostenstad et al., 1997) (Chapter 26), XLA (Jacobs et al., 2008), and glycogen storage disease type 1b (Visser et al., 2002).

Granulocyte-macrophage colony-stimulating factor (GM-CSF) has been used in neutropenic syndromes, but the increased cytotoxicity has limited its use (Roy-Ghanta & Jordan, 2010).

Neither cytokine cures these disorders, but they will increase the absolute neutrophil count to near-normal levels. Cure of some of these diseases can sometimes be accomplished by stem cell transplantation

Chronic Granulomatous Disease

General: CGD patients (Chapter 52) are unusually susceptible to Aspergillus and other fungal infections, so patients should rigorously avoid situations where fungal spores can be inhaled or introduced into the skin. Thus, gardening, hay rides, lawn mowing, and digging should be discouraged.

Antimicrobials: CGD patients require continuous prophylactic antibiotics, usually using TMP-SMX (5 mg/kg/day) (Margolis et al., 1990), and antifungal prophylaxis, usually with itraconazole (100–200 mg/day) (Mouy et al., 1994).

Prompt recognition and treatment of infections is of crucial importance. In refractory patients not responding to intravenous antibiotics, leukocyte transfusions may be of value (Yomtovian et al., 1981). Surgical therapy is required for hepatic abscesses or osteomyelitis. Steroids combined with antibiotics and antifungals have also been used in severe refractory infections including inoperable liver abscesses (Yamazaki-Nakashimada et al., 2006, Leiding et al, 2012).

IFN-γ: Immunomodulatory therapy with IFN-γ is used in many centers throughout the United States though less so in Europe. A randomized, double-blind study showed that recombinant human IFN-γ reduced the frequency and severity of infectious episodes in CGD patients, especially those not compliant with antimicrobial prophylaxis (International Chronic Granulomatous Disease Cooperative Study Group, 1991). Since IFN-γ does not increase NADPH oxidative responses, bacterial killing activity or cytochrome b558 levels, it may work by enhancing non-oxidase defenses (Klebanoff et al., 1992; Malmvall and Follin, 1993).

The minimal toxicity and significant clinical effectiveness have led to the recommendation to treat CGD patients of all inheritance patterns in the United States with IFN-γ, 50 μg/M2 body surface, administered subcutaneously three times each week.

However, in Europe, prophylaxis with TMP-SMX and antifungals remains the cornerstone of therapy in adults and older boys; in younger children, BMT is the therapy of choice.

Gastrointestinal and genitourinary complications: CGD patients develop obstructive granulomatous lesions of the esophagus, gastric outlet, and urinary tract. Corticosteroids usually reverse these lesions (Chin et al., 1987). Multiple short courses of high-dose oral steroids may be necessary. Some patients who develop inflammatory colitis are also treated with steroids and/or anti-TNF treatments such as etanercept.

Transplantation: BMT with pretransplant conditioning has been successful in CGD patients, particularly younger patients (Seger et al., 2002; Soncini et al., 2009). Less toxic conditioning regimens prior to transplantation have also been used with promising results (Gungor et al., 2005; Horwitz et al., 2001).

Leukocyte Adhesion Defects

Severe mouth ulcers and periodontal disease are observed in most patients (Chapter 53), so all forms of LAD necessitate good oral hygiene. Continuous antimicrobial therapy may be necessary to prevent cutaneous and deep-seated infections. Daily white blood cell transfusions for 1 or more weeks may be needed to treat severe, life-threatening infections.

Because LAD II is associated with a defect in fucosylation, a patient with a deficiency of the leukocyte selectin CD15a has been treated successfully with oral fucose (Marquardt et al., 1999).

De Ugarte et al., (2002) used GM-CSF formulated for local application to treat nonhealing wounds in patients with LAD and other granulocyte abnormalities (e.g., CGD, glycogen storage disease type 1b).

BMT is readily accomplished in LAD I. Patients with this disorder engraft well because the adhesion molecules that LAD I patients lack contribute to graft rejection (Le Deist et al., 1989).

Hyper-IgE Syndromes

These patients have multiple problems, including skin infections, eczema, osteoporosis, dental abnormalities, and infectious complications such as deep-seated abscesses and pneumatoceles (Chapter 38).

Continuous antimicrobial therapy is usually necessary to keep these patients' cutaneous and deep-seated abscesses under control (Buckley, 2004). Prompt treatment of infections, notably sinusitis and bronchitis, and in many cases continuous prophylactic treatment with antibiotics may prevent acute pneumonia, lung abscesses, and pneumatocele formation. Patients with hyper-IgE syndromes may need prophylactic antifungal therapy since Aspergillus is often the cause of death.

No specific immunotherapeutic regimen has been successful (Freeman and Holland, 2008; Roberts and Stiehm, 1996). IVIG is of minimal benefit but may reduce the IgE levels (Kimata et al., 1995; Wakim et al., 1998). Transfer factor, cimetidine, and ascorbic acid have been used without clinical benefit. Levamisole was inferior to placebo in a controlled, double-blind study (Donabedian et al., 1982). Isotretonin was used in a single case without proven benefit.

Glycogen Storage Type 1b

These patients have neutropenia, functional defects of neutrophil function, and recurrent infections, including sinusitis, pneumonia, and septicemia. Continuous therapy with TMP-SMX has been recommended, and GM-CSF or G-CSF may be beneficial (Hurst et al., 1993).

Chediak-Higashi Syndrome

Although vitamin C corrects some of the defects in vitro, its use in patients with Chediak-Higashi syndrome (Chapter 54) has not been effective (Gallin et al., 1979). Other treatments are supportive, including antibiotics for infection and corticosteroids to treat the accelerated phase of the disease.

BMT has been successful in these patients, particularly if done early, although it will not reverse the neurological abnormalities (Eapen et al., 2007).

Syndromic Mucocutaneous Candidiasis

All patients with syndromic mucocutaneous candidiasis [CMC] (Puel et al., 2012) (Chapter 22) require prophylaxis with anti-fungals, with careful monitoring to avoid resistance to the drug. With increasing understanding of the immunopathogenesis, new therapeutic agents will become available in the next few years.

COMPLEMENT DEFICIENCIES

No specific treatment is available for most complement deficiencies (Sullivan and Winkelstein, 2004). Careful management, however, can improve the health and survival of patients (see Chapter 55). Infections in complement-deficient patients, notably those with C2, C3, C5, C6, C7, C8, properdin, factor H, or factor I deficiencies, should be treated promptly with antibiotics at the first onset of fever or meningismus. An antipneumococcal drug has to be included as this is a common organism, along with meningococci, in these patients.

Long-term penicillin therapy should be considered when meningococcal disease is endemic and for patients with a history of previous severe infections (Potter et al., 1990).

The patient and close household contacts should be immunized against *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria meningitides*. Repeat vaccinations (every 3–5 years) may be necessary if titers diminish to nonprotective levels.

The pediatric conjugated pneumococcal vaccine and the conjugated meningococcal vaccine are recommended in addition to the polysaccharide vaccine for more durable immunity against these illnesses. For unimmunized patients over age 24 months, two doses of conjugated vaccine 8 weeks apart followed by antibody titers 1 month later is recommended.

A deficiency of an early-acting component predisposes to immune complex diseases. Carriers of C2 deficiency may also have a propensity to develop autoimmune diseases. Other family members should be studied for complement deficiency, and if present, genetic counseling can be offered.

Hereditary Angioedema

An exception to the rule that there are no specific therapies for complement deficiencies is hereditary angioedema (HAE). This is an autosomal recessive disorder associated with deficiency or abnormal function of C1 inhibitor (C1INH). The therapy of HAE involves the treatment of acute attacks and prophylaxis of recurrent attacks (Buyantseva et al 2012, Zuraw, 2008).

Management of acute episodes of angioedema must be treated as early as possible and tailored to the extent of the problem. Laryngeal swelling requires urgent evaluation of the airway for possible intubation or tracheostomy, followed by C1INH concentrate (plasma derived or recombinant), given intravenously; this is usually effective within 30 to 60 minutes. Alternatively newly licensed contact system modulators, acting on the kinnin pathway, are also safe and effective (Buyantseva, LV., Sardana, N., Craig, TJ. 2012 Update on treatment of hereditary angioedema Asian Pac J Allergy Immunol 30:89–98). Acute abdominal pain or severe cutaneous swelling can also be treated with C1INH concentrate or kinin modulators.

Less severe attacks can be treated with tranexemic acid, an antifibrinolytic agent. Steroids and antihistamines are no value. Patients with serious symptoms have to be carefully monitored in a hospital to ensure that the angioedema does not progress.

Patients with a history of laryngeal obstruction or serious gastrointestinal involvement are candidates for long-term prevention of attacks. Impeded androgens such as danazol, stanozolol, and oxandrolone are frequently used to increase serum concentrations of the normal C1INH by increasing transcription of the wild-type C1INH gene. The goal of this prophylactic therapy is to maintain the C1INH functional level at approximately 50 percent of normal. Long-term therapy in adults is possible, but patients have to be monitored for adverse reactions, including abnormal liver function tests, microscopic hematuria, and weight gain. Attenuated androgens should not be used in children with open epiphyses on a long-term basis.

For patients with recurrent attacks who fail to respond to or cannot receive androgens, regular infusions of C1INH can be considered for prophylaxis during high-risk periods, and patients are taught to self-infuse in some centers. However, intermittent treatment is usually acceptable.

SUMMARY

General care of the immunodeficient patient requires close monitoring of growth, nutrition, personal hygiene and habits, living conditions, school and work situations, and psychological adjustment to the disease. The most important aspect of the care of an immunodeficient patient is to prevent, recognize, and treat all infectious episodes vigorously. Associated disorders such as anemia, thrombocytopenia, respiratory or gastrointestinal problems, autoimmune and inflammatory disorders are managed by conventional therapy. Avoidance of live-virus vaccines, nonirradiated blood, and CMV antibody–positive blood is crucial for living with some of these illnesses. PCP prophylaxis is necessary in T-cell immunodeficiencies.

Specific therapies that are effective include Ig replacement therapy in patients with antibody deficiency, PEG-ADA injections for ADA deficiency, and IFN-γ for CGD (in some centers) and for IL-12 or IFN-γ receptor deficiencies. Other cytokines, including G-CSF and GM-CSF, are of value in certain selected disorders and replacement C1INH or kinin modulators in HAE.

Stem cell transplantation was pioneered in patients with primary immunodeficiency and continues to be a life-saving procedure for patients with many of these disorders. Minimal

conditioning ("mini-transplants") is being increasingly performed in selected syndromes as a safe alternative to BMT and full conditioning.

Progress in our understanding of the molecular basis of these disorders has paved the way for gene therapy, which is promising and at the same time a challenge.

BONE MARROW TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCY DISEASES

Rebecca H. Buckley, Despina Moshous, and Alain Fischer

HISTORY OF BONE MARROW TRANSPLANTATION

Bone marrow transplantation (BMT) was first attempted as a treatment for aplastic anemia. In 1939, Osgood et al. infused a few milliliters of marrow into patients with aplastic anemia without benefit (Osgood, 1939). Except in identical twins (Pillow et al., 1966), however, the majority of the early attempts at marrow grafting in man failed, due to lack of knowledge regarding tissue typing, immunosuppression, and supportive care. A major breakthrough was made in the late 1960s when the human major histocompatibility complex (MHC) was discovered (Amos & Bach, 1968). Shortly after that, transplants of unfractionated human leukocyte antigen (HLA)-identical allogeneic bone marrow restored the immune function in two patients with fatal primary immunodeficiency diseases, one patient with severe combined immunodeficiency (SCID) (Gatti et al., 1968) and the other with Wiskott-Aldrich syndrome (WAS) (Bach et al., 1968). The correction of these two conditions, as well as the later correction of many other forms of immunodeficiency by BMT (Antoine et al., 2003; Buckley et al., 1999; Friedrich, 1996), implied that the underlying defects in most immunodeficiencies are intrinsic to cells of one or more hematopoietic lineages and that they are not due to failure of the microenvironment to support the growth and development of those cells.

PRINCIPLE OF BMT

In the early 1950s it was observed that the hematopoietic systems of lethally irradiated mice could be reconstituted by bone marrow cells from a mouse of the same strain (Lorenz et al., 1952). These observations constituted the proof of principle that self-replicating cells in normal bone marrow can give rise to erythrocytes, granulocytes, cells of the monocyte-macrophage lineage, megakaryocytes, and immunocompetent T and B cells (Brenner et al., 1993; Wu et al., 1967, 1968). Based on these findings, BMT has been used in attempts to replace defective, absent, or malignant cells of the recipient with normal replicating hematopoietic and immunocompetent cells, first in children with therapy-resistant leukemia using an identical twin as donor after supralethal irradiation (Thomas, 1957, 1959). However, allogeneic marrow grafting continued to be mainly unsuccessful. Between 1939 and 1969, 203 transplants were reported, predominately in patients with aplastic anemia, leukemia, and malignancy, but also in 15 patients with immunodeficiencies (Bortin, 1970). The only three surviving patients were those treated for immunodeficiency, including the two mentioned above. The causes of death were mainly graft rejection, infection, and graft-versus-host disease (GVHD).

Unfractionated BMT offers little risk to the donor, as it involves removal of a tissue that is readily regenerated. Bone marrow cells are usually obtained by aspiration from multiple sites along the iliac crests, the sternum, or (in small children) from the upper third of the tibia, while the donor is under general anesthesia (Martin et al., 1987; Thomas et al., 1975). The aspirate is placed in heparinized tissue culture medium and then passed through metal screens to remove bone spicules. If T-cell depletion is necessary, the marrow is first processed to remove T cells; nucleated marrow cells are then enumerated and the cells are given intravenously to the recipient.

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR PRIMARY IMMUNODEFICIENCY DISEASES: SPECIAL CONSIDERATIONS

Primary goal: immune reconstitution. Unlike the situation in patients with malignancies or global bone marrow

failure, the goal of hematopoietic stem cell transplantation (HSCT) in patients with primary immunodeficiency is to provide normal hematopoietic donor stem cells to correct the underlying genetic deficits in the recipient's immune system. In classic severe combined immunodeficiency (SCID), no pre-transplant immunosuppression is needed because these patients lack T cells and are therefore unable to reject a graft (Buckley, 2004). In other forms of primary immunodeficiency or hypomorphic ("leaky") SCIDs, however, there is usually enough residual T-cell function to cause rejection. Therefore, pre-transplant conditioning agents must be used. Drugs commonly used to ensure the acceptance of solid organ grafts have deleterious effects on the very cells one is trying to engraft in patients with genetically determined immunodeficiency. Thus, any chemotherapy must be given *prior* to infusion of the hematopoietic stem cells to avoid injury to the donor cells.

GVHD: A MAJOR OBSTACLE TO SUCCESSFUL BMT

In further contrast to the situation in solid organ transplantation, successful marrow engraftment in the early days of transplantation required HLA identity (at least for HLA class II determinants) between donor and recipient, primarily because of the extreme susceptibility of the HSCT recipients to GVHD. In the past, this was particularly problematic for patients with SCID and complete DiGeorge syndrome because they cannot reject foreign T cells and therefore developed severe, sometimes fatal, GVHD caused by T cells in unirradiated blood products even before transplantation. Until 3 decades ago, the requirement for an HLA-identical donor limited the possibility of a BMT to patients with an HLA-identical sibling donor, and the likelihood that any given sibling would be a match is only one in four. However, one of the most important advances in the treatment of primary immunodeficiency diseases over the past decades has been the development of methods to avoid GVHD by T-cell depletion and thus to enable transplantation of half-matched (haploidentical) parental stem cells (Antoine et al., 2003; Buckley, 2004; Buckley, 2011; Buckley et al., 1999; Friedrich, 2010).

THE CHALLENGE OF ONGOING INFECTIONS

Although greater awareness of primary immunodeficiencies among pediatricians has led to earlier diagnosis of these rare conditions in recent years, infants and children with primary immunodeficiency often become infected with opportunistic infectious agents prior to diagnosis. These infections cause particular problems from the standpoint of urgency of need for transplantation and may limit the possibility of using chemotherapeutic conditioning agents. This is particularly true for infections with viruses such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenoviruses, and parainfluenza viruses, for which limited or no effective treatment is available (Buckley, 2004; Teigland et al., 2013). Important progress has been made in the past decade, as molecular diagnosis is now readily available. Detection of increasing viral load, even prior to the onset of clinical symptoms, enables the physician to initiate preemptive antiviral treatment to avoid organ damage and to monitor the efficacy of antiviral treatment strategies (Watzinger, 2004). However, most patients with SCID are not discovered prior to their developing one of these viral infections and they can have a fulminating course in which the anti-virals are ineffective. Toxicity of different antiviral agents is also a major concern, as well as development of resistance to therapy. This is especially true for patients with haploidentical donors, in whom the delay for efficient T-cell reconstitution after HSCT necessitates often prolonged antiviral treatment, as sufficient host T-cell response is essential to definitively clear the virus. Therefore, the development of adoptive immunotherapy based on the infusion of virus-specific donor T lymphocytes is currently receiving major attention. This therapeutic strategy is promising in viral infections with EBV (Heslop, 2010), CMV (Feuchtinger, 2010), or adenovirus (Feuchtinger, 2008) but may increase the risk of GVHD. Adoptive immunotherapy for invasive aspergillosis is also under development (Tramsen, 2009).

PERSISTENCE OF TRANSPLACENTALLY ACQUIRED MATERNAL T CELLS

Leukocytes from the mother often enter the fetal circulation during pregnancy. SCID fetuses with transplacentally acquired maternal T cells have no capacity to reject these cells, which frequently persist in the infant's circulation. These maternal T cells are usually unable to respond normally to mitogens and fail to correct the infant's underlying immunodeficiency. They may or may not cause clinical signs of GVHD, such as "eczema" or splenomegaly (Palmer et al., 2007). They can, however, create special problems (or benefits) when BMT is performed for these SCID infants. If a donor other than the mother is used and no pretransplant chemotherapeutic conditioning is given, there is always the risk of a graft-versus-graft (GVG) reaction. If unfractionated HLA-identical sibling marrow is infused, this can lead to rejection of the maternal T cells, with or without a clinical GVG reaction (Friedman et al., 1991). By contrast, if a T-cell–depleted haploidentical graft is given from the father without pretransplant conditioning, rejection of the paternal graft can occur, again with or without a clinical GVG reaction (Palmer et al., 2007). On the other hand, if T-cell–depleted haploidentical stem cells are given from the mother without pretransplant conditioning, immune reconstitution is often accelerated (Barrett et al., 1988), again with or without clinical signs of GVHD. However, if GVHD occurs in this setting, it usually requires either no treatment or only transient use of steroids.

CONDITIONING REGIMENS ARE NOT ALWAYS NEEDED

In contrast to the situation in patients with malignancy or marrow aplasia, it has been repeatedly shown that infants

with SCID or with complete DiGeorge syndrome who have absent T-cell function do not require pretransplant immunosuppression for successful BMT (Buckley, 2004, 2011; Buckley et al., 1999; Myers et al., 2002). Opinions differ on whether SCID patients should be given conditioning, and some transplant centers have recommended conditioning for SCID patients with high numbers of NK cells (Antoine et al., 2003). However, studies of NK cell KIR receptors in SCID patients and their donors did not reveal any significant effect of these receptors on graft acceptance or GVHD (Keller et al, 2007). Patients with most non-SCID types of primary immunodeficiency or hypomorphic SCID, especially those with significant residual T-cell numbers and function, need to be preconditioned with chemotherapeutic agents to prevent graft rejection (see below) (Parkman, 1991).

POSTTRANSPLANT GVHD PROPHYLAXIS IS NOT ALWAYS NEEDED

As is the case for pretransplant conditioning, posttransplantation prophylaxis against GVHD is not necessary in SCID patients after transplantation of HLA-identical or rigorously T-cell–depleted HLA-haploidentical marrow (Buckley, 2011; Buckley et al., 1999; Myers et al. 2002). In non-SCID patients, GVHD prophylaxis is recommended in a geno-identical or pheno-identical transplant setting, but it can be omitted in T-cell–depleted haploidentical transplants. Rigorous depletion of donor T cells is the most effective means of GVHD prophylaxis.

SOURCES OF STEM CELLS FOR HSCT AND DONOR SELECTION

For patients with SCID and many other forms of primary immunodeficiency, allogeneic HSCT is currently the only curative approach. (Antoine et al., 2003; Buckley, 2004, 2011; Friedrich, 1996; Haddad et al., 1998; Gennery et al., 2010; Neven, 2009). Transplantation by using a geno-identical sibling donor results in highest survival and is the treatment of choice, but only a few patients have an HLA-matched sibling. The various sources of stem cells are listed in Table 60.1.

Table 60.1 **SOURCES OF STEM CELLS FOR TRANSPLANTATION**

HLA-identical sibling marrow
Haploidentical parental marrow
T-cell–depleted by soy lectin/sheep red blood cells
T-cell–depleted by monoclonal antibodies
T-cell–depleted by CD34/CD133 positive selection
Matched unrelated adult marrow
Unfractionated
T-cell–depleted by CD34/CD133 positive selection
Unfractionated related or unrelated cord blood

UNFRACTIONATED GENO-IDENTICAL BONE MARROW OR PERIPHERAL BLOOD

If a patient with SCID or other form of primary immunodeficiency is fortunate enough to have an HLA-identical sibling, unfractionated bone marrow cells can be given, and this is the treatment of choice. In most cases, both T-cell and B-cell immunity have been fully reconstituted by such matched transplants, with evidence of function detected as early as 2 weeks following transplantation due to adoptive transfer of mature donor T, B and NK lymphocytes. Patients with SCID have required far fewer unfractionated nucleated marrow cells for successful immune reconstitution than the number needed to treat leukemia or aplastic patients; as few as 4×10^6 $CD34^+$ cells per kilogram recipient body weight have resulted in immunological reconstitution (Friedrich, 1996). However, there is some evidence that higher numbers of stem cells result in better immune reconstitution (Buckley et al., 1999). Unfractionated marrow cells will also engraft in HLA-disparate SCID recipients who lack cellular immunity, but fatal GVHD can be anticipated in the haploidentical setting because unfractionated marrow cell suspensions contain, in addition to stem cells, mature T cells. In rare cases, umbilical cord blood from an HLA-identical sibling may be available.

MATCHED UNRELATED BONE MARROW, PERIPHERAL BLOOD, OR CORD BLOOD

In the absence of a geno-identical donor, matched unrelated donors may be an alternative stem cell source. Donor registries were created to facilitate volunteer stem cell donor searches. In 1988, the Bone Marrow Donors Worldwide (BMDW) was created as an initiative of the Immunobiology Working Party of the European Group of Blood and Marrow Transplantation (EBMT). In 1992, the National Marrow Donor Program was established in the United States. Since then, numerous similar registries have been created. BMDW's first edition in February 1989 contained the donor files of eight registries with a total of 155,000 voluntary donors. In its last edition, 64 stem cell donor registries from 44 countries and 44 cord blood banks from 26 countries are listed in the BMDW directory, including currently almost 15 million donors: more than 14.4 million voluntary stem cell donors as well as more than 400,000 cord blood units (source: http://www.bmdw.org).

Despite the growing number of unrelated volunteer stem cell donors, the probability of identifying a matched unrelated donor ranges from about 60 to 70 percent for Caucasians to under 10 percent for some ethnic minorities, depending on the patient's genetic background and the diversity of HLA within his or her ethnic population (Beatty, 1995; Koh, 2008). It is thus still difficult to identify an unrelated donor for patients with rare HLA antigens, and only approximately 30 percent of patients will have an HLA-matched sibling, a matched unrelated stem cell donor, or a matched unrelated cord blood unit. Furthermore, the search for an unrelated donor is a cumbersome and time-consuming process that necessitates identifying, typing, and harvesting cells from the unrelated donor.

As the average time interval between initiation of the search and the donation of marrow is about 4 months (Heemskerk, 2005), this approach is not practical for patients who urgently need transplantation. This option is also quite expensive (Tiercy et al., 2000).

T-CELL–DEPLETED HAPLOIDENTICAL BONE MARROW OR PERIPHERAL BLOOD.

For patients without any possibility of identifying an HLA-matched related donor, or for patients in such a poor clinical condition that the time needed for the unrelated donor search is too long, an alternative approach is the use of mismatched related family donors. As most of these donors will share only one HLA haplotype with the recipient, they are referred to as haploidentical donors. The immense advantage of parental haploidentical donors is due to the fact that they are not only rapidly available for the transplantation but that they remain easily accessible during the posttransplantation course for eventual further stem cell harvesting, such as a stem cell boost or adoptive cellular therapy.

In contrast to previous reports (Grunebaum, 2006), it has been recently shown in the so far largest cohort study on the outcome of patients with primary immunodeficiencies that in SCID patients the use of a matched unrelated donor does not confer a significant advantage over a haploidentical donor, whereas in the non-SCID patients matched unrelated donors or other identical relatives still show a clear advantage over haploidentical donors (Gennery et al., 2010). Thus, in SCID patients who lack an HLA-identical family member, the treatment of choice is a T-cell–depleted haploidentical transplant from a family member, unless a matched unrelated donor is available very rapidly and the patient's clinical condition is sufficiently stable to allow a delay in HSCT.

The improvement in use of haploidentical stem cell donors has been made possible through major advances in graft manipulation, (Handgretinger, 2008). Following the leads from his own work in mice (Reisner et al., 1978) and from Muller-Ruchholtz et al.'s (1976) work in rats, Reisner et al. (1983) demonstrated in the early 1980s that removal of most mature T cells from half-matched parental marrow allowed successful immune reconstitution of human infants with SCID by the remaining cells without subsequent GVHD. Since that time, this principle has successfully been applied many times to the treatment of SCID (but not as successfully to other primary immunodeficiency diseases) (Table 60.2; adapted from Gennery et al., 2010) (Antoine et al., 2003; ; Buckley, 2011; Buckley et al., 1986, 1999; Dror et al., 1993; Fischer et al., 1986; Giri et al., 1994; Moen et al., 1987; O'Reilly et al., 1986; Stephan et al., 1993; Wijnaendts et al., 1989).

The option to use a haploidentical donor, however, virtually ensures that all infants with SCID can benefit from HSCT. Usually a mother or father (rather than a sibling) is the donor, since the volume of marrow donation required is much larger for this type of transplant. In SCID patients with persistence of transplacentally transferred maternal T cells, a mother is often a better donor than a father, unless there are health issues that preclude the use of the mother (i.e., if she is pregnant or positive for HIV or hepatitis B antigen). In the remaining patients, the donor choice should take into consideration the number of shared HLA antigens, CMV and EBV positivity, as well as the age and number of preceding pregnancies, which may increase the risk of GVHD (Atkinson, 1986; Loren, 2006).

One condition in which a haploidentical transplant is expected to have no benefit is the complete DiGeorge syndrome, where T-cell–depleted marrow cells will be ineffective to restore T-cell immunity, since there is no thymus to promote the thymus-dependent T-cell differentiation of donor stem cells. The reported successful outcome after unfractionated HLA-identical marrow transplants into complete DiGeorge patients is due to the adoptive transfer of mature T cells that were "educated" in the donor's thymus (Goldsobel et al., 1987).

T-CELL DEPLETION METHODS

High transplant-related mortality, due to early and severe GVHD when using T-cell–replete haploidentical bone marrow, was a major obstacle to overcoming HLA barriers and represented an area of intense research in the 1970s. An important milestone was reached when Reisner et al. developed a technique to efficiently remove mature T cells from the graft prior to HLA-mismatched transplantation to prevent GVHD (Reisner, 1978).

Soybean lectin, sheep erythrocyte agglutination. The first technique successfully used for ex vivo T-cell depletion of the donor marrow involves agglutination of most mature marrow cells with soybean lectin, followed by sedimentation of clumped cells and subsequent removal of T cells from the unagglutinated marrow by sheep erythrocyte rosetting and density-gradient centrifugation (Reisner et al., 1983; Schiff et al., 1987). The final cell preparation contains few if any lymphocytes, is phytohemagglutinin (PHA) and mixed leukocyte culture (MLC) nonresponsive, consists of immature myeloid cells and stem cells, and represents less than 5 to 10 percent of the initial number of nucleated marrow cells (Schiff et al., 1987). This method, unlike CD34 selection devices, leaves all other immature marrow cells (including CD34-negative stem cells) available in the cell suspension for use in the transplant. It allows stable immunological reconstitution in SCID patients after haploidentical parental donor transplants and reduces significantly the incidence of acute and chronic GVHD, as observed first by Reisner et al. (1983) in the early 1980s and confirmed by several other groups in the following years (reviewed in (Friedrich, 2010). Newly developed T cells were found to be tolerant to the HLA-haploidentical recipient.

Monoclonal antibody and complement lysis. Another method of depleting postthymic T cells from donor marrow is incubation with monoclonal antibodies to human T cells plus a source of complement (Filipovich et al.; 1984; Reinherz et al., 1982; Waldmann et al., 1984). Antibodies employed for this complement-mediated T-cell depletion have included T12, Leu 1, CT-2, OKT3, and CD52 (Campath-1). T-cell

Table 60.2 TYPE OF IMMUNODEFICIENCY ACCORDING TO DONOR ORIGIN AND HLA MATCHING

depletion is not as effective as with the above approach, possibly due to modulation of T-cell antigens from the surface of the T cells without destroying them. As a consequence, more frequent and severe GVHD has been observed.

CD34+ cell selection by affinity columns. The most common method of T-cell depletion is the use of commercially available antibody affinity columns that positively select for $CD34^+$ cells (Gordon et al., 2002; Handgretinger et al., 2001; Schumm et al., 1999). Further development of this technique resulted in an increased purity of the isolated $CD34^+$ cells and a high degree of depletion of T cells (4.5- to 5-log reduction) and B cells (>3-log reduction) (Handgretinger, 2008). However, in this method, CD34-negative stem cells are discarded, along with other cells that could be important in promoting immune reconstitution, such as dendritic cells. This rigorous T-cell depletion requires no additional pharmacological GVHD prophylaxis. A major concern is the delayed immune reconstitution with the genuine risk of severe viral infections, especially CMV and adenovirus infections.

CD133 selection. Recently, the pentaspan molecule CD133 has been judged to be a marker of more primitive hematopoietic progenitors. Lang et al. (2004) evaluated a CD133-based selection method in 10 pediatric patients given stem cells from matched unrelated (n = 2) or mismatched related donors (n = 8). Engraftment occurred in all patients (sustained primary, n = 8; after reconditioning, n = 2). No primary acute GVHD of a magnitude greater than grade II or chronic GVHD was observed.

CD3/CD19 depletion. This innovative graft engineering of peripheral stem cells is based on depletion of $CD3^+$ T cells and $CD19^+$ B cells by negative selection, thus allowing NK cells, monocytes, and dendritic and myeloid cells to remain in the graft (Handgretinger, 2008). This technique, which should yield cell suspensions more comparable to the soy lectin method, has been used so far especially in children

with hematological malignancies; early studies indicate that patients with primary immunodeficiency may also benefit from this method.

Unfractionated, matched unrelated adult marrow. Most patients with primary immunodeficiency will not have an HLA-identical sibling donor, and matched unrelated marrow donors (MUDs) are now widely used, especially in non-SCID patients, who do not require urgent transplantation. As humans are an outbred population, the matching is unlikely to be perfect (Tiercy et al., 2000) for matched unrelated adult bone marrow or unrelated cord blood. Minor locus histocompatibility antigen differences are also much more likely to be present than in the related donor setting, resulting in a higher probability of GVHD. Another important drawback with using MUD adult donors is that it takes approximately 4 months (6 weeks to 12 months) to identify an unrelated adult donor.

Cord blood. One rich source of hematopoietic stem cells for transplantation is unfractionated cord blood (Wagner et al., 1995). Part of the rationale for using cord blood is that the incidence and severity of GVHD appears to be lower with MUD cord blood than with MUD adult unfractionated marrow transplants, even in the presence of one or two HLA antigen mismatches (Barker & Wagner, 2002; Wagner et al., 2002). However, well-matched cord blood units should be preferred, as GVHD contributes to a poorer outcome, especially in immunodeficient patients with preexisting viral infections. The fact that it generally takes less time to locate a matched cord blood unit than an adult MUD may privilege the use of unrelated umbilical cord blood over MUD in patients with immunodeficiencies. The efficacy of unrelated cord blood transplants with regard to immune reconstitution has been documented in several series (Bhattacharya, 2005; Frangoul, 2010). Several groups have also reported successful cord blood transplantation from HLA-identical siblings in patients with genetic disorders, including immunodeficiencies (Barker & Wagner, 2002; Grewal et al., 2003; Stary et al., 1996; Vowels et al., 1993; Wagner et al., 1995, 2002). Affecting the success rate of cord blood transplants is the number of nucleated cells present in the unit, especially the number of $CD34^+$ cells: it has been shown that at least 1.7×10^5 $CD34^+$ cells per kilogram recipient body weight are needed (Wagner et al., 2002). In addition, there may be a much longer period of thrombocytopenia following cord blood transplants than after HLA-identical unfractionated marrow transplants (Thomson et al., 2000).

Most of the current protocols for cord blood transplantation call for pretransplant conditioning, regardless of the underlying genetic diagnosis of the patient. Successful umbilical cord transplantation has, however, been achieved in some SCID patients without pretransplant conditioning (Toren et al., 1999). GVHD prophylaxis is routinely given after transplants from unrelated cord blood donors. The conditioning and GVHD prophylaxis both contribute to a long period of immune impairment posttransplantation, which is self-defeating if the goal of transplantation is immune reconstitution. Control of viral infections may also be a concern, as cord blood lacks viral-specific cytotoxic T cells, and immune reconstitution is slower than following HSCT with replete marrow, resulting in delayed viral clearance. Furthermore, the nonavailability of the original donor for a boost may be another disadvantage of unrelated cord blood transplantation. Ex vivo expansion methods of cord blood progenitor cells prior to stem cell transplantation are under evaluation.

FETAL LIVER CELLS AS A STEM CELL SOURCE

Anecdotal cases have been reported using fetal liver cells to effect immune reconstitution in SCID (Keightley, 1975). Subsequent series of fetal liver cell transplantations in a larger number of patients confirmed the potential of these cells to correct T-cell immunodeficiency, but durable engraftment was achieved in less than 30 percent of the patients, and it can be speculated that (in the absence of conditioning prior to transplantation) the observed donor T lymphocytes derived from committed lymphoid progenitors rather than from engrafted hematopoietic stem cells (Rappeport, 2010).

IN UTERO BMT

The availability of early prenatal diagnosis for several primary immunodeficiencies offers the option of in utero treatment. Two infants with γ_c-deficient SCID received $CD34^+$ paternal stem cells intraperitoneally during the first half of gestation and developed immune function postnatally (Flake et al., 1996; Wengler et al., 1996). Previous experience with in utero treatment had not been very successful (Touraine, 1996). Since then, a number of in utero transplantations for immunodeficiencies have been performed (reviewed in (Muench, 2005). The major concern is that in utero transplantation necessitates invasive procedures on the fetuses, and on more than one occasion. Furthermore, there is always the risk of GVHD or of a GVG reaction because of the likely presence of transplacentally transferred maternal T cells. If either GVG or GVHD occurs, there is no way of detecting or treating it; thus, fetal wastage could be a consequence. Benefits of in utero transplantation over immediately postnatal transplantation in settings where parents do not wish pregnancy termination following prenatal SCID diagnosis have to be carefully assessed. In utero BMT obviously may reduce the risk of infectious complications. On the other hand, early postnatal haploidentical BMT in SCID offers excellent results, as it has been found to be successful in more than 94 percent of cases (Buckley, 2004; Buckley et al., 1999; Myers et al., 2002; Buckley, 2011). This makes it difficult to justify the risk to the fetus associated with in utero transplantation procedures, for which an overall survival rate of only 64 percent has been reported (Muench, 2005). To date, in utero transplantation is thus not generally recommended in families with a known risk for SCID. Immediate diagnosis at birth through newborn screening (Buckley, 2012) and prompt transfer to an experienced center performing stem cell transplantation for immunodeficiency remains the treatment of choice

GRAFT REJECTION AND GVHD

Unlike solid organ transplantation, allogeneic marrow transplantation is complicated not only by the possibility of graft rejection by the recipient, but also by the potential of immune cells in the transplanted marrow to react against the recipient (i.e., causing GVHD).

Prevention of graft rejection. As noted above, immunosuppressive and myeloablative agents used to prevent graft rejection must be given *prior* to the infusion of marrow cells to avoid injury to the donor cells. In transplant recipients with some potential to reject grafts, factors influencing the likelihood of engraftment of donor marrow cells are (1) the degree of immunocompetence of the recipient, (2) the degree of MHC disparity between donor and recipient, (3) the degree of presensitization of the recipient to the histocompatibility antigens of the donor, (4) the number of stem cells administered, (5) the type of conditioning regimen given the recipient, and (6) whether or not T-cell–depletion techniques are used. Initially, total body irradiation (TBI) was used to prepare non-SCID immunodeficiency patients for BMT, but it was later recognized that TBI could be safely replaced by busulfan at dosages (16–20 mg/kg total) that did not produce comparable adverse late effects (Blazar et al., 1985). This is due to the fact that preparation of the recipient needs only be directed at immunosuppression and "spacing" (i.e., making room in the marrow for donor cells). Concerns were the reduced bioavailability of the oral busulfan in young patients (below the age of 2 to 4 years) (Blazar et al., 1985; Vassal et al., 1993) and the observation of a high variability of busulfan disposition among young children (by a factor of 6) (Vassal et al., 1993). These results demonstrate the need for an individual, close adjustment of busulfan in infants and young children. A major achievement was the introduction of an intravenous form of busulfan and the development of busulfan plasma-level monitoring and dose adjustment at the individual level (Bartelink, 2009; Vassal, 2008). The drug can also be given only once or twice a day (Bartelink, 2008; Bostrom et al., 2003; Dalle et al., 2003; Fernandez et al., 2002). Until recently, there was a general consensus on the use of 8 to 16 mg/kg busulfan and 200 mg/kg cyclophosphamide with or without antithymocyte globulin (ATG) as a conditioning regimen in non-SCID immunodeficiency in the setting of HLA-identical BMT (Parkman, 1991). Concerns on the toxicity of this conditioning regimen, especially with regard to the development of veno-occlusive disease (VOD) in small infants, led to the introduction of fludarabine-based regimens in association with busulfan with or without serotherapy (ATG or Campath H1), which have already been used successfully in HSCT for nonmalignant pediatric diseases (Jacobsohn, 2004). This conditioning allows stable engraftment in immunodeficient patients with a geno- or phenol-identical donor, but not in non-SCID patients receiving a T-cell–depleted haploidentical graft (unpublished experience of the group of Alain Fischer). In latter cases, the addition of thiotepa (10–15 mg/kg) allows engraftment without inducing an exaggerated toxicity. So far, the results of the busulfan/fludarabine-based regimen are encouraging, and a decrease in toxicity with regard to VOD has been observed. Other European centers prefer fludarabine/treosulfan-based conditioning (Slatter, 2011).

NONMYELOABLATIVE CONDITIONING REGIMENS

The interest of myeloablative conditioning lies in the prevention of rejection by removing host-versus-graft reactivity, creating marrow space, and if necessary eradicating malignant cells. In this setting, a full chimerism is often achieved in the early posttransplant period. In HSCT for genetic disorders other than SCID, myeloablative doses of cytoreductive agents are used to eradicate genetically abnormal stem cells before allogeneic transplantation. In patients with preexisting organ damage and infections, significant morbidity and mortality may be observed after traditional myeloablative conditioning regimens employing busulfan and cyclophosphamide or irradiation. Therefore, there has been increasing interest in developing conditioning regimens that are less toxic (Barta et al., 2001; Feinstein et al., 2001; Gaspar et al., 2002; Horwitz et al., 2001; Mielcarek et al., 2002; Nagler et al., 1999; Pulsipher & Woolfrey, 2001; Woolfrey et al., 2001;Satwani et al 2008).

Nonmyeloablative regimens may be an attractive alternative for patients with primary immunodeficiencies in whom the eradication of malignancy is not required. Immune deficiency syndromes are examples of disorders that primarily affect a single lineage, such as the lymphoid or myeloid lineages. Therefore, unlike in malignant disease, a complete donor chimerism is not necessary to cure the disease, as reconstitution of an unaffected lineage is not required and for most immunodeficiencies, a mixed chimerism is sufficient to achieve immune reconstitution.

The introduction of the first nonmyeloablative conditioning regimens was based on the hypothesis that the donor T cell itself participates in the creation of its own marrow niche through a subclinical GVH reaction directed toward recipient hematopoietic cells, thus avoiding the need for myeloablative conditioning and improving the immediate and long-term outcome of the patient through less toxicity (Slavin, 1998). Nonmyeloablative conditioning regimens using fludarabine, ATG, and low-dose busulfan (8 mg/kg) have shown that intense immunosuppression can be sufficient to establish full or partial donor chimerism and that full myeloablation is not required for creation of marrow space. They are also referred to as "reduced-intensity conditioning" (RIC), and they produce significantly less toxicity while allowing partial or full chimerism in most patients (Slavin, 1998).

In contrast to these RIC regimens (Slavin, 1998), which still contain myeloablative molecules like busulfan or melphalan but at a reduced dose, "minimal intensity conditioning" (MIC) regimens are based on immunosuppressive agents and are truly nonmyeloablative. As they rely on graft-versus-marrow effect to create marrow space, graft rejection may occur in certain patients; however, graft rejection is less of an obstacle in patients with immunodeficiency. There is also concern that MIC regimens might be associated with an increased GVHD risk (Veys, 2010). The different approaches

of reduced-intensity transplantation have recently been reviewed by Veys (2010); his group was also the first to report the combination of fludarabine, melphalan, and ATG (FMA) in eight patients with immunodeficiencies (SCID and non-SCID patients with significant comorbidities before HSCT), seven of whom were surviving with donor cell engraftment 8 to 17 months after transplant (Amrolia, 2000). Since then, an overall survival of 82 percent was reported in a large series of 113 patients who had undergone nonmyeloablative conditioning between 1998 and 2006 (93 RIC and 20 MIC) (Satwani, 2008). 18 patients presented with an important pretransplant organ toxicity and 81 percent had stable donor engraftment.

Although nonmyeloablative regimens are significantly less cytotoxic than high-dose alkylating agents and TBI, they are profoundly immunosuppressive. Thus, viral infections/reactivations (including CMV, adenovirus, and EBV) remain clinical obstacles when nonmyeloablative stem cell transplants are performed. GVHD prophylaxis with cyclosporine and methotrexate, with added mycophenolate mofetil in some cases, has been necessary because GVHD is common following nonmyeloablative transplantation.

Special attention has to be paid to the choice of the conditioning regimen for radiosensitive SCID patients who present with increased sensitivity to ionizing radiation. In consequence they also display increased sensitivity to alkylator-based chemotherapy, which has been traditionally used prior to HSCT. The development of novel nontoxic conditioning regimens for patients with intrinsic radiosensitivity and chemosensitivity will be a challenge for the future, with a potential benefit not only for radiosensitive SCID patients but also for other immunodeficient patients undergoing HSCT (Dvorak, 2010).

Use of anti-CD52, Campath 1, monoclonal antibody in vivo. It has become common practice to include the in vivo administration of alemtuzumab (anti-CD52, Campath 1) in reduced-intensity or conventional pretransplant ablation protocols for patients who are receiving peripheral blood stem cell transplants. While this approach has been effective in controlling GVHD and improving engraftment, there were concerns about a longer period of immunodeficiency posttransplantation (Chakrabarti et al., 2004) and about the development of lethal lymphoproliferative disease (Snyder et al., 2004). Although alemtuzumab-based T-cell–depleted allogeneic HSCT seems to be associated with a high frequency of EBV reactivation, it has been shown recently that the risk of post-transplant lymphoproliferative disorder is low (<1 percent) when using a strategy of preemptive rituximab therapy (Carpenter, 2010). Patients need to be carefully monitored for infection/reactivation of viruses.

GVHD

GVHD is the major barrier to widespread successful application of BMT for the correction of many diseases (Deeg & Henslee-Downey, 1990; Ferrara, 2009; Ferrara & Deeg, 1991; Glucksberg et al., 1974; Martin et al., 1987; Parkman, 1991; Reddy, 2009).

PATHOPHYSIOLOGY OF GVHD

Acute GVHD reflects an exaggerated but normal inflammatory response of donor T cells to host antigens (Ferrara, 2009), especially the highly polymorphic HLAs, which are encoded by the MHC. Therefore, the incidence of acute GVHD is directly related to the degree of HLA disparity between the donor and the recipient. However, despite HLA identity between patient and donor, approximately 40 percent of recipients of HLA-identical grafts will still develop acute GVHD due to genetic differences in "minor" histocompatibility antigens.

The complex interplay between the donor and host innate and adaptive immune responses leading to GVHD (recently reviewed by Choi, 2010; Ferrara, 2009; and Paczesny, 2010) can be divided in three different phases (Reddy, 2003). In the first phase, antigen-presenting cells (APCs) are activated by the underlying disease, prior infections, and the transplant conditioning regimen, leading to tissue injury in the recipient (Ferrara & Deeg, 1991) with subsequent release of proinflammatory cytokines (Sorror, 2004). Increased levels of TNF-α receptor I, a surrogate marker for TNF-α, 1 week after HSCT, strongly correlated with the later development of GVHD (Choi, 2008). Damage to the gastrointestinal tract from the conditioning may lead to systemic translocation of additional inflammatory molecules that further enhance the activation of host APCs (Hill, 2000). The second step involves donor T-cell activation, proliferation, differentiation, and migration in response to host APCs.

The effector phase of acute GVHD involves both cellular (such as cytotoxic T lymphocytes and NK cells) and soluble inflammatory mediators (such as TNF-α, IFN-γ, IL-1, and nitric oxide) (Ferrara & Deeg, 1991). The complex interplay between these soluble and cellular mediators amplifies local tissue injury and further promotes inflammation and target tissue destruction (Ferrara, 2009).

In contrast to acute GVHD, the pathophysiology of chronic GVHD is poorly understood (Ferrara, 2009), and there are limited data specific to pediatrics (Baird, 2010). Historically, alloreactive donor T cells have been thought to be the primary factor implicated in chronic GVHD. However, the role of direct T-cell–mediated allogeneic immune responses in cGVHD is not clear, and there is no strong correlation between the number of minor histocompatibility antigen-specific T cells and chronic GVHD (Baird, 2010).

Acute GVHD. The three main organs subject to acute GVHD are the skin, the liver, and the gastrointestinal tract. In a comprehensive review, Martin et al. (1990) found that at the onset of acute GVHD, 81 percent of patients had skin involvement, 54 percent had involvement of the gastrointestinal tract, and 50 percent had liver involvement. Experimental data suggest that the lungs might also be targets of acute GVHD (Cooke, 1996). Acute GVHD begins usually 6 or more days posttransplantation (or posttransfusion in the case of nonirradiated blood products) (Anderson & Weinstein, 1990) with high unrelenting fever, a morbilliform maculopapular erythematous rash, and/or severe diarrhea (Glucksberg et al., 1974). The rash becomes progressively confluent and may

involve the entire body surface; it is both pruritic and painful and eventually leads to marked exfoliation. Eosinophilia and lymphocytosis may develop, eventually followed by hepatosplenomegaly, abnormal liver function tests, and elevation in blood conjugated bilirubin levels. The diarrhea is watery and voluminous and may become bloody as the disease progresses. Nausea, vomiting, and severe cramping abdominal pain can occur as a consequence of the gastrointestinal involvement, which is accompanied by a protein-losing enteropathy. The latter contributes to marked generalized edema ("third-spacing") seen in more severe acute GVHD. The most severe forms of acute GVHD are also characterized by bone marrow aplasia, marked susceptibility to infection (Gratama et al., 1987; Parkman, 1991; Skinner et al., 1986), and death in a high proportion of cases.

GVHD is usually mild and self-limited in SCID hosts who receive unfractionated HLA-identical marrow (Parkman, 1991). However, historically, GVHD was found to be moderate to severe despite HLA identity in 60 percent of recipients given pretransplant irradiation or immunosuppressive drugs, and it was fatal in 15 to 20 percent (Deeg & Henslee-Downey, 1990; Glucksberg et al., 1974; Martin et al., 1987). The severity of GVHD increases with the recipient's age (Parkman, 1991; Storb et al., 1986), the use of HLA-matched unrelated donors, and, if a related donor is not HLA-identical, with the degree of genetic disparity.

The staging of acute GVHD is based on the severity and number of organ systems involved. The initial grading criteria were developed by Glucksberg in 1974 (Glucksberg et al., 1974). Most pediatric centers have adopted the modified Glucksberg grading scale (Przepiorka, 1995), which takes into consideration the staging of the GVHD of the gastrointestinal tract based on volume per kg of body weight. The overall grades are classified as I (mild), II (moderate), III (severe), and IV (very severe):

- *Grade I:* 1+ to 2+ skin rash without gut involvement and with no more than 1+ liver involvement
- *Grade II:* 1+ to 3+ skin rash with either 1+ to 2+ gastrointestinal involvement or 1+ to 2+ liver involvement or both
- *Grade III:* 2+ to 4+ skin rash with 2+ to 4+ gastrointestinal involvement with or without 2+ to 4+ liver involvement. Decrease in performance status and fever also characterize grades II and III, with increasing severity per stage.
- *Grade IV:* The pattern and severity of GVHD is similar to those in grade III, with extreme constitutional symptoms.

Chronic GVHD. Historically, GVHD is termed *chronic* when it occurs after 100 days posttransplant. As this arbitrary definition does not consider the clinical manifestations, there is current consensus that clinical features (rather than the timing of their occurrence) should guide the classification in acute, chronic, or "overlap syndrome." Criteria for the diagnosis and staging of chronic GVHD have been proposed by the National Institutes of Health (NIH) Consensus Development Project (Filipovich, 2005).

Chronic GVHD may evolve from acute GVHD (progressive type), develop after resolution of acute GVHD (quiescent or interrupted type), or occur de novo. An overlap syndrome is defined by the concomitant presence of clinical features of acute and chronic GVHD (Choi, 2010). Characterized by a combination of auto- and allo-immune dysregulation with significant immune deficiency, chronic GVHD is an important complication after allogeneic HSCT (Lee, 2003). It is it also the major cause of late mortality in HSCT patients and accounts for significant morbidity (Jacobsohn, 2010).

Although the incidence of chronic GVHD tends to be lower in children (20–50 percent) than in adults (60–70 percent), an increase has been observed in children recently due to the larger use of peripheral blood stem cells and the increased age of transplant recipients (Choi, 2010; Lee, 2003). In children, the rates of chronic GVHD vary from as low as 6 percent in matched sibling cord blood transplants (Rocha, 2000; Wagner, 1995) and 15 percent in recipients of HLA-matched sibling bone marrow transplants (Rocha, 2000) to as high as 65 percent in MUD peripheral blood stem cell transplants (Meisel, 2007). Predisposing factors for the development of chronic GVHD include preceding acute GVHD, older recipient age, male recipient of a female donor graft (in particular if the donor is multiparous), and, as mentioned above, the use of peripheral blood stem cells (Lee, 2003; Zecca, 2002).

Chronic GVHD can affect most organs of the body, most commonly the skin. To confirm the diagnosis of chronic GVHD, at least one distinctive manifestation for chronic GVHD is required, such as oral or vaginal lichenoid findings, ocular sicca, skin dyspigmentation, scleroderma, or bronchiolitis obliterans. Skin lesions of chronic GVHD resemble scleroderma, with hyperkeratosis, reticular hyperpigmentation, atrophy with ulceration, and fibrosis and limitation of joint movement. The gastrointestinal tract, lungs, joints, and liver can be affected as well (Choi, 2010). Chronic GVHD remains a major source of morbidity, decreased quality of life, and mortality in children receiving HSCT. However, it is hoped that the development of new assessment tools and therapies will improve the outcome for children.

Prevention of GVHD. The best approach to GVHD is prevention. Ex vivo T-cell depletion from the donor marrow or blood is the most effective means of limiting both acute and chronic GVHD, but at the cost of serious side effects (such as graft rejection, delayed immune reconstitution, life-threatening infections, and EBV-associated lymphoproliferative disorders). In vivo T-cell depletion uses alemtuzumab, a monoclonal antibody specific for CD52 antigen, which is abundantly expressed on the surface of lymphocytes (Barge, 2006; Kottaridis, 2000), or ATG, a polyclonal antibody (of either horse or rabbit origin) directed against various human T-cell epitopes (Bacigalupo, 2001).

For patients receiving pretransplant chemotherapy prior to unfractionated HLA-identical marrow transplants, GVHD prophylaxis is necessary. The most widely used primary GVHD prophylaxis following full myeloablative conditioning was initially described in 1986 (Storb et al., 1986) and is based on

cyclosporine A associated with a short course of methotrexate (15 mg/M^2 on the first day posttransplantation and 10 mg/M^2 on days 3, 6, and 11). In subsequent years, large randomized studies compared the association of cyclosporine/methotrexate versus tacrolimus/methotrexate and showed no overall survival advantage despite a reduced incidence of grade II to IV acute GVHD with tacrolimus (Horowitz, 1999; Nash, 2000; Ram, 2009). Cyclosporine and tacrolimus are both calcineurin inhibitors impeding the function of the cytoplasmic enzyme calcineurin, which is critical for T-cell activation.

Sirolimus, initially used in solid organ transplantation, has become an attractive alternative prophylactic agent due to its nonoverlapping toxicities with calcineurin inhibitors and the different mechanisms of action (Choi, 2010). GVHD prophylaxis based on the combination of tacrolimus and sirolimus results in rapid engraftment, a reduced incidence of acute GVHD and transplant toxicity, and improved survival (Cutler, 2007).

GVHD prophylaxis in the setting of RIC is based on the association of a calcineurin inhibitor (such as cyclosporine or tacrolimus) with mycophenylate mofetil (MMF) (Mohty, 2004), the prodrug of mycophenolic acid. MMF selectively inhibits the enzyme inosine monophosphatase dehydrogenase, which is needed for the de novo synthesis of guanosine nucleotide and consecutively T-cell proliferation (Choi, 2010). In patients receiving cord blood transplantation, MMF is also often preferred to methotrexate because of the reduced toxicity with regard to neutropenia and mucositis (Choi, 2010).

TREATMENT OF GVHD

Once acute GVHD develops, adequate and timely treatment is necessary irrespective of conditioning. Systemic corticosteroids are widely used as initial treatment, and the primary response to the first-line treatment of acute GVHD remains the most important predictor of long-term survival (Levine, 2010; Weisdorf et al., 1990); efficient treatment is more and more difficult with increasing severity of GVHD. In addition to the above-mentioned drugs, anticytokine and anticytokine receptor antibodies have also been employed to mitigate GVHD (Deeg & Henslee-Downey, 1990); the most useful of these have been antibodies to the IL-2 receptor (anti-CD25) (Srinivasan et al., 2004).

Despite a variety of immunosuppressive and immunomodulatory drugs and second-line treatments, there is no consensus on standard treatment for acute and/or chronic GVHD, and the therapeutic approach is often tailored to the patient and his or her comorbidities. To discuss the numerous treatment options is beyond the scope of this work. Several recent reviews outline the management of GVHD in children (Choi, 2010), with regard to acute (Jacobsohn, 2008) and chronic GVHD (Baird, 2010; Jacobsohn, 2010). Preemptive treatment strategies and innovative approaches aiming at immunomodulation rather than at immunosuppression are needed to ultimately improve long-term outcome in GVHD.

SEQUELAE OF PRETRANSPLANT CHEMOTHERAPY FOR BMT

VOD. VOD is a major cause of mortality following conditioning regimens based on cytoreductive agents, which damage the hepatic vascular endothelium (Eltumi et al., 1993; McDonald et al., 1985). Diagnosis of VOD according to McDonald's criteria requires two of the following: hyperbilirubinemia, hepatomegaly and/or right upper quadrant pain, and weight gain with or without ascites. Distinguishing VOD from other causes of liver damage can be difficult after BMT, particularly when thrombocytopenia poses an unacceptable risk for diagnostic percutaneous liver biopsy in the early posttransplant period. Most often the diagnosis will be made on clinical criteria; however, serum concentrations of the aminopropeptide of type III procollagen (PIIINP) above a standard deviation score of 8 have been predictive of VOD and similarly useful in the diagnosis and monitoring of this condition (Eltumi et al., 1993; Ho, 2008; Pihusch, 2005).

In addition to hepatic damage caused by use of chemotherapeutic agents for pretransplant conditioning, such agents can also result in considerable pulmonary toxicity posttransplantation, leading to prolonged oxygen dependency and to pulmonary arterial hypertension. Often this problem is difficult to distinguish from delayed-onset pulmonary complications involving both the airway and lung parenchyma, which are also observed frequently after HSCT. They include infectious complications in the immunocompromised host (such as CMV pneumonia) but also noninfectious late complications like bronchiolitis obliterans (BO), bronchiolitis obliterans organizing pneumonia (BOOP), and idiopathic pneumonia syndrome (IPS).

Defibrotide, a single-stranded polydeoxyribonucleotide with antithrombotic and fibrinolytic effects on microvascular endothelium, had shown therapeutic efficacy upon early intervention for VOD in a pediatric retrospective multicenter study (Corbacioglu, 2004). Two pediatric nonrandomized studies on the efficacy of defibrotide showed that the VOD incidence and severity were reduced in the defibrotide group compared to a historical control group, suggesting that defibrotide might be effective in preventing and treating VOD (Corbacioglu, 2006; Qureshi, 2008). Randomized trials are now required to definitively establish the role of defibrotide.

Growth retardation and hormonal disturbances. Growth retardation and hormonal disturbances frequently occur in children who are long-term survivors after HSCT for malignancies, who were given specific chemotherapy prior to pretransplant conditioning (Clement-De Boers et al., 1996; Ranke, 2005). In this setting, sterility is common (Sanders, 1996). There are fewer long-term data available for patients who received HSCT for inborn errors of the immune system. In 149 SCID patients treated by allogeneic HSCT between 1972 and 2004 at Necker Hospital, Paris, France (Neven, 2009), showed that 15 percent of the 94 long-term survivors presented with growth failure, with a weight and height below 2 standard deviations at some point in their follow-up longer than 2 years after HSCT. Concomitantly, significant clinical events (such as autoimmune and inflammatory complications

or chronic GVHD) were noted in all but one of these patients, and growth failure improved with resolution of the concomitant clinical events in all but one. No growth-hormone deficiency was found in the analyzed patients, whereas thyroid-hormone deficiency was found in 2 patients. In only 3 of the 39 patients aged older than 15, adult weight or height were below –2 standard deviations. All patients aged 15 and older have completed clinically normal pubertal development (Neven, 2009).

IMMUNE RECONSTITUTION AFTER BMT

BMT for SCID

BMT has been more widely applied and was more successful in infants with SCID than in any other primary immunodeficiency (Antoine et al., 2003; Buckley, 2004, 2011; Buckley et al., 1999; Friedrich, 1996; Gennery et al., 2010; Haddad et al., 1998). Since the first such transplant was done, more than 1,200 patients with SCID worldwide have received transplants of HLA-identical or haploidentical bone marrow or of unrelated marrow or cord stem cells (Antoine et al., 2003; Buckley, 2011; Cowan, 2008; Gennery et al., 2010; Grunebaum, 2010; Neven, 2009).

A recent survey of the European Group for Blood and Marrow Transplantation and the European Society for Immunodeficiency reported on 699 infants with SCID who had received BMT from 1968 to 2005 (Table 60.2). The proportions of the different genetic forms of SCID remained stable over time. Two hundred three patients had received transplants from a genotypically (135) or phenotypically (68) HLA-identical relative and 81 from a MUD, whereas 415 had received T-cell–depleted haploidentical related transplants (Gennery et al., 2010; Fig. 60.1).

The preceding European report on 566 transplantations in 475 SCID patients during the period from 1968 to 1999 showed that the 3-year survival with sustained engraftment was significantly better after HLA-identical than after mismatched transplantation (77 percent vs. 54 percent ; $p = 0.002$) (Antoine et al., 2003). These findings were in line with previously published survival rates for SCID patients receiving transplants at the two largest centers in Europe, Hopital Necker in Paris (Stephan et al., 1993) and the University of Ulm (Friedrich et al., 1993): 80 percent for HLA-identical unfractionated marrow recipients and approximately 55 percent for recipients of haploidentical, T-cell–depleted marrow. Similar survival statistics had also been reported by SCID transplant centers in the United States (Dror et al., 1993; O'Reilly, 1991; O'Reilly et al., 1986).

The most recent European data show that the survival continues to improve over time, reaching a survival rate of about 90 percent for transplantations for patients with SCID when using a geno-identical sibling donor (Gennery et al., 2010). The outcome for selected patients (newborns without any preexisting infection) is even better (Brown, 2011; Myers et al., 2002), underlining the fact that neonatal screening for SCID may significantly improve the outcome for SCID patients (Buckley, 2012). One of the most significant findings

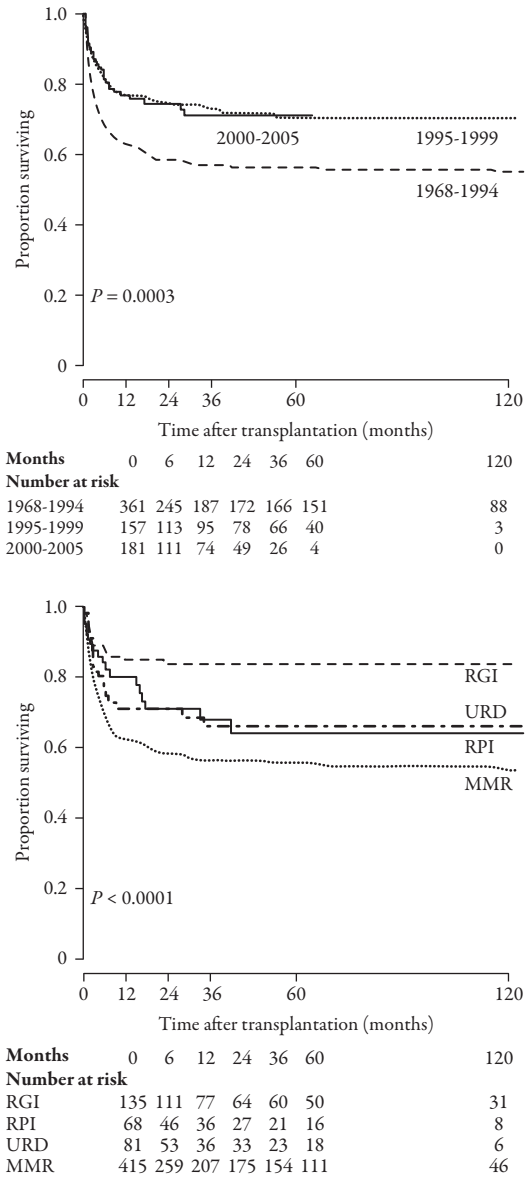

Figure 60.1 Cumulative probability of survival in patients with SCID after HSCT according to to the period in which transplanted, donor source (related or URD), HLA matching. MMR, Mismatched related; RGI, related genoidentical; RPI, related phenoidentical and whether B cells were present or absent in the SCID patients. (From Gennery et al, *J Allergy Clin Immunol* 126(3):602-10, 2010, with permission)

from this European investigation was that there is no longer a significant advantage for a MUD over an HLA-mismatched related donor for SCID patients transplanted between 2000 and 2005, with 3-year survival rates of almost 70 percent in both cases (69 percent for MUD vs. 66 percent in mismatched related donor). This is in contrast to previous reports that showed a clear survival advantage for MUD over haploidentical donors in SCID recipients (survival rate of 80.5 percent vs. 52.5 percent respectively) (Grunebaum, 2006), and it is due to the improved survival of the patients with haploidentical donors, thus enabling clinicians to proceed rapidly to transplantation even if there is no geno- or pheno-identical familial donor. The number of MUD transplants increased over time:

while only 28 patients with SCID were reported in the former European series as having received MUD transplants between 1968 and 1999, and 63 percent were surviving (Antoine et al., 2003), there were 46 MUD transplants in the period from 1999 to 2005, and 69 percent were surviving (Gennery et al., 2010). The steady improvement over time in the survival rates of SCID transplant recipients is most likely due to early diagnosis (Figure 60.3) and more effective prevention or treatment of disease-related and transplantation procedure complications, notably infections and GVHD. The improvement over time of the HSCT outcome in SCID patients is a major accomplishment, since SCID is 100 percent fatal without transplantation or enzyme replacement therapy, helpful only for ADA deficiency, approximately 16 percent of SCID (Buckley, 2011; Buckley et al., 1997; Stephan et al., 1993).

RHB recently reported the long-term outcome, according to molecular type, of 166 consecutive SCID infants who had received nonconditioned related donor bone marrow transplants at Duke University Medical Center over 28.3 years, the largest single center experience in the world (Buckley, 2011). Age at diagnosis ranged from newborn to 21 months. The grafts were T-cell–depleted in the 149 HLA-haploidentical and also in 9 of the 17 HLA-identical transplants. Forty-nine patients received from one to three additional T-cell–depleted marrow transplants, from either the original donor or another haploidentical relative. No pretransplant conditioning or posttransplant GVHD prophylaxis was given, except in two patients who received cyclosporine for 1 month because of cutaneous GVHD from transplacentally transferred maternal T cells at presentation. Five of the infants who received haploidentical marrow transplants were also given unrelated placental blood transplants. Four of the latter received pretransplant conditioning, and they were also given posttransplant prophylaxis against GVHD. The overall survival rate was 76 percent (Figure 60.2). Of the 126 survivors, 125 had survived 1 or more years after transplantation, 110 were alive 5 or more years, and 83 had survived for 10 or more years. Median follow-up of surviving patients was 10 years.

Survival of the 48 infants transplanted during the first 3.5 months of life was significantly higher (94 percent) than the survival of the patients who were transplanted after that age (69 percent; $p = 0.001$). Thirty of the 40 deaths were due to viral infections. GVHD, usually Grade 1 and not requiring treatment, occurred in 45 of the 149 patients given T-cell–depleted haploidentical parental marrow, in 8 of 17 given HLA-identical marrow, and in 4 of 5 given placental blood (Buckley, 2011).

The long-term outcome of immune reconstitution in these patients was reported earlier showing that T cell function, T cell diversity and thymic output continued into the third decade despite the lack of pre-transplant conditioning, supporting the possibility of stem cell engraftment (Sarzotti-Kelsoe et al., 2009). In addition, to determine the long-term clinical outcome, a questionnaire was sent to the parents of the survivors and the patients were also seen in clinical follow-up as well. There were few patients with serious health problems, none with chronic or severe GVHD, few with autoimmune problems, and 86% were considered healthy by their families (Railey et al., 2009). Many had gone to college or graduate school, including one who was in medical school. Four of the survivors had become parents of normal children.

Problems encountered with T-cell–depleted haploidentical transplants. The period of vulnerability to infection is possibly longer in recipients of T-cell–depleted marrow compared to those who receive unfractionated HLA-identical marrow because of the 90 to 120 days required for donor stem cells to develop into T cells in the recipient's thymus (Buckley et al., 1986) and the fact that there are no adoptively transferred donor T cells. However, because patients who receive unfractionated transplants usually receive GVHD immunosuppressive agents for many months posttransplantation, they are also at risk for infection. Prior to the introduction of anti-CD20 antibodies (Rituximab), the occurrence of B-cell lymphoproliferative disease was a major problem with this type of transplantation, whereas it did not usually occur in recipients of unfractionated HLA-identical marrow (Filipovich et al., 1994; Levine, 1994; Shearer et al., 1985; Trigg et al., 1985).

Posttransplant lymphoproliferative disorder (PTLD) caused by EBV has often been fatal in high-risk allogeneic HSCT recipients. The development of monoclonal antibodies and EBV-specific cytotoxic T lymphocytes (CTLs) has considerably improved the treatment options for EBV-PTLD, allowing a balance between outgrowing EBV-infected B cells and the EBV CTL response, or targeting the B cells with monoclonal antibodies or chemotherapy (Heslop, 2009). It has been shown that preemptive therapy with rituximab in children is safe but only partly effective in haploidentical HSCT recipients (Comoli, 2007). Infusion of EBV-specific CTLs can further rescue patients who progress to PTLD under rituximab treatment. A recent review showed that preemptive use of rituximab and EBV-specific CTLs significantly reduced the risk of death due to EBV-PTLD in HSCT recipients, with survival rates of 89.7 percent and 94.1 percent, respectively (Styczynski, 2009).

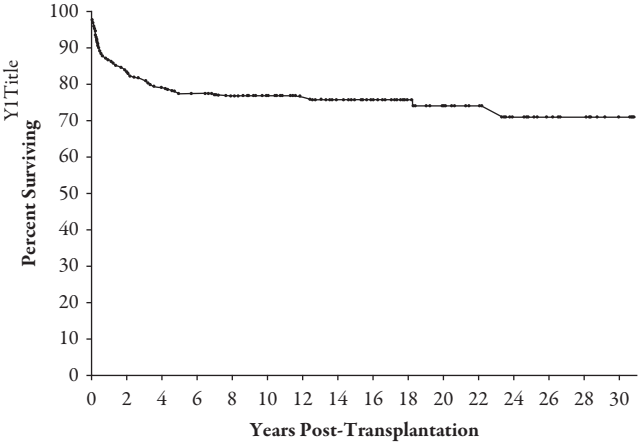

Figure 60.2 Thirty-one year survival (76%) of 173 SCID patients given non-ablated, related donor bone marrow transplants at Duke University Medical Center: 18 HLA-identical, 155 HLA Haploidentical.

Other problems encountered following haploidentical transplants include resistance to engraftment and frequent failure to obtain engraftment of donor B cells or to develop B-cell function. The first author (R.H.B.) has attempted to overcome both of the latter two problems by performing nonablative "booster" transplants. A study was conducted of 49 SCID patients (28.7 percent of 171 SCIDs transplanted over 30 years) who had received booster transplants to define the long-term outcome, factors contributing to a need for a booster and factors that predicted success (Teigland et al., 2013). Of the 49 patients, 31 (63 percent) are alive for up to 28 years. Age at initial transplantation was found to have a significant effect on outcome (mean of 194 days old for living patients, versus a mean of 273 days old for deceased patients, $p = 0.0401$). Persistent viral infection was present in most deceased booster patients. In several patients, the use of two parents as sequential donors resulted in striking T and B cell immune reconstitution. A majority of the living patients have normal or adequate T-cell function and are healthy. The development of adoptive immunotherapies or novel approaches to accelerate de novo thymopoiesis is currently receiving much attention (Reimann, 2010). Strategies to hasten posttransplant immune reconstitution without triggering GVHD such as the recently reported adoptive transfer of regulatory T cells in haploidentical recipients, which was shown to be able to prevent GVHD, promote lymphoid reconstitution, and improve immunity to opportunistic infections (Di Ianni, 2011).

Kinetics of development of immune function. The time to development of immune function following haploidentical stem cell grafts is quite different from that after unfractionated HLA-identical marrow. In contrast to the rapid emergence of immune function within 2 weeks after the latter type of grafts due to adoptive transfer of donor T, B and NK cells, lymphocytes with mature T-cell phenotypes and functions fail to appear in significant number until at least 3 to 4 months after transplantation of T–cell-depleted marrow (Buckley et al., 1986; Dror et al., 1993; Moen et al., 1987; Wijnaendts et al., 1989). This same result holds true even if pretransplant conditioning is given (Friedrich et al., 1993) or if T-cell–depleted, HLA-identical sibling marrow is used (R.H.B., unpublished). Thus, regardless of whether the donor is HLA-identical or -haploidentical, it takes between 90 and 120 days for stem cells in T-cell–depleted marrow to mature into functioning T cells in SCID infants (Buckley et al., 1986). The reason for this delay is not known, but presumably this is how long thymic maturation of stem cells takes. This period of time is not unlike that in intrauterine life, in which PHA-responsive cells do not appear until around 12 weeks of gestation. The first function to develop after transplantation is NK-cell function. Shortly after NK cells, T-cell function appears, simultaneously with the development of phenotypically normal T cells. Chimerism studies reveal that such T cells are always 100 percent of donor origin (Buckley et al., 1999). Thus, the tiny architecturally abnormal epithelial thymi of all forms of SCID treated thus far appear to have the ability to cause normal stem cells to become phenotypically and functionally normal T cells (Patel et al., 2000; Myers et al., 2002; Sarzotti-Kelsoe et al., 2009). These observations also indicate that the thymic microenvironment of most infants with SCID is capable of differentiating not only fully matched but also half-matched normal stem cells to become mature and functioning T lymphocytes and long-term follow-up studies have shown that this continues even into the third decade post-transplantation (Sarzotti-Kelsoe et al, 2009).

Damage to the thymic epithelium due to pre-HSCT conditioning, viral infections and acute and/or chronic GVHD may cause delayed and incomplete T-cell reconstitution (Cavazzana-Calvo, 2009; Olkinuora, 2011). Genetic analyses of the cells from such chimeric patients have revealed that all T cells are of donor origin, whereas the B cells, antigen-presenting cells, neutrophils, platelets, and red cells remain those of the recipient in a large majority of cases unless pretransplant conditioning is given (Brady et al., 1996; Buckley et al., 1986; Friedrich et al., 1993; Schouten et al., 1988; van Leeuwen et al., 1994; Vossen et al., 1993).

B-cell function develops much less often and some patients fail to develop B-cell function altogether, despite normal T-cell function (Buckley, 2004; Buckley, 2011 ; Buckley et al., 1986, 1999; Dror et al., 1993; Giri et al., 1994; Moen et al., 1987; Neven, 2008; Wijnaendts et al., 1989).

An extensive review of B-cell reconstitution (as presented in 19 reports from the United States and Europe on posttransplantation immune reconstitution in patients with SCID over the most recent two decades) was performed by R.H.B. (Buckley, 2011). The finding was that while the use of pretransplantation chemoablation may result in a higher percentage of B-cell chimerism and function it did not guarantee normal B-cell function, as a significant percentage of patients required long-term immunoglobulin replacement. Moreover, the mortality was much greater at those centers that used pretransplant conditioning.

The first author and her colleagues have recently reported the results of analyses of B cell function in 125 surviving SCID marrow recipients at Duke University Medical Center prior to and long-term after non-ablative BMT, according to their molecular type (Buckley et al., 2013). Studies included blood immunoglobulin measurements; antibody titers to standard vaccines, blood group antigens and bacteriophage Φ X 174; flow cytometry to examine for markers of B cell immaturity, memory, switched memory B cells and BAFF receptor expression; B cell chimerism; B cell spectratyping; and B cell proliferation. The results showed that B cell chimerism was not required for normal B cell function in IL7Rα-Def, ADA-Def and CD3-Def SCIDs. In X-linked-SCID, Jak3-Def SCID and those with V-D-J recombination defects, donor B cell chimerism was necessary for B cell function to develop. Thus, the most important factor determining whether B cell function develops in SCID T cell chimeras is the underlying molecular defect. In some types, host B cells function normally once T cells develop. In those molecular types where host B cell function did not develop, donor B cell chimerism was necessary to achieve B cell function.

BMT FOR IMMUNODEFICIENCIES OTHER THAN SCID

Allogeneic BMT has been found to be effective in conferring improved immune function in an increasing number of genetically distinct immunodeficiencies other than SCID (Tables 60.3 and 60.4) (Buckley & Fischer, 1999; Fischer et al., 1986, 1990, 1994; Friedrich, 1996; Le Deist et al., 1989; Szabolcs, 2010). A recent survey from the European Group for Blood and Marrow Transplantation and the European Society for Immunodeficiency analyzed the outcome of 783 patients with various forms of non-SCID primary immunodeficiencies who had received transplants from 1968 to 2005 (Gennery et al., 2010).

Indications. Indications for BMT in non-SCID primary immunodeficiency obviously depend on a critical assessment of life expectancy, as well as quality of life in a given setting. Disease prognosis alone is not usually sufficient to lead to such a decision. Age, past clinical history, and sequelae of illnesses (chronic viral infection, immunosuppressive treatment required for control of autoimmunity, organ dysfunction), clinical course of previously affected family members, gene mutation determination when available, context of medical care (distance from specialized centers), and psychological assessment of the child and the family are some of the many factors to be taken into consideration when attempting to decide for or against BMT.

As greater experience with BMT has been gained, many of the factors leading to increased mortality and morbidity have decreased with time. It is not appropriate to assess the risks associated with BMT based on results reported in the early 1980s. For instance, in Europe, the rate of success in BMTs performed since October 1985 (up to March 1991) was 81.5, versus 52 percent before October 1985 (Antoine et al., 2003). A specific example is seen in the case of chronic granulomatous diseases, where recent comparisons of conservative treatment versus BMT have led to a change in attitude (see below). Over the past few years, the use of curative HSCT in early childhood has expanded due to the impressive results achieved for matched, unrelated, or cord blood donors after RIC (Seger, 2010). These remarks emphasize the need for careful updating of BMT registries to aid the medical community in making decisions about patients with primary immunodeficiency diseases.

BMT IN NON-SCID IMMUNODEFICIENCIES

BMT has not been as uniformly effective in the treatment of patients with non-SCID T-cell immunodeficiencies as it has in SCID (Fig. 60.4). Such patients have somewhat less severe immune dysfunction than do those with SCID, and this enables them to reject marrow grafts. However, an increasing number of transplants with HLA-identical sibling marrow or matched unrelated adult marrow, peripheral blood stem cells, and cord blood have been successful after chemoablation (Tables 60.3 and 60.4).

The recent survey from the European Group for Blood and Marrow Transplantation and the European Society for Immunodeficiency on 783 non-SCID patients shows an improved 3-year survival for genotypically and phenotypically HLA-identical related donors: 79 percent and 76 percent respectively for the period from 2000 to 2005 compared to 71 percent and 53 percent for the period from 1995 to 1999 and 72 percent and 46 percent for the period before 1995 (Gennery et al., 2010).

Following the improved results with T-cell–depleted HLA-haploidentical BMT for the treatment of SCID, this approach was also tried for the treatment of other lethal immunodeficiency diseases. In contrast to the significant improvement in the survival rate of SCID patients receiving a haploidentical T-cell–depleted graft, which now reaches 66 percent, the outcome of haploidentical HSCT in non-SCID patients is still poor: the 3-year survival was 55 percent in the last European survey for the period from 2000 to 2005 (compared to 41 percent for the period before 2000) (Gennery et al., 2010).

Delay in the development of T- and B-cell function (6–40 months) causes significant infectious complications that remain a major concern in recipient of T-cell–depleted HLA-haploidentical transplants. As discussed above, the development of new immunotherapies may contribute to improve the outcome of high-risk haploidentical transplants in non-SCID patients. Because of the poor outcome of haploidentical grafts, a search for a MUD should be undertaken in the absence of HLA-matched siblings.

Wiskott-Aldrich syndrome (see Chapter 43). This defect is the second most common primary immunodeficiency for which BMT has been applied (for a recent review see Pai,

2010). After only partial correction was achieved with the first BMT given to a WAS patient in 1968 (Bach et al., 1968), full correction was achieved in other WAS patients in 1978 by use of a more effective conditioning regimen (Parkman et al., 1978). Transplantation has since been successful in 85 to 90 percent of patients who had an HLA-identical sibling donor (Tables 60.2 and 60.5) (Brochstein et al., 1991; Ozsahin et al., 1996). In the absence of an HLA-identical donor, T-cell–depleted haploidentical marrow transplants have been tested: Rumelhart et al. (1990) reported success in three of four WAS patients, whereas in another series only one of six survived (Brochstein et al., 1991). MUD bone marrow, peripheral blood, and cord blood transplants have been also successful (Knutsen et al., 2003; Lenarsky et al., 1993; Miano et al., 1998; Pai, 2006).

Table 60.4 IMMUNODEFICIENCES OF THE PHAGOCYTIC SYSTEM CURABLE BY ALLOGENEIC BONE MARROW TRANSPLANTATION

Chronic granulomatous diseases (X-linked and AR)
Leukocyte adhesion deficiency type I
Chediak-Higashi syndrome
Immunodeficiency with partial albinism (Griscelli disease)
Familial hemophagocytic lymphohistiocytosis
Interferon γ receptor deficiencies
Severe congenital neutropenia and other neutropenias (cyclic neutropenia, Shwachmann syndrome)

Recently, Friedrich et al. reported on 39 WAS patients treated by HSCT since 1983 (15 transplants from HLA-identical unrelated donors, 15 from mismatched parental donors, and 9 from matched siblings). The overall survival rate was 90 percent in patients with matched donors and 50 percent in patients after nonidentical transplantation, with a mean follow-up time of 11 years. Treatment failures in the latter group were mainly related to graft rejections and to GVHD and infections following repeat transplants (Friedrich, 2009). Other series have reported an overall survival of 78.2 percent (18/23) in a cohort of 23 WAS patients (including 16 MUD) and a survival of 81.2 percent (13/16) of MUD BMT recipients (Pai, 2006). Other single-center reports show a survival of 69 percent in 13 patients (Munoz, 2007) and a 5-year failure-free survival rate of 65.7 percent in 57 patients (Kobayashi, 2006).

There are also a few reports of the use of unrelated umbilical cord blood stem cell transplantation in patients with WAS (n = 3, Knutsen, 2003; n = 1, Diaz de Heredia, 2008; n = 15, Kobayashi, 2006), showing that unrelated umbilical donor cord blood may be a valid option for children with WAS lacking an HLA-identical sibling donor.

Due to the rarity of this disorder, multicenter studies are mandatory to accurately evaluate the outcome with regard to the different donor sources. In a report from the International Bone Marrow Transplant Registry, 170 WAS patients had been transplanted, and the 5-year probability of survival (95 percent confidence interval) for all WAS subjects was 70 percent (63–77 percent) (Filipovich et al., 2001). Probabilities differed by donor type: 87 percent (74–93 percent) with HLA-identical sibling donors, 52 percent (37–65 percent) with other related donors, and 71 percent (58–80 percent) with MUD (p = 0.0006). Boys who had received a MUD transplant before age 5 had survivals similar to those receiving HLA-identical sibling transplants. The European experience from a similar timeframe demonstrated 81 percent survival of 32 matched sibling donor recipients and only 45 percent survival of 43 mismatched related transplant recipients during the period from1968 to 1999 (Antoine, 2003). In the following years, from 2000 to 2005, only 3 mismatched related transplants were carried out in a total of 49 HSCTs for WAS, while there was a significant increase in MUD transplants (n = 35) (Gennery et al., 2010). Due to accumulating experience with MUD transplants and advances in donor–recipient matching allowing improved selection of unrelated donors, 77.7 percent of larger centers routinely offered unrelated donor transplants for WAS patients, as revealed by an international survey of 73 centers in 2002 (Conley, 2003).

Figure 60.4 Cumulative probability of survival in non-SCID patients, according to donor source (related or unrelated donor) and HLA matching and type of immunodeficiency through all periods. MMR, Mismatched related; RGI, related genoidentical; RPI, related phenoidentical. (From Gennery et al., *J Allergy Clin Immunol* 126(3):602–10, 2010, with permission).

All aspects of WAS are corrected by marrow transplantation, including the eczema, autoimmunity, and risk of lymphomas. This indicates that these disease complications were related to the immunodeficiency. Similarly, thrombocytopenia and the bleeding tendency disappeared after successful BMT. With increasing numbers of successfully transplanted patients, the long-term outcome, including quality of life, is receiving more and more interest. A recent European long-term, retrospective, multicenter study reported on 96 WAS patients who received transplants between 1979 and 2001 and survived at least 2 years following HSCT (Ozsahin, 2008). The most striking finding was the observation of chronic GVHD-independent autoimmunity in 20 percent of patients. This fact was strongly associated with a mixed/split chimerism status ($p < 0.001$), suggesting that residual host lymphocytes mediate autoimmune disease despite the presence of donor lymphocytes. Furthermore, patients younger than 2 years of age at HSCT (including also those with a mismatched related donor) had a higher chance of long-term survival and a better quality of life than older patients (Ozsahin, 2008).

Important progress has been achieved with regard to survival. Bone marrow, peripheral blood stem cell, or cord blood transplantation for patients with WAS should be performed as early in life as possible, especially in the presence of an HLA-identical sibling. Matched unrelated marrow, peripheral blood stem cells, or cord blood transplants can be effective if performed before the age of 5 years. The poor results with T-cell–depleted HLA-haploidentical BMTs in this condition stress the need for careful evaluation of whether to even attempt HLA-haploidentical BMT in WAS patients who lack both HLA-identical related and unrelated donors (Fischer et al., 1994). Nevertheless, WAS patients who develop refractory thrombocytopenia and/or severe autoimmune manifestations should be considered for HLA-haploidentical BMT.

HSCT FOR OTHER T-CELL DEFICIENCIES, PHAGOCYTIC CELL DISORDERS, AND HEMOPHAGOCYTIC SYNDROMES

An increasing number of patients with other inborn errors of the immune system have become eligible for HSCT, as discussed in detail in the specific chapters on the different genetic conditions. Due to important progress with regard to HSCT procedures and supportive care, there will be more and more patients in whom transplantation is no longer contraindicated. As with all types of transplants in infants with SCID (Fig. 60.1 and 60.2), the long-term (10-year) outcome of HLA-identical BMT for most forms of primary immunodeficiency appears reasonably satisfactory. Correction of the underlying deficiency is sustained despite frequent mixed chimerism in the absence of TBI usage. Sequelae are generally limited to consequences of the primary disease.

Continued international studies are needed to carefully assess the best therapeutic strategies for a given disease without neglecting the long-term outcome, including quality of life.

FUTURE OF HSCT IN THE TREATMENT OF PRIMARY IMMUNODEFICIENCY

It is abundantly clear that allogeneic HSCT cures many children with life-threatening immunodeficiency diseases. Until gene therapy is perfected, it will remain the standard of care for such conditions. Thus far, HSCT seems to be associated with acceptable long-term sequelae, although outcome beyond a follow-up of 30 to 40 years is not yet known. However, some of the long-term survivors have had chronic GVHD and extensive lesions of verruca vulgaris (Laffort et al., 2004; Neven, 2009). Except in the case of SCID, major problems still exist for the many patients who lack an HLA-identical sibling. Stem cell and lymphocyte cell manipulation could provide a better chance of success in the future, while alternative therapies might be developed for more diseases. Better assessment of genetic mutations associated with diseases, as well as individual cofactors, should also lead to a better delineation of which child should receive a transplant.

GENE THERAPY

Fabio Candotti and Alain Fischer

INTRODUCTION

As currently practiced, gene therapy can be defined as "the transfer of exogenous genes to somatic cells of a patient in order to correct an inherited or acquired gene defect, or to introduce a new function or trait." In the past two decades, gene therapy has moved from the speculative stage to clinical applications as clinical gene transfer protocols have been applied to inherited genetic defects, malignancies, and infectious diseases. Primary immunodeficiency diseases (PIDs), especially severe combined immunodeficiencies (SCID), have played a major role in this process as they have provided a proving ground for the first therapeutic applications (Blaese et al., 1995) as well as the first evidence that gene therapy can be curative (Aiuti et al, 2002a; Cavazzana-Calvo et al, 2000). Several advantages have made PIDs attractive candidate diseases for gene therapy. First, they are often curable by allogeneic hematopoietic stem cell transplantation (HSCT), which translates into the possibility that they should be also treatable with procedures combining ex vivo manipulation and reinfusion of autologous, gene-corrected hematopoietic stem cells. Second, the target cells reside in the bone marrow, a readily accessible tissue, which makes them amenable to ex vivo gene transfer, the procedure that currently offers the best chance of success. In addition, the regulation of genes responsible for many PIDs (i.e., adenosine deaminase [ADA] deficiency, chronic granulomatous disease [CGD], X-linked severe combined immunodeficiency [X-SCID], and leukocyte adhesion deficiency [LAD]) is relatively simple, and while currently available technology does not allow easy reproduction of the physiological control mechanisms of gene expression, the available gene transfer vectors are more than adequate to provide expression of these genes at levels required for clinical benefit. Finally, for several PIDs, gene-corrected progenitors and mature cells will have a survival advantage over the unmodified, affected cell populations. This selective survival translates into the very advantageous possibility that even low gene transfer efficiency may have therapeutic effects.

Because of the extensive recent progress in their molecular and biological characterization, several PIDs also fulfill the general prerequisites for any gene therapy approach that are based on the comprehensive knowledge of the molecular and cellular basis of the candidate disease. In general, the sequence of the cDNA of the gene responsible for the disease represents one critical piece of information for preliminary experiments of corrective gene transfer; however, the elucidation of the genomic organization and the characteristics of the promoting element(s) are also of great practical importance. Moreover, the specific function(s) and regulatory mechanisms of expression of the gene of interest should be clearly understood and the potential deleterious effects of overexpression investigated. Where possible, the safety and efficacy of gene transfer protocols should be tested on animal models, either naturally occurring or experimentally generated. Finally, it is fundamental to verify that the correction of the genetic defect can induce the restoration of gene function(s) in affected cells.

The complete and careful consideration of these issues is critical for development of new gene therapy strategies and should help defining the answer for the ethical dilemma that is proposed whenever the "traditional" treatment for the candidate disease is already highly successful.

Performing gene therapy for PIDs involves a series of specific difficulties. As mentioned, the ultimate target of corrective gene transfer for PIs is the hematopoietic stem cell (HSC). Targeting the HSC is an exceptionally challenging task for several reasons. First, cells demonstrating the characteristics of "true" hematopoietic progenitors are extremely infrequent in the hematopoietic tissues and have thus far eluded

all attempts to characterize their specific cellular phenotype, making their collection and enrichment laborious and inefficient. In addition, HSCs are mostly quiescent and therefore resistant to the insertion of genetic material mediated by viral vectors requiring active cell division. Extensive studies have been dedicated to the identification of "ex vivo" culture conditions that could stimulate HSCs to proliferate, thus making them susceptible to gene integration, without inducing differentiation and loss of long-term repopulating ability. Cytokines and growth factors like interleukin (IL)-3, IL-6, stem cell factor (SCF), thrombopoietin, and Flt-3 ligand, together with culture supports such as fibronectin, have been demonstrated to be of primary importance to this goal (Dao et al., 1997; Hanenberg et al., 1996; Kohn, 1999; Piacibello et al., 1997, 1999; Zandstra et al. 1997). Culture conditions using these reagents have resulted in major improvements in our ability to efficiently introduce genes into HSCs in large animal models (Kiem et al., 1998; Tisdale et al., 1998). However, the current levels of gene transfer may still not be adequate for achieving therapeutic effects in hematopoietic diseases in which corrected cells will not have a strong selective advantage over the mutated ones (e.g., thalassemias or sickle cell disease). On the other hand, this progress has resulted in successful clinical protocols for X-SCID, ADA deficiency, and Wiskott-Aldrich syndrome (WAS) (Aiuti et al., 2002a; Boztug et al., 2010; Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002), thus forming the basis for future applications to other PIDs.

Another obstacle to gene therapy for PIDs is that several of the causative genes that have been identified have expression restricted to specific hematopoietic elements or particular cellular phases of cell development (Table 61.1). In most gene transfer vectors currently available for clinical use, the gene of interest is under the transcriptional control of strong viral promoters and is therefore expected to give rise to unregulated expression of the such gene in transduced HSCs and all deriving cellular elements. This strong, ubiquitous promoter activity raises the concern that constitutive expression of an ectopic gene could have detrimental consequences on the differentiation and/or function of targeted populations. The need for precise regulation of gene expression represents a formidable challenge for the development of gene therapies. The use of gene-specific promoting and/or enhancing elements can be exploited to obtain regulated and/or tissue-specific expression of the therapeutic sequences, as shown for the WAS cDNA (Martin et al., 2005). Alternatively, inducible or repressible systems could also be utilized to modulate gene expression.

Finally, patients with inherited disorders of immunity may present with complete lack of expression of the affected gene(s) or show detectable levels of nonfunctional (mutated) gene product(s). It is not obvious which one of these two possibilities represents the better scenario for successful gene therapy. In the case of subjects carrying "null" mutations, there is the possibility that the newly expressed molecule could induce an immune response resulting in the elimination of the transduced, therapeutic cell populations; on the other hand, in the presence of mutations allowing for the expression of an inactive gene products, the mutated molecules could manifest dominant-negative effects in the presence of the correct protein(s), generating the need to obtain very high levels of expression of the transgene to achieve therapeutic effects.

METHODS FOR GENE TRANSFER

A variety of systems have been developed for gene transfer and expression in mammalian cells. In the case of inherited genetic errors, the choice of a gene delivery system is dictated by the need for persistent expression of the therapeutic gene. This can be most readily achieved if the exogenous genetic material is stably integrated into the host cell genome, thus ensuring the transmission of the transferred gene to the progeny of that cell during normal cell division. In the absence of integration, the inserted gene may be diluted out as the cell divides, and thus the therapeutic effects will ultimately be lost. Gene transfer vectors based on integrating viral systems such as gammaretroviruses, lentiviruses, and spumaviruses have been widely used for preclinical and clinical applications of gene therapy for PIDs.

VECTORS BASED ON RETROVIRUSES

Retroviral vectors are gene transfer constructs that reproduce the replication and integration mechanisms of retroviruses. The Moloney murine leukemia virus (MoMLV) of the mammalian type C retroviruses has been the most extensively studied retrovirus model (Miller, 1992), although other viruses from this group have also been exploited. More recently, vectors based on the two other major groups of retroviruses, lentiviruses and spumaviruses, have also become widely used.

MoMLV Vectors

A complete, wild-type MoMLV particle is composed of two copies of the viral RNA contained within a protein capsid and an external phospholipid envelope. Important enzymes, such as the retroviral reverse transcriptase, integrase, and protease, are also packaged within the virion.

The retrovirus life cycle is constituted by (1) binding of the retroviral envelope to a specific receptor on the cell membrane followed by internalization of the viral capsid; (2) uncoating and reverse transcription of viral genomic RNA to produce double-stranded viral DNA; (3) migration through the cytoplasm to the nucleus; and (4) integration of the proviral DNA into the host cell genome. Integration occurs, however, only if the targeted cells are actively proliferating, presumably because nuclear membranes must be disrupted for nuclear DNA transport. After reverse transcription the viral genome (provirus) consists of 8.3 kb of double-stranded DNA containing the *gag*, *pol*, and *env* genes flanked by the viral long terminal repeats (LTRs). The *gag* and *env* genes encode the structural proteins of viral core and envelope, respectively, while the reverse transcriptase, integrase, and protease are derived from the *pol* region. The two identical LTRs contain sequences promoting and enhancing transcription, as well as a polyadenylation signal (polyA). Between the 5′ LTR and the *gag* gene is a region of the genome (termed Ψ) containing the encapsidation

Table 61.1 PRESENT STATUS AND CHALLENGES OF GENE THERAPY APPROACHES FOR IMMUNODEFICIENCY DISEASES

DISEASE	EFFICACY OF BMT	POTENTIAL TARGET CELLS FOR GENE TRANSFER	STATUS OF CORRECTIVE GENE TRANSFER STUDIES	CHALLENGES	AVAILABLE ANIMAL MODEL
ADA-SCID	Good (HLA-identical)	BM, CB, T	Ongoing clinical trials	Adequacy of immune repertoire in T-cell–directed protocols	muKO
CGD	Poor	BM, CB	Ongoing clinical trial	No selective advantage	muKO
LAD I	Good	BM, CB	Prior clinical experience; current preclinical	Tissue-specific gene expression, no selective advantage	muKO
X-SCID	Good	BM, CB	Ongoing clinical trials	Definition of risk of insertional oncogenesis	Dog, muKO
JAK3-SCID	Good	BM, CB	Prior clinical experience	Definition of risk of insertional oncogenesis	muKO
WAS	Good (HLA-identical)	BM, CB	Ongoing clinical trials	Coexistence of gene-corrected and residual mutated cells may be problematic.	muKO
PNP deficiency	Poor*	BM, CB, T	Approved clinical trial	Adequacy of immune repertoire in T-cell–directed protocols	muKO
ZAP70-SCID	Good*	BM, CB	Preclinical	Lineage/differentiation stage restricted expression	muKO
MHC class II deficiency	Poor	BM, CB	Preclinical	Regulated gene expression	muKO
X-HIM	Fair	BM, CB, T	Preclinical	Regulated gene expression, no selective advantage	muKO
XLA	Limited experience	BM, CB	Preclinical	Restricted gene expression	Xid mouse, muKO
RAG-1	Good	BM, CB	Preclinical	Balance efficacy/toxicity	muKO
RAG-2	Good	BM, CB	Preclinical	High levels of gene expression may be necessary.	muKO
CD3γ deficiency	Good*	BM, CB, T	Preclinical	Regulated gene expression	muKO
Artemis deficiency	Fair	BM, CB	Preclinical	Toxicity of ectopic expression?	muKO
Reticular dysgenesis	Poor	BM, CB	Preclinical	Need for expression in myeloid lineages	zfMO

*Only few cases reported.

BM, bone marrow progenitors; CB, cord blood progenitors; T, peripheral T lymphocytes; muKO, murine knockout model; zfMO, zebrafish morpholino knockdown model.

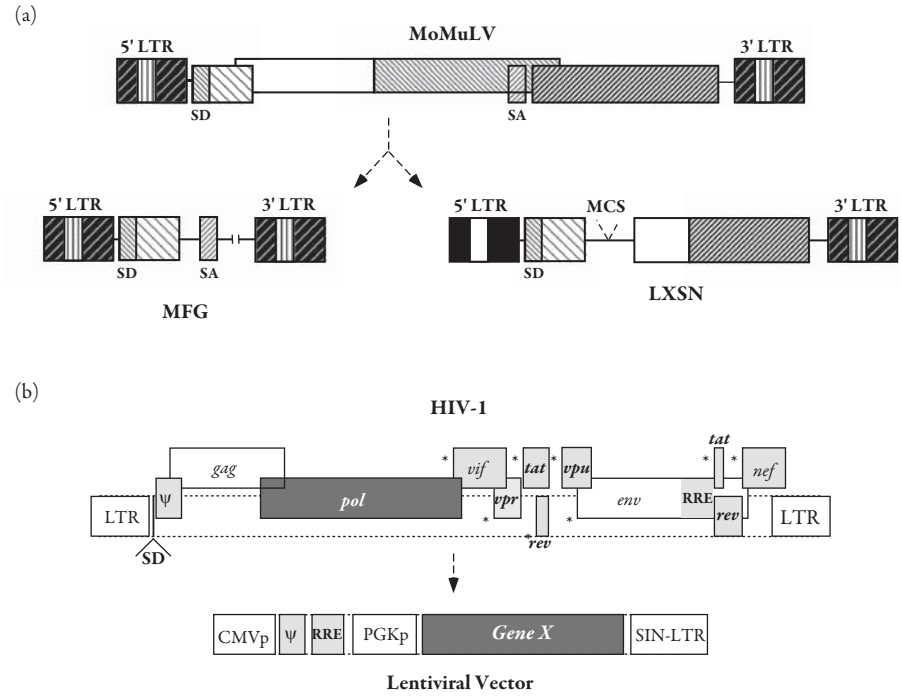

Figure 61.1 (A) Schematic representation of the Moloney leukemia virus (MoMuLV) and MoMuLV-based LXSN (244) and MFG (245) retroviral vectors. The organization of MoMuLV *gag*, *pol*, and *env* genes, as well as of splice donor (SD) and acceptor (SA) sites, packaging signal sequence (ψ), and long tandem repeats (LTRs) is represented. The MoMuLV *gag*, *pol*, and *env* sequences are deleted to obtain the backbone of retroviral vectors. The MFG cassette is an example of a "splicing vector" and maintains both splice donor and acceptor sites of the MoMuLV *env* coding sequence, thus mimicking the natural pattern of viral mRNA splicing. In the LXSN cassette and the MoMuLV 5′ LTR is replaced with the homologous region from the Moloney murine sarcoma virus (MoMuSV). MCS, multiple cloning site; *neo*, neomycin resistance gene; SV40p, SV40 early promoter region. (B) Schematic representation of HIV-1 and of a general lentiviral vector. The organization of HIV-1 *gag*, *pol*, and *env* genes, as well as of the *vif*, *vpr*, *rev*, *vpu*, and *nef* accessory genes and of *tat* and RRE regulatory sequences, is shown. The splice donor (SD) site is indicated and the alternative splice acceptor sites are marked with asterisks. The packaging signal sequence (ψ) and long tandem repeats (LTRs) are represented. Only the packaging signal, RRE region, and 3′ LTR are conserved in the lentiviral vector construct. CMVp, cytomegalovirus promoter; PGKp, phosphoglycerate kinase promoter; SIN, self-inactivating.

sequence that is necessary for efficient packaging of the viral genomic RNA into the capsidic structure (Temin, 1984).

To obtain viral vectors incapable of replicating in the transduced cells, the genes encoding viral proteins are deleted and replaced with selectable markers and/or multiple cloning sites for the insertion of experimental genes (Fig. 61.1). To obtain complete and infectious viral particles, "packaging" cell lines have been developed that express the *gag*, *pol*, and *env* gene products but are unable to encapsidate the viral genomic RNA because of mutations or deletions in their Ψ region. However, these cells allow packaging of the genome of retroviral vectors in which the Ψ region is conserved (Fig. 61.2).

Several packaging cells are available that contain and express different *env* genes, which affords them different host ranges. Among these, the PG13 (Miller et al., 1991) and the FlyRD18 (Cosset et al., 1995) packaging lines incorporate the gibbon-ape leukemia virus (GALV) and the ct endogenous virus (CEV) envelope proteins, respectively. In hematopoietic cells and progenitors, the expression levels of receptors for GALV and CEV are higher than the receptor for the Moloney envelope, and in some cases, receptors can be metabolically upregulated (Bunnell et al., 1995). These characteristics make these packaging cells effective tools for diseases potentially treatable by gene transfer into peripheral blood elements or HSCs (Kelly et al., 2000; Kiem et al., 1998).

Another packaging system is based on the incorporation of the vesicular-stomatitis virus envelope protein G (VSV-G) into the virions of MoMLV-derived vectors. The particles carrying the VSV-G have the advantage of a broader host range compared to virions encapsidated into the amphotropic envelope protein and allow the generation of concentrated, high-titer retroviral vector preparations (Rebel et al., 1999).

In vitro gene transfer is usually achieved by single or repeated exposure of the target cells to retroviral supernatants. Alternative procedures involve cocultivation of retroviral producer and target cells, which can increase gene transfer efficiency but pose significant hurdles to the development of clinical protocols.

One advantage of using retroviral vectors for gene transfer is the broad range of infectable cell types and the efficient gene integration that can be achieved with dividing cells. Retroviral-based vectors, however, also present drawbacks. The maximum amount of DNA that these vectors can accommodate is limited to about 8 kb, a size that prevents the transfer of large genomic sequences. Furthermore, retroviral vectors integrate randomly in the host cell genome, raising a twofold problem.

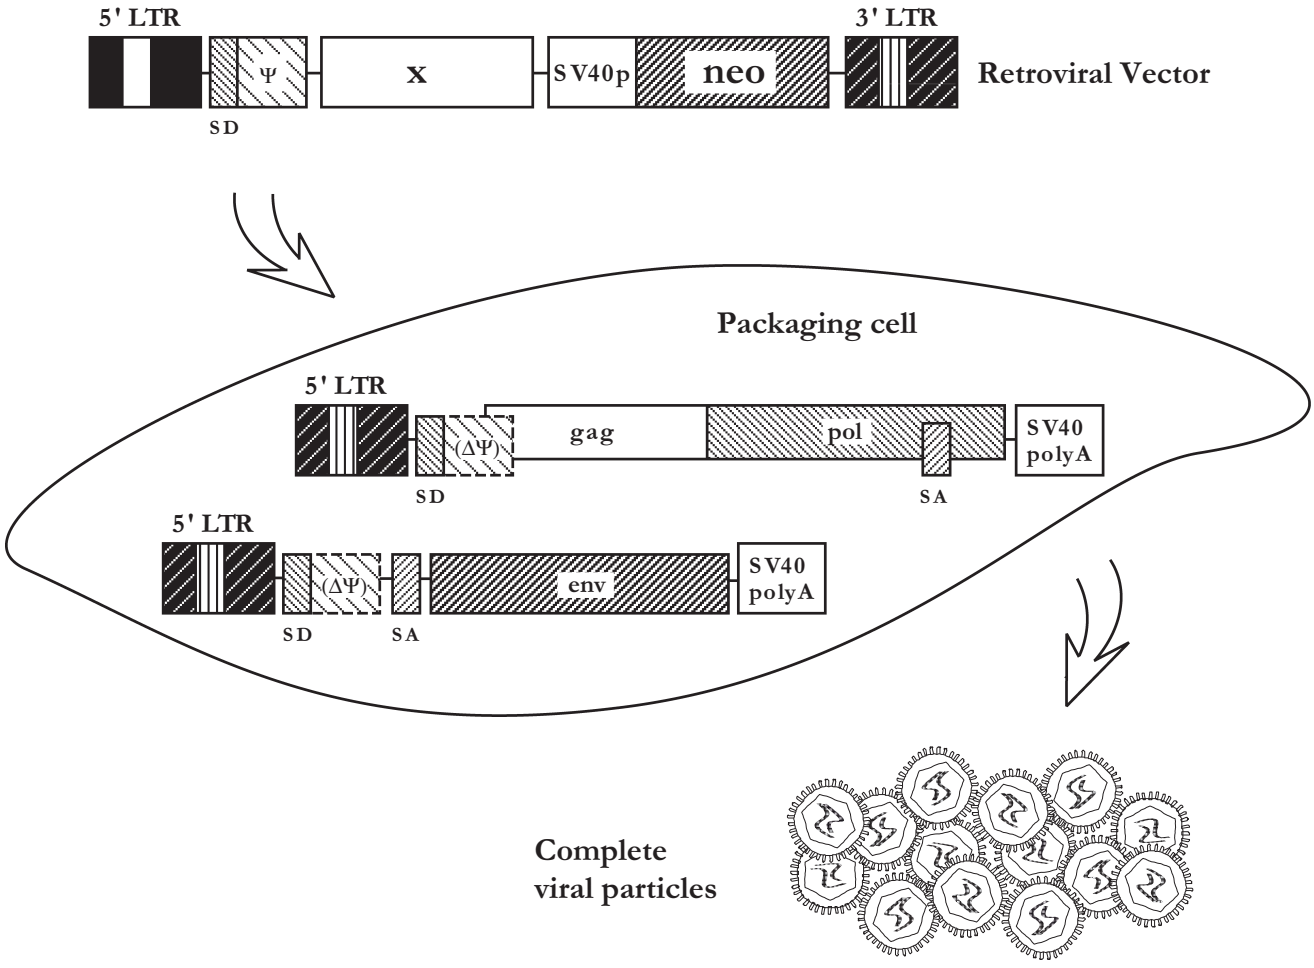

Figure 61.2 Production of retroviral vector supernatants. The retroviral construct is transfected into the packaging cell line that contains the "helper" MoMuLV modified genomes. The *gag*, *pol*, and *env* genes provide the necessary viral proteins, whereas deletions of the packaging signal sequences prevent the encapsidation of the "helper" genomic RNA into virions. The retroviral vector, however, contains the complete packaging signal and generates RNA molecules that can be efficiently encapsidated. Finally, infectious viral particles containing the recombinant retroviral vector can be obtained in the culture supernatant. Lentiviral vector production is achieved following similar procedures. However, in most cases, transient cotransfection of the lentiviral vector and helper HIV-1 sequences is performed.

First, the levels of gene expression can drastically vary from cell to cell depending on the particular site of proviral integration. These "position effects" are thought to depend on the basal chromatin structure at the integration site and can completely silence transgene expression in some cases while augmenting expression in others. Clearly, many genes operate within tightly regulated ranges of expression, and this wide variability is not acceptable. Second, the random integration events could theoretically disrupt critical genetic sequences leading to cell death or activation of oncogenes, resulting in malignancy. The risk of insertional oncogenesis is unfortunately real, as recently indicated by the development of a leukemia-like disorder in subjects treated with retroviral-mediated gene transfer as a treatment for X-SCID (Hacein-Bey-Abina et al., 2008; Howe et al., 2008) and WAS (Braun et al., 2011).

Lentiviral Vectors

Gene transfer vectors based on lentiviruses such as HIV-1 have advantages over retroviral vectors for transduction into quiescent lymphocytes and HSCs. The genome of HIV-1 is more complex than that of other retroviruses. In addition to the structural *gag*, *pol*, and *env* genes, it also contains two regulatory genes, *tat* and *rev*, and four additional transcripts, *vif*, *vpr*, *vpu*, and *nef*, which encode accessory proteins critical for viral replication and pathogenesis.

In contrast to type C retroviruses, the replicative cycle of lentiviruses is independent of cell division and dissolution of the nuclear envelope during cell mitosis. Lentivirus vectors are therefore potentially able to integrate into the genome of nondividing host cells. A number of gene transfer systems based on HIV-1, HIV-2, and non-primate lentiviruses, such as equine infectious anemia virus (EIAV) and feline immunodeficiency virus (FIV), have been described (Arya et al., 1998; Naldini et al., 1996a; Olsen, 1998; Poeschla E et al., 1998; Poeschla EM et al., 1998; Reiser et al., 1996; Uchida et al., 1998). Naldini et al. (1996a) first developed an HIV-1-based gene transfer system in which replication-defective viral particles were obtained by pseudotyping the HIV-1 core—that is, packaging it into heterologous envelope of the MoMLV or the

VSV-G protein. This strategy not only increased the safety of the system by excluding the HIV envelope but also broadened the tropism of the vectors to allow transduction of many cell types. Several studies have shown that lentiviral vectors can efficiently transduce nondividing cells in experimental conditions (Case et al., 1999; Kafri et al., 1997; Miyoshi et al., 1997, 1999; Naldini et al., 1996b; Poeschla E et al., 1998; Poeschla EM et al., 1998; Uchida et al., 1998; Zufferey et al., 1997) and have affirmed this class of vectors as useful tools for gene therapy of diseases affecting tissues composed of quiescent or postmitotic cells, such as neuronal and retinal cells, hepatocytes, myocytes, and lymphohematopoietic cells.

Obvious biosafety concerns have been raised for vectors derived from HIV-1, a highly pathogenic human virus. These included the worry that unwanted recombination events during vector production could generate replication-competent viruses. If this occurred, patients receiving gene therapy could be at risk for infection by an HIV-like virus. In addition, treated patients carrying integrated HIV sequences might subsequently come in contact with wild-type HIV, in which case recombination between virus sequences in vivo could mobilize the gene therapy vector, leading to spread of a new virus to additional patient cells or even to infection of individuals in contact with the patient (Evans & Garcia, 2000). Systems have been generated that use nonoverlapping split-genome packaging constructs and self-inactivating vector cassettes to decrease these risks (Dull et al., 1998; Miyoshi et al., 1998; Zufferey et al., 1998).

On the other hand, mapping studies of lentiviral vector integration sites indicate that these vectors may have less tendency to target dangerous transcription start sites than vectors based on MLV (Biffi et al., 2011; Hematti et al., 2004; Ronen et al., 2011; Wu et al., 2003), thus supporting the notion that these vectors may be less prone to induce insertional oncogenesis.

Foamy Virus Vectors

Foamy viruses (FV) are nonpathogenic retroviruses that are commonly found in mammalian species. In contrast with other retroviruses, reverse transcription in FV occurs during virion formation, and infectious viral particles therefore contain DNA genomes. This characteristic may improve transduction of quiescent cells, in which inefficient reverse transcription can prevent transduction by oncoviral or lentiviral vectors. This and other favorable characteristics, including broad tropism, large genome size (>13 kb), and lack of pathogenicity, have stimulated their development as gene transfer vectors. The FV genome contains the *gag*, *pol*, and *env* genes, but also three additional genes (*bel-1*, *bel-2*, *bel-3*) located between *env* and the 3′ LTR and expressed from an internal viral promoter. The *bel-1* gene encodes for Tas, a transcriptional transactivator of the FV LTR and internal promoter. In the absence of Tas, the FV LTR is silent. The function of the *bel-2* and *bel-3* genes is unknown. The FV Gag protein contains a functional nuclear localization signal, raising the possibility that nuclear entry of FV genomes is independent of mitosis (Rethwilm, 1995).

In the past 10 years, replication-defective FV vectors have been generated and perfected. The initial version of the vectors carried deletions that abolish *bel-1* expression and contain expression cassettes (composed on an internal promoter and the gene of interest) within the two FV LTRs. More recent constructs have reduced the FV sequences to a minimum, making abundant space (>9 kb) for a transgene (Park et al., 2002; Russell & Miller, 1996; Trobridge et al., 2002; Wu et al., 1998; Wu & Mergia, 1999). Transient expression systems or packaging cells provide the structural and regulatory FV gene products and allow for production of complete, infectious viral particles (Russell & Miller, 1996; Trobridge et al., 2002; Wu & Mergia, 1999). The virions are stable, are not inactivated by human serum (Wu et al., 1998), and can be concentrated by ultracentrifugation to titers of about 10^7/mL (Trobridge et al., 2002).

FV vectors have been shown to efficiently enter quiescent cells where functional vector genomes survive until these cells are stimulated to divide, suggesting that, similar to HIV vectors, a stable intracellular transduction intermediate is formed (Mergia et al., 2001; Russell & Miller, 1996). This property may account for the ability of FV vectors to efficiently transduce hematopoietic cells, including murine and human pluripotent HSCs (Josephson et al., 2002; Trobridge et al., 2002; Vassilopoulos et al., 2001; Zucali et al., 2002), which has supported their use to correct animal models of hematopoietic diseases, such as Fanconi anemia, LAD type 1, and WAS (Bauer et al., 2011; Si et al., 2008; Uchiyama et al., 2012).

RESULTS OF GENE THERAPY TRIALS FOR IMMUNODEFICIENCIES

ADA DEFICIENCY

Genetic defects resulting in loss or severe reduction of ADA (MIM *608958, #102700; EC 3.5.4.4) result in extreme reduction of lymphocyte numbers and impairment of immune functions (Hirschhorn, 1993; Markert, 1994) (see Chapter 14). Complete ADA deficiency causes SCID (ADA-SCID).

In the mid-1980s, ADA deficiency was identified as the initial candidate disorder for trials of gene therapy because of a combination of favorable characteristics. The organization of the ADA gene and cDNA was well known, and ADA gene function and regulation had been clearly defined (Orkin et al., 1983; Valerio et al., 1983; Wiginton et al., 1983). A wide array of enzyme concentrations, ranging from 10 percent of normal to about 50 times the normal mean, was known to be compatible with normal immunity (Daddona et al., 1983; Valentine et al., 1977). This situation provided an ideal scenario where the expression of the transferred gene was not required to be tissue-specific or tightly regulated. In addition, the experience from allogeneic hematopoietic stem cell transplantation (HSCT) experiments suggested that normal ADA-expressing cells had a selective advantage over the ADA-deficient bone marrow progenitors, thus eliminating the need for myeloablation preceding the infusion of the patient gene-corrected HSCs. Finally, the fact that some HSCT patients achieving

engraftment of only donor T cells were shown to have full reconstitution of lymphocyte functions provided the rationale for the correction and reinfusion of patient mature T lymphocytes as an alternative, and technically less complex, gene therapy approach.

The first clinical gene therapy protocol for ADA deficiency was begun on September 14, 1990, at the National Institutes of Health (NIH). It enrolled two ADA-deficient girls with persisting signs of immunodeficiency despite the institution and regular administration of polyethylene glycol-ADA (PEG-ADA) replacement therapy. This protocol involved apheresis of peripheral blood and culture of each patient's peripheral blood mononuclear cells with IL-2 and anti-CD3 antibody to stimulate intense proliferation of the small number of T lymphocytes from each patient's circulation. Once actively proliferating, cells were exposed to supernatants containing the LASN retroviral vector expressing the human ADA cDNA and expanded about 100-fold before being reinfused into the patient (Tuschong et al., 2002). Over a 2-year period, both patients underwent a series of treatments with the intention to target, and thus correct, a large proportion of each patient's T-cell repertoire. Both children improved or developed de novo several humoral and cellular immune functions, including the ability to produce IgM in vitro upon stimulation of cultured cells with pokeweed mitogen (PWM), improved in vivo antibody responses to vaccines against *Haemophilus influenzae* type B (HIB) and tetanus toxoid, normalization of isohemoagglutinin titers and T-cell counts, development of cutaneous delayed-type hypersensitivity to various antigens, normalization of T-cell production of IL-2 after stimulation with specific antigens (tetanus toxoid and influenza A virus), and development of in vitro cytolytic T-cell–specific activity against allogeneic cells and influenza A virus-infected autologous cells. All these immune responses were absent or barely detectable before gene therapy (Blaese et al., 1995).

Ten years after the last cell infusion, about 20 percent of circulating T cells from the first patient still contained the ADA vector and expressed the transgene, while less than 0.1 percent of T cells from the second patient had detectable vector sequences. Both patients continue to receive weekly injections of PEG-ADA, although at a reduced dose. Numbers of peripheral blood CD3+ T cells remained in the normal range for 7 years even as the dose of PEG-ADA was lowered by 50 to 60 percent, but more recently showed signs of decline, although their proliferative responses to mitogens and recall antigens have remained at the lower range for healthy controls.

The marked difference between the two patients in the achieved level of gene marking and ADA expression appears to be the result of several factors. In vitro proliferation of cells from the second patient was poor, limiting the transduction efficiency. In addition, this patient developed a persistent immune response against the retroviral envelope and the lipoprotein components of the fetal calf serum used to culture the cells, and this response may have induced immune-mediated elimination of infused cells (Muul et al., 2003; Tuschong et al., 2002).

The long-term clinical benefit of this first gene therapy trial is difficult to evaluate because of the concomitant administration of PEG-ADA. Nevertheless, several unique pieces of information could be drawn from this study, including the safety of administering genetically modified autologous T cells, the long persistence (>12 years) of such cells in vivo, and the long-term transgene expression that can be obtained in vivo by the MoMLV retroviral promoter (Muul et al., 2003). In addition, the results of this trial point out that immune responses, even in immunodeficient patients, can confound the outcome of gene therapy experiments in unpredicted ways (Muul et al., 2003; Tuschong et al., 2002).

Following protocol and vector preparations identical to those used in the NIH trial, in August 1995 Dr. Sakiyama and colleagues from Hokkaido University School of Medicine in Sapporo treated a Japanese ADA-SCID patient with 11 infusions of genetically modified autologous T lymphocytes over a period of 20 months. Periodic analysis of peripheral blood lymphocytes showed transduction frequencies of 10 to 20 percent (Egashira et al., 1998; Onodera et al., 1998), accompanied by gradual increases of ADA enzyme activity in the patient's circulating T cells to levels comparable to those of a heterozygous carrier. Evidence of improvement of the patient's immune function after gene therapy included increased T-lymphocyte counts and delayed-type hypersensitivity responses, appearance of isohemagglutinins, increase in serum immune globulin, and specific antibody production (Egashira et al., 1998; Kawamura et al., 1999; Onodera et al., 1998). Similarly to the first patient in the NIH trial, follow-up studies demonstrated long-term persistence of transduced and polyclonal T cells (Misaki et al., 2001).

A second gene therapy clinical trial for ADA deficiency began in 1992 in Milan, Italy; Bordignon and coworkers used two distinguishable forms of the same retroviral vector to transduce separately lymphocytes and bone marrow cells from two ADA-deficient patients who had showed a progressive decline of efficacy of PEG-ADA therapy. This study involved the in vitro culture, retroviral transduction, and reinfusion of patients' lymphocytes and bone marrow cells and aimed to define the specific contribution of gene-corrected mature T lymphocytes and bone marrow progenitors to long-term immune reconstitution (Bordignon et al., 1993). The two patients were treated with intravenous infusions of autologous transduced cells over a period of 9 to 24 months, during which PEG-ADA dosage was decreased. Normalization of lymphocytes counts and isohemoagglutinin titers, restoration of antigen-specific antibody production, and mitogen- as well as antigen-specific T-cell proliferation were observed in both patients. At the molecular level, both forms of the integrated provirus were individually detectable in the patients' peripheral lymphocytes, with the clear long-term predominance of the construct used to transduce bone marrow cells. Of particular interest, vector-derived ADA activity was detectable in bone marrow cells, peripheral lymphocytes, and also in mature granulocytes and erythrocytes, indicating that the correction of bone marrow progenitors was stably transferred to their progeny (Bordignon et al., 1995).

Similar to the previous U.S. study, the clinical impact of gene therapy in these patients was difficult to assess because of concomitant administration of PEG-ADA, which on the one

hand might have contributed to the immunological improvement, but on the other may also have abolished the potential selective advantage of genetically engineered cells over the defective cell populations in ADA-deficient patients. One of the patients treated in Italy with multiple infusions of transduced peripheral blood lymphocytes offered the opportunity to evaluate the latter hypothesis directly when complications attributed to the PEG-ADA treatment developed that justified the discontinuation of the enzyme injections. Withdrawal of PEG-ADA led to a selective growth advantage of gene-transduced and ADA-expressing circulating T lymphocytes that from a prevalence of about 3 percent eventually reached nearly 100 percent. Absolute $CD3^+$ T-cell counts also rose to levels significantly higher than those observed during PEG-ADA treatment, and intracellular ADA activity increased to levels of approximately 50 percent of normal individuals. These findings were accompanied by full restoration of T-cell function that had been inadequate during PEG-ADA treatment. The increase of lymphocyte ADA activity, however, was not sufficient to achieve systemic detoxification; red blood cell deoxyribonucleotides (dAXP) increased to levels substantially higher than those observed in ADA-deficient patients treated with BMT (Aiuti et al., 2002b). These findings suggested that even high numbers of genetically corrected lymphocytes were insufficient for achieving full, lasting metabolic correction of ADA deficiency and justified additional attempts by the same investigators at correcting the HSC as a more efficient approach for gene therapy of this disease.

Following up on these findings, and reasoning that an initial developmental advantage was important for the transduced HSC, the Italian investigators decided to create space in the bone marrow by administering a low dose of busulfan (2 mg/kg/day for 2 days before infusion of gene-corrected cells) to a series of 10 ADA-deficient patients before the infusion of gene-corrected cells. This approach revealed extremely effective: nine patients showed immune reconstitution with increases in T-cell counts and normalization of T-cell function. In five patients, B-cell function was restored as assessed by antigen-specific antibody responses after vaccination. Eight patients have remained off PEG-ADA therapy in the long term. The degree of myelosuppression was generally mild and resulted in prolonged neutropenia and thrombocytopenia only in two patients. Importantly, ADA enzymatic activity was documented in blood mononuclear cells and red cells at levels significantly higher than at baseline and resulted in significant reduction of toxic levels of deoxyadenosine nucleotides in the red cells.

The presence of the retroviral ADA gene was detected in bone marrow (in 5 percent of $CD34^+$ cells) and peripheral blood specimens (50–90 percent of T cells, B cells, and natural killer [NK] cells). The fraction of gene-corrected CD34+ cells found in patients at 1 year after treatment correlated with the dose of infused gene-corrected $CD34^+$ cells and the actual response to the myelosuppressive agent. All patients were alive and there were no adverse events due to the retrovirally transduced cells. PEG-ADA was initiated or restarted in two patients, due to insufficient efficacy of the procedure (Aiuti et al., 2002a, 2009). Because in this trial, in addition to receiving chemotherapy, patients also were not given PEG-ADA, it remains to be established what variable had the major impact on the outcome of the procedure.

These very exciting results marked a clear difference from those obtained from previous clinical gene transfer attempts into the HSC of ADA-deficient patients that were carried out in the mid-1990s in the United States and Europe that did not include either the use of chemotherapy or the withdrawal of PEG-ADA. One such trial had been initiated by Kohn and collaborators in 1993 at the Children's Hospital Los Angeles. Notably, this was the first gene therapy protocol utilizing umbilical cord blood $CD34^+$ hematopoietic progenitors. Three newborns were enrolled in this protocol, which involved separation of $CD34^+$ progenitors from the cord blood immediately after birth, repeated retroviral transductions with the normal ADA cDNA, and intravenous infusions into the patients on their fourth day of life. PEG-ADA treatment was also instituted and maintained in all three patients. Serial molecular studies demonstrated that integrated vector sequences were detectable in bone marrow-derived $CD34^+$ cells, in granulocyte-macrophage colony-forming units (CFU-GM), and in both the mononuclear and polymorphonuclear mature leukocyte populations of all three infants (Kohn et al., 1995).

Four years after the infusion of gene-corrected cells, 1 to 10 percent of circulating T lymphocytes contained the transduced gene, whereas only 0.01 to 0.1 percent of other hematopoietic elements were vector-positive. After PEG-ADA treatment was stopped in the patient carrying the highest percentage of gene-corrected T lymphocytes (around 10 percent), the proliferative response to tetanus toxoid was lost, as were most of circulating B and NK cells. Reduction of total numbers of $CD3^+$ and $CD4^+$ T lymphocytes was also observed; however, the percentage of circulating T cells containing the transduced ADA gene increased to 30 to 100 percent, and lymphocyte proliferation response to PHA was retained. These findings and the development of an upper respiratory tract infection induced the investigators to reinstate PEG-ADA therapy, leading to restoration of clinical and laboratory findings to prewithdrawal levels. The low levels of ADA gene marking and expression did not justify the suspension of PEG-ADA treatment in the other patients (Kohn et al., 1998).

These observations supported the notion that ADA gene-corrected T cells have a selective survival advantage over unmodified lymphocytes. However, the trial also demonstrated that the level of transduced progenitors (particularly for B and NK cells) was not sufficiently high to guarantee sustained, adequate immune function in the absence of enzyme replacement. A possible contributing reason for these findings was that the expression of ADA afforded by the LASN vector in HSCs was not adequate to allow differentiation and function of large numbers of mature lymphocytes. Based on this last hypothesis, a two-site trial using ADA vectors with higher expression capabilities was started in 2001 at Children's Hospital Los Angeles and NIH with the aim of comparing the relative efficacy of two different vectors in vivo after transduction in bone marrow $CD34^+$. In the first phase of this trial, patients were maintained on

PEG-ADA treatment and no chemotherapy was administered. Long-term, low-level marking was achieved in two of four treated patients, but no immunological improvement was obtained. In its second phase, the trial involved low-dose busulfan chemotherapy and withdrawal of PEG-ADA treatment. Six patients were enrolled, with three achieving adequate immune reconstitution off PEG-ADA. These results demonstrated that the use of reduced-intensity conditioning improved the level of engraftment of gene-modified stem cells and the subsequent production of ADA-expressing lymphocytes, contributing to immune reconstitution. In addition, the use of two retroviral vectors in each patient in this trial indicated the superiority of a vector carrying backbone modifications aimed to reduce methylation and silencing in vivo (Candotti et al., 2012).

An additional French and British pilot trial of gene therapy for ADA deficiency in 1993 involved retroviral transduction of HSCs isolated from bone marrow (Hoogerbrugge et al., 1996). Three ADA-deficient children were enrolled. The results were disappointing, since vector-containing cells were detectable by polymerase chain reaction (PCR) 6 months after the treatment in the bone marrow of only one patient, and no signal was detected in the peripheral blood of any of the three children. No clinical improvement was observed in these patients. Based on their preclinical results in the Rhesus model, the authors theorized the need for preemptive myeloablation to obtain efficient engraftment of gene-corrected stem cells in ADA deficiency. Following this hypothesis, a more recent British trial enrolled six patients who were treated following withdrawal of PEG-ADA and administration of nonmyeloablative chemotherapy with melphalan (140 mg/m^2) or busulfan (4 mg/kg). In two of these patients, PEG-ADA was restarted due to absence of measurable gene marking in peripheral blood cells. The other patients showed increase in T-cell and B-cell numbers, with normalization of lymphocyte responses to PHA and anti-CD3 and adequate immunoglobulin production in three patients. Significant reduction of deoxyadenosine nucleotide levels was observed after gene therapy in the patients who were able to discontinue PEG-ADA (Gaspar et al., 2006, 2011a).

Based on cumulative data from more than 40 ADA-SCID patients treated with gene therapy, it appears that selective advantage of gene-corrected cells is not sufficient to provide immune reconstitution in the absence of preparative chemotherapy. This notion is also supported by the results of the Japanese clinical trial that was started in 2003 with the enrollment of two patients who received gene-corrected CD34$^+$ bone marrow cells after discontinuation of PEG-ADA, but without chemotherapy. Recent results from this trial indicate that full immune reconstitution was not achieved in the absence of conditioning (Otsu et al., 2010).

In summary, while BMT from an HLA-identical sibling remains the therapy of choice for ADA deficiency, the results obtained by the pioneering and current clinical trials have indicated that gene therapy approaches can be effective and to date maintain a record of safety. Indeed, it can be argued that gene therapy should be considered as the first treatment option in the absence of a matched family donor.

CHRONIC GRANULOMATOUS DISEASE

Genetic defects involving gp91^{phox}, p22^{phox}, p47^{phox} and p67^{phox}, have been identified in CGD patients who, because of impaired superoxide production in phagocytic cells, usually present early in life with abscesses and/or granuloma formations in the skin, liver, lungs, or bone due to catalase-positive bacteria and fungal pathogens (see Chapter 52). Current management of CGD patients includes antibiotic prophylaxis, administration of IFN-γ, and allogeneic HSCT (Kang EM et al., 2011). For several patients, however, available therapeutic options remain unsatisfactory, and cloning of the genes encoding all the elements of the NAPDH oxidase system (Forehand & Johnston, 1994; Roos, 1994) has allowed gene therapy strategies to be developed.

Several groups have demonstrated the feasibility of viral vector gene transfer in reconstituting the respiratory burst activity of B-cell lines and monocytes from CGD patients (Li et al., 1994; Sekhsaria et al., 1993; Thrasher et al., 1992; Thrasher, Casimir et al., 1995; Thrasher, de Alwis et al., 1995). The ultimate target for gene correction of CGD, however, is the HSC because of the very limited lifespan and the reduced proliferative state of mature phagocytes.

In vitro preclinical studies have demonstrated that CD34$^+$ hematopoietic progenitors derived from peripheral blood after granulocyte colony-stimulating factor (G-CSF) mobilization and genetically corrected by retroviral-mediated gene transfer can show restoration of superoxide production when induced to differentiate into mature monocytes and neutrophils (Becker et al., 1998; Li et al., 1994; Porter et al., 1996; Sekhsaria et al., 1993; Weil et al., 1997). In addition, in vivo restoration of respiratory burst in p47^{phox} and gp91^{phox} knockout mice was demonstrated following gene correction of bone marrow cells with retroviral vectors (Bjorgvinsdottir et al., 1997; Mardiney et al., 1997). On the basis of these encouraging results, Malech and coworkers at the NIH initiated a phase I clinical study for gene therapy of the autosomal recessive form of CGD due to defective expression of the NAPDH complex p47^{phox} subunit. Five CGD patients were subjected to pharmacological mobilization of CD34+ hematopoietic progenitors that were then collected from the peripheral blood by apheresis. Enriched CD34$^+$ cells were transduced in vitro using a retroviral vector expressing cDNA encoding p47^{phox} and then reinfused into the patients without myelosuppression. The appearance of NAPDH oxidase activity in phorbol myristate acetate (PMA)-stimulated peripheral blood granulocytes was followed in each subject over time. At variable intervals between 15 and 32 days after infusion of transduced progenitors, all patients showed oxidase-positive granulocytes, with maximum percentages ranging between 0.004 percent and 0.05 percent. The presence of the transduced gene in the DNA of peripheral blood lymphocytes was confirmed by PCR detection. Oxidase-positive cells were detected for a minimum of 79 and a maximum of 172 days (Malech et al., 1996). Although silencing of the transduced gene has not been excluded, these findings are consistent with loss of the transduced cells and with the possibility that more differentiated progenitors, rather than true self-renewing HSCs, were the primary transduction target in this study.

The same research group conducted a second clinical trial aimed at correction of the more common X-linked form of CGD (X-CGD), caused by mutation of the gp^{91phox} subunit of the NAPDH oxidase. Using a high-titer retroviral vector and improved transduction procedures, four X-CGD patients each received two to four infusions of gp^{91phox}-transduced $CD34^+$ cells. Despite these modifications, the levels of NAPDH-positive neutrophils observed in treated patients ranged between 0.2 and 0.06 percent and persisted for only 6 to 14 months (Malech et al., 1998, 2000).

Similar results were obtained by Dinauer et al. in another phase I trial for X-CGD at the University of Indiana Medical School, where two subjects were treated using mobilized peripheral blood $CD34^+$ cells transduced with a murine stem cell virus–based retroviral vector. In this case, 0.007 to 0.05 percent NAPDH-positive neutrophils were detected in both patients for a period of about 9 months (Goebel & Dinauer, 2003).

The results of these early gene transfer studies for CGD indicated the need for modifications of procedures aimed at increasing efficacy and opened the way to the next series of clinical trials that introduced nonmyeloablative conditioning.

The NIH group administered low-dose busulfan (10 mg/kg) prior to infusion of retrovirally transduced mobilized $CD34^+$ cells in three X-CGD patients with refractory infections. Functionally corrected cells were detected in the peripheral blood of two patients up to levels of 4 to 24 percent of neutrophils, which was associated with complete or partial resolution of the infections. However, corrected cells remained detectable in the long term at levels of around 1 percent in only one patient (Kang EM et al., 2011).

In January 2004, a new trial in Germany by Grez and collaborators used a retroviral vector expressing $gp91^{phox}$ under the transcriptional control of the spleen focus-forming virus LTR to target G-CSF–mobilized $CD34^+$ progenitor cells of two patients with X-CGD. Before the infusion of gene-corrected cells, patients were given intravenous busulfan (4 mg/kg for 2 consecutive days), which resulted in transitory myelodepression from which patients recovered by day 30 after treatment. Around 15 percent of neutrophils were found to be NAPDH-positive early after treatment. This fraction increased due to insertional activation of the *PRDM16* and *MDS1/EVI1* genes in clonal cell populations that expanded with time. However, epigenetic inactivation of the vector gradually reduced the NAPDH-positive neutrophils to less than 5 percent by 1 to 2 years after treatment. Unfortunately, activation of the EVI1 due to retroviral insertion resulted in myelodysplasia with monosomy 7 in both treated patients (Evans & Garcia, 2000). The first patient suffered from septic shock in the context of myelodysplastic syndrome (MDS) and died 2.5 years after gene therapy. The second subject was treated with allogeneic stem cell transplantation and died of complications (Ott et al., 2004; Stein et al., 2010; Aiuti et al., 2012).

The same protocol was used in Switzerland by Seger and collaborators, who enrolled a X-CGD boy with severe *Aspergillus* infection. NAPDH-positive neutrophils were detected at levels up to 30 percent, and the procedure resulted in eradication of the fungal infection (Bianchi et al., 2009). Unfortunately, also this patient developed MDS and has undergone allogeneic stem cell transplantation (Aiuti et al., 2012).

Another gene therapy trial using a Moloney retroviral vector was conducted in South Korea and enrolled two X-CGD patients. Mobilized peripheral blood $CD34^+$ cells were transduced and infused after a conditioning regimen of fludarabine and busulfan. The level of NAPDH-positive cells reached 6 to 14 percent of neutrophils, but the correction was short term and declined to less than 1 percent in both patients 3 years after treatment (Kang HJ et al., 2011).

Additional, unpublished experience of gene therapy for CGD has been generated by Thrasher in London, where conditioning with melphalan (140 mg/m^2) and either the vector employed in the German trial or the NIH construct were used. Similar to other trials, in the short term (<2 months), low levels of $gp91^{phox}$ expression were detected in treated patients (Grez et al., 2011).

In summary, therefore, the current experience with gene therapy of CGD points to a yet unexplained difficulty in achieving long-term engraftment of transduced cells. The lack of a strong selective advantage of gene-corrected populations in this disease may play a major role and may indicate that more significant levels of HSC transduction and engraftment will be needed to obtain clinical benefit.

More efficient methods of gene transfer are also being developed based on lentiviral vectors (Naumann et al., 2007; Roesler et al., 2002; Santilli et al., 2011; Saulnier et al., 2000). Alternatively, in vivo selection of gene-corrected cells could be engineered by the addition of drug resistance markers such as the multidrug resistance (MDR) or dihydrofolate reductase (DHFR) genes to gene transfer vectors. Studies of these approaches in animal models are ongoing and are likely to provide clear indications on the prospects of future success of gene therapy for CGD.

LEUKOCYTE ADHESION DEFICIENCY TYPE I

LAD I is an inherited defect of leukocyte functions caused by the absence or reduced levels of expression of the common β_2-integrin subunit (CD18) (Harlan, 1993). LAD I primarily affects motion functions of granulocytes that fail to migrate into inflamed tissues and exert their phagocytic functions. Affected patients initially present with retarded separation of the umbilical cord and subsequently develop recurrent severe bacterial and fungal infections (Etzioni, 1994; Fischer et al., 1988) (see Chapter 52). Allogeneic BMT from an HLA-matched related donor has been demonstrated to be curative for this disease. The insertion of normal cDNA into the stem cells of a patient may therefore lead to genetic correction of this disease, and studies utilizing viral vectors have demonstrated in vitro functional reconstitution of CD18 molecules in LAD I lymphocytes (Bauer et al., 1995; Hibbs et al., 1990; Wilson et al., 1990).

The expression of CD18 is limited to myeloid cells and lymphocytes; however, functional adhesion molecules require dimerization of CD18 with other subunits (CD11a, CD11b, or CD11c) also expressed only by the same cell types. Expression of CD18 in other lineages deriving from gene-

corrected HSCs and normally not expressing CD18 should therefore not result in unregulated and unwanted expression of complete adhesion molecules.

Similarly to CGD, because of the short lifespan of myeloid cells, the target for corrective gene transfer of LAD I is necessarily the HSC. Retroviral vectors have been used to demonstrate reconstitution of CD18 expression in granulocytes differentiated in vitro from gene-corrected $CD34^+$ cells (Bauer et al., 1998; Yorifuji et al., 1993). Following these studies, a clinical protocol for gene therapy of LAD I at the University of Washington in Seattle used retroviral-mediated correction of G-CSF–mobilized peripheral blood $CD34^+$ cells. Bauer and Hickstein (2000) reported results from the two LAD I patients treated. Peripheral blood $CD34^+$ cells were obtained by pharmacological mobilization with G-CSF and exposed to a retroviral vector expressing CD18 before being reinfused into the patients. One month after the infusion of transduced $CD34^+$ cells, both patients showed low percentages (0.03–0.04 percent) of $CD18^+$ myeloid cells, and one patient had some evidence of functional correction, as $CD18^+$ myeloid cells were demonstrated to migrate into a site of inflammation. Unfortunately, gene-corrected cells were not detectable beyond 2 months after treatment in these two patients (Bauer & Hickstein, 2000).

Allogeneic HSCT studies in a canine model of LAD I have shown that very low levels of donor $CD18^+$ neutrophils (<500/μL) were sufficient to reverse the disease phenotype and that nonmyeloablative conditioning is adequate for correction of the disease phenotype (Bauer et al., 2004, 2005; Sokolic et al., 2005). These experiments were followed by HSC gene-correction experiments in this model using murine retroviral vectors (Bauer et al., 2006), FV vectors (Bauer et al., 2008), and lentiviral vectors (Hunter et al., 2011a, 2001b; Nelson et al., 2010) that, in most cases, showed correction of the canine LAD phenotype. However, no selective survival advantage of gene-corrected myeloid cells is expected in LAD I. As with CGD, strategies involving adequate preparative myeloablation, in vivo selection, and the use of efficient vectors will likely prove useful in improving the outcome of future gene therapy trials for LAD I.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY

X-SCID is caused by mutations of the common gamma chain (γ_c) of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Noguchi et al., 1993; Puck et al., 1993). Affected males present with a combined impairment of T- and B-cell immunity, despite the presence of B cells in normal or even elevated numbers (see Chapter 10). Allogeneic BMT can be curative for these patients, and it generally shows good success in terms of survival (Antoine et al., 2003; Buckey, 2004) (see Chapter 60). However, especially in the case of haploidentical donors, transplanted patients often achieve only partial chimerism of hematopoietic lineages, with persistence of autologous B lymphocytes and impairment of humoral immune function that requires continuous replacement therapy with immunoglobulins (Antoine et al., 2003). Such unsatisfactory results have fostered the development of gene therapy approaches for this disease.

In preclinical studies, several groups of investigators have shown that retroviral-mediated transfer of the γ_c into B lymphoblastoid cell lines derived from X-SCID patients can correct a series of cellular defects, including γ_c membrane expression, IL-2 high-affinity binding and internalization, ligand binding-mediated phosphorylation of JAK3 and JAK1 tyrosine kinases, as well as IL-2–induced cell proliferation (Candotti et al., 1996; Hacein-Bey et al., 1996; Taylor et al., 1996). More importantly, normal development of mature T lymphocytes (Hacein-Bey et al., 1998) and NK cells (Cavazzana-Calvo et al., 1996) was demonstrated from gene-corrected X-SCID HSCs in vitro. In addition, in vivo experiments in mouse models of X-SCID have shown the safety and efficacy of γ_c gene transfer in bone marrow stem cells, with reconstitution of lymphoid development and function in these animals (Aviles Mendoza et al., 2001; Lo et al., 1999; Otsu et al., 2000, 2001; Soudais et al., 2000).

These results formed the basis for the first clinical gene transfer protocol for X-SCID, launched in 1999 in Paris, France. This trial involved retroviral γ_c gene transfer into $CD34^+$ bone marrow cells harvested from X-SCID patients who lacked HLA-identical bone marrow donors and enrolled 10 typical X-SCID patients. The results of this trial have been reported and showed that as soon as 60 to 90 days after the infusion of gene-corrected cells, T lymphocytes expressing γ_c appeared in the circulation and reached normal values within 4 to 8 months in eight patients (Cavazzana-Calvo et al., 1996; Ginn et al., 2005; Hacein-Bey-Abina et al., 2002, 2003a, 2010). Most importantly, these T lymphocytes were polyclonal and functionally competent, as demonstrated by normal responses to stimulation with mitogens and specific antigens. In contrast with the T lymphocytes, the NK cell counts declined to values lower than normal after an initial significant rise during which restoration of NK cell function was observed. In addition, despite the fact that virtually no B cells carried the γ_c transgene 6 to 10 years after gene therapy, close-to-normal serum levels of IgG, IgA, and IgM were demonstrated in four, five, and seven patients, respectively. All patients initially developed specific antibody responses to tetanus and diphtheria toxins, as well as poliovirus vaccines, but positive titers were not consistently detected in the long term, and three patients required immunoglobulin replacement therapy. Not surprisingly, based on the predicted lack of selective advantage in myeloid lineages, only 0.01 to 1 percent of the patients' monocytes and granulocytes showed evidence of genetic correction (Cavazzana-Calvo et al., 2001; Hacein-Bey-Abina et al., 2002, 2010; Sun et al., 1997).

This series of patients clearly demonstrated that γ_c gene transfer can restore the immune system in X-SCID patients. Although the restoration was incomplete with regard to the numbers of gene-corrected B and NK cells, the effects of the treatment were sufficient to provide protective immunity and to allow the patients to return home and lead a normal life. The failure of the treatment in 2 of the total of 10 patients treated in Paris was attributed to the specific characteristics of these two patients. The first subject had chronic infections that may

have affected the engraftment of gene-corrected cells (Hacein-Bey-Abina et al., 2002), while the second patient, treated in Australia, received a low number of gene-corrected cells and suffered from a significant viral infection early after treatment (Ginn et al., 2005). In addition, one of these two patients was an atypical patient of 15 years of age at the time of treatment, thus raising the possibility that loss of thymic function may have contributed to the failure of the procedure in this case.

Starting late in 2002, a series of four patients who had been treated with gene therapy about 3 to 5 years earlier presented with uncontrolled clonal T-cell proliferation. The malignant behavior of such proliferation required conventional treatment for T acute lymphoblastic leukemia to be administered, in one case followed by matched unrelated BMT.

In all cases, the adverse event was the result of insertional oncogenesis due to the aberrant expression of the *LMO2* (LIM domain only-2) or *CCND2* (cyclin D2) oncogenes induced by the integration of the γ_c retroviral vector in the proximity of the gene regulatory regions (Hacein-Bey-Abina et al., 2003a, 2003b, 2008). LMO2 is required for normal hematopoiesis and is activated in childhood acute T-cell leukemias by chromosomal translocation (Larson et al., 1994). CCND2 is normally active during early thymopoiesis and downregulated thereafter, which implicates its overexpression in T-cell leukemia development. Although our understanding of the mechanism underlying the development of LMO2- and CCND2-mediated lymphoproliferation remains incomplete, it appears plausible that the enhancer activity of the retroviral vector promoter was responsible for the activation of the LMO2 and CCND2 promoters and consequent deregulated LMO2 and CCND2 gene expression. Vigorous cell proliferation of LMO2- and CCND2-expressing cells due to the selective advantage conferred to them by the concomitant expression of the γ_c gene may have provided a "second hit" and favored secondary changes leading to the onset of the overt malignancies.

Whether or not the leukemic transformation observed in these patients can thus be attributed to a specific cooperation between γ_c and LMO2/CCND2 in the context of a strong selective advantage conferred by the genetic correction remains to be established, but it is obviously of critical importance as it could change the assessment of the risk that similar events may occur after retroviral-mediated gene transfer into HSCs for other diseases. These serious adverse events have had major repercussions on the field of gene therapy in general. It is clear that a complete reassessment of the risks of gene therapy for X-SCID and of the validity of the previous safety studies in animal models is warranted to provide an understanding of how to safely continue clinical experimentation of an approach that has provided clear clinical benefit but also unintended severe complications.

Despite aggressive therapy, one of the four patients who developed lymphoproliferation died, while the others remain in remission up to 10 years after the occurrence of the severe adverse event and conventional chemotherapy (Hacein-Bey-Abina et al., 2010).

In July 2001, a second gene therapy trial for X-SCID was started by Thrasher et al. at the Great Ormond Street Hospital in London, UK. The protocol design was similar to the French trial, with the exception of slight differences in culture conditions (lower concentration of IL-3 and serum-free medium) and the use of a gibbon-ape leukemia virus (GALV) pseudotyped vector. During the following 4.5 years, 10 children (4–46 months of age) were enrolled and treated; all patients had substantial improvements of clinical features and immunological function. The latter included recovery of T-cell numbers (up to normal numbers in six patients), normal T-cell proliferative responses (except in one patient), and a polyclonal T-cell receptor (TcR) Vβ repertoire (in six subjects). Improvement of humoral immunity was also observed that allowed discontinuation of prophylactic immunoglobulin replacement treatment in four patients (Gaspar et al., 2004, 2011b). Altogether, these data confirm the results obtained in the French trial and corroborate the notion that gene therapy can be curative for X-SCID. Also similar to the French trial, one patient developed LMO2-overexpressing T-cell leukemia about 24 months after treatment and responded to standard chemotherapy (Howe et al., 2008).

The French and British groups have also described the failure of their gene therapy protocol in two older X-SCID patients (20 and 15 years old) who had presented later in life with attenuated clinical phenotype. Neither patient showed significant changes of immunological parameters despite successful transduction of $CD34^+$ bone marrow cells and demonstration of transitory vector marking in B, NK, and myeloid cells in one patient. The authors hypothesized the compromised thymopoiesis in these older patients had posed restrictions to the efficacy of the procedure (Thrasher et al., 2005).

One additional trial was begun at the NIH in 2003 with the aim of offering a rescue treatment option for older X-SCID patients who had failed to respond to previous haploidentical BMT treatment. Three patients (11, 10, and 14 years old) were enrolled in this trial, which targeted G-CSF–mobilized peripheral blood $CD34^+$ cells. T-cell numbers and function significantly improved in the youngest subject, but no immunological improvement was observed in the other two subjects. Multilineage retroviral marking was documented in all three children (Chinen et al., 2007). The loss of thymic potential in these older patients may be a formidable challenge to the success of the procedure.

The occurrence of insertional oncogenesis in 20 percent of typical X-SCID patients treated with gene therapy vectors using the strong murine retroviral promoter/enhancer combination stimulated a series of effort to develop novel constructs to capitalize on the demonstrated efficacy of gene therapy for X-SCID while enhancing the safety of the procedure. Based on the notion that proto-oncogene activation was caused by enhancer-mediated promoter induction, an enhancer-less murine retroviral vector was generated and tested for efficacy in the mouse model of X-SCID (Thornhill et al., 2008). Based on the satisfactory results, a multicenter study including centers in London, Paris, Boston, Cincinnati, and Los Angeles has begun and had enrolled four patients as of December 2011. Data are available only for the first patient at about 6 months after treatment and are encouraging, showing increase of T-cell numbers to one third of normal values

and normalization of proliferative responses to mitogens (Pai et al., 2011). An alternative approach has been developed by Sorrentino and colleagues, who have elected to use a lentiviral vector to express the γc because of the reduced propensity of this class of vectors to integrate near gene transcriptional start sites (Wu et al., 2003). A two-site clinical trial using such vector (Zhou et al., 2010) is open at the St. Jude Children's Research Center in Memphis, where typical X-SCID patients will be enrolled, and at NIH, where atypical older patients will be treated. The latter arm of the trial will use nonmyeloablative conditioning to improve the efficacy of engraftment of gene-corrected cells.

JAK3 DEFICIENCY

The JAK3 member of the Janus family of protein tyrosine kinases is a lymphoid tissue-specific tyrosine kinase (Kawamura et al., 1994) involved in the signal transduction pathway of several cytokines, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (Asao et al., 2001; Habib et al., 2002; Johnston et al., 1995). Patients with mutations of JAK3 usually present with autosomal-recessive SCID (Candotti et al., 1997; Macchi et al., 1995; Notarangelo et al., 2001; Russell et al., 1995) with clinical characteristics virtually identical to those presented by X-SCID patients, except for the fact that JAK3 deficiency can also be found in female patients (see Chapter 10).

Because of the clear similarities between the effects of γ_c and JAK3 genetic defects, the theoretical possibilities for gene therapy are analogous. Retrovirally mediated gene correction has reconstituted IL-2 and IL-4 responses in JAK3-deficient cell lines (Candotti et al., 1996; Oakes et al., 1996), leading to the hypothesis that the gene correction of HSCs may be a useful therapy for JAK3-deficient patients. Preclinical in vivo studies have demonstrated the feasibility of retroviral-mediated gene correction of JAK3 deficiency in murine models using irradiated adult recipients and nonirradiated newborn animals (Bunting et al., 1998, 1999, 2000). Of note, an in vivo selective advantage of transduced cells over untransduced JAK3-deficient counterparts was demonstrated for lymphoid lineages, suggesting that treatment procedures similar to those used in the gene therapy trial for X-SCID could lead to successful results in JAK3 deficiency. Based on these results, Sorrentino et al. at the St. Jude Children's Research Hospital in Memphis attempted the genetic correction of bone marrow $CD34^+$ cells of a JAK3-deficient patient who had failed to respond to BMT. Infusion of retrovirally transduced cells was attempted twice in this patient, resulting in low levels of marking without significant change of immunological status (Sorrentino et al., 2003). The reasons for unsatisfactory outcome are not clear at the moment, and it is hoped that further investigations in additional patients will clarify prospects for gene therapy for this disease.

WISKOTT-ALDRICH SYNDROME

WAS is characterized by eczema, thrombocytopenia, recurrent infections, autoimmune disorders, and a high incidence of lymphomas (Fischer, 1993; Sullivan et al., 1994). The breadth and severity of WAS symptoms make management of this disease a complex problem (Mullen et al., 1993). The WAS gene encodes a highly proline-rich protein, WASp (Derry et al., 1994), that has been implicated in actin organization in the cytoskeleton (see Chapter 43). The unsatisfactory results of haplodentical BMT in WAS patients (Antoine et al., 2003; Filipovich et al., 2001; Moratto et al., 2011; Ozsahin et al., 2008) justify efforts to test the safety and efficacy of gene therapy for this disease.

Studies in WAS lymphoblastoid B cell lines (Candotti et al., 1999; Huang et al., 2000), as well as T-cell lines and primary T lymphocytes (Dupre et al., 2002; Wada et al., 2002; Strom et al., 2003) have shown that retroviral-mediated gene transfer can correct the phenotype of WAS cells. More recent experiments have shown that *WAS* gene transfer using lentiviral vectors can provide functional correction of WAS patients' T cells with higher efficacy (Dupre et al., 2004). More importantly, in vivo models of gene therapy using knockout mice have shown that T-cell numbers and responses can be improved in animals treated with both retroviral and lentiviral *WAS* gene transfer, albeit at reduced levels compared to wild-type animals (Blundell et al., 2008; Bosticardo et al., 2011; Catucci et al., 2011; Charrier et al., 2004; Dupre et al., 2006; Klein et al., 2003; Marangoni et al., 2009; Strom et al., 2002). Interestingly, competitive repopulation experiments have also documented a selective advantage of wild-type over *WAS* knockout cells (Strom et al., 2002), thus suggesting that gene-corrected lymphocytes could similarly have a selective advantage over unmodified populations after gene therapy. These observations are in line with the reports of somatic reversion of *WAS* mutations in T-lymphocyte progenitors of WAS patients that resulted in significant numbers of WASp-expressing circulating T lymphocytes with selective survival advantage in vivo over WASp-negative cells (Wada et al., 2001, 2003, 2004).

Following up on in vitro functional restoration experiments of human hematopoietic progenitors using a MoMLV-based retroviral vector (Dewey et al., 2006), the first clinical trial of gene therapy for WAS started in Germany in 2006 and enrolled 10 patients in the following 3 years. Mobilized peripheral blood $CD34^+$ cells were transduced (with transduction efficiency about 50 percent) and reinfused into patients after conditioning with busulfan (8 mg/kg). The procedure resulted in a significant increase of WASp-expressing platelets and lymphocytes over time, up to 80 to 90 percent. Treated subjects showed a significant increase of platelet numbers and normalization of T-cell numbers and function, NK-cell function, immunoglobulin production, and responses to vaccines. One patient failed to respond to treatment because of an insufficient cell dose. All other patients markedly improved their clinical status, including bleeding tendency, susceptibility to infections, and autoimmunity. Unfortunately, insertional oncogenesis mediated by LMO-2 activation occurred in four patients and resulted in T-cell leukemia (Boztug et al., 2010; Braun et al., 2011).

More recently, a multicenter gene therapy trial using the lentiviral construct extensively tested in the mouse models described above opened in Milan, London, Paris, and Boston.

It is hoped that the increased theoretical safety of this class of vectors will protect patients from the occurrence of leukemic adverse events, and efficacy results are eagerly awaited by the scientific and clinical communities.

PRECLINICAL EXPERIMENTS OF GENE THERAPY FOR OTHER IMMUNODEFICIENCIES

PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY

In most cases, the immunological disorder associated with genetic deficit of purine nucleoside phosphorylase (PNP—EC 2.4.2.1) is restricted to the T-cell compartment, while B-cell functions are generally normal (see Chapter 14). Enzyme replacement therapy, by means of irradiated red blood cell transfusions (Rich et al., 1980), has not been definitively proved to be beneficial for PNP deficiency, and allogeneic HLA-matched BMT is the current therapy of choice, although reports indicating its success in patients with PNP deficiency are limited.

The lack of PNP activity leads to the block of the same purine salvage pathway that is affected by the genetic deficit of ADA. The biochemical defects of ADA and PNP deficiency are similar, so the prospect for successful gene therapy of PNP deficiency also seems likely.

In preclinical studies using retroviral- and lentiviral-mediated gene transfer, in vitro reconstitution of PNP activity in T lymphocytes derived from PNP-deficient subjects has been described (Liao et al., 2008; Nelson et al., 1996). These results suggested that T cells could potentially be used as vehicles for therapeutic PNP gene expression, and clinical protocols testing this hypothesis have been proposed but not implemented. Contrary to ADA-SCID, no enzyme replacement treatment is available for this disease. PNP-deficient patients are usually lymphopenic; for this reason, the possibility remains that PNP-deficient patients will not have a sufficiently developed peripheral T-cell repertoire to achieve meaningful immune reconstitution with T-lymphocyte–directed gene therapy. Therefore, the correction of the gene defect at the level of HSC seems the best strategy, and the preliminary partial restoration of the PNP-deficient mouse model using bone marrow stem cell-directed gene correction (Liao et al., 2008) provides a platform for further development of the approach.

ZAP-70 DEFICIENCY

Mutations affecting the expression of ZAP-70 protein tyrosine kinase are a rare cause of autosomal recessive SCID characterized by absence of mature circulating $CD8^+$ T lymphocytes and TcR signal transduction defects in peripheral $CD4^+$ T cells (Arpaia et al., 1994; Chan et al., 1994; Elder et al., 1994) (see Chapter 15). Since ZAP-70–deficient patients have been successfully treated by allogeneic BMT, this disease is another candidate for stem cell gene correction. The presence of circulating T lymphocytes in these patients has allowed the establishment of HTLV-1–transformed T-cell lines that have been used as targets for corrective gene transfer as a preliminary study of the feasibility of a gene therapy approach for this disease. Upon retroviral-mediated gene transduction of the normal ZAP-70 cDNA into T cells from a ZAP-deficient patient, it was possible to achieve expression of ZAP-70 kinase that was appropriately tyrosine phosphorylated upon TcR engagement. More importantly, reconstitution of in vitro kinase activity of the transduced ZAP-70 and normalization of calcium mobilization after TcR stimulation in gene-corrected cells was demonstrated (Taylor et al., 1996). In following experiments, Steinberg and coworkers transferred the ZAP-70 cDNA into primary T lymphocytes obtained from ZAP-70–deficient patients. Upon gene correction, several biological functions were restored in these T cells, including TcR signaling, Ras-mitogen-activated proten kinase (MAPK) activation, and IL-2 secretion. In addition, and importantly, selective growth advantage of gene-corrected cells was observed after in vitro culture of transduced cells (Steinberg et al., 2000), suggesting that the genetic correction of few HSCs and/or lymphoid progenitor cells may generate significant numbers of corrected T lymphocytes and restoration of T-cell immunodeficiency.

Because of the normally restricted expression of the ZAP-70 protein to specific lymphoid lineages, evaluation of potential deleterious effects of the ectopic expression of ZAP-70 in cell types normally not expressing this protein is a concern. However, gene correction of bone marrow cells of ZAP knockout mice using a retroviral vector expressing the human ZAP-70 gene resulted in the development of mature, polyclonal and functional T lymphocytes, while expression of the retroviral transgene in B cells did not affect their function (Otsu et al., 2002). Altogether, these data indicate that retroviral-mediated transfer of the ZAP-70 gene may prove to have a therapeutic benefit for patients with ZAP-70 deficiency.

To avoid some of the technical difficulties of HSC gene therapy, investigators have developed gene therapy approaches for ZAP-70 based on in situ gene correction of T-lymphoid progenitors in the thymus. This approach has been pursued using lentiviral vectors (Adjali et al., 2005) or simple electroporation of the correcting gene sequences (Irla et al., 2008). Intrathymic injection of a lentiviral vector or electroporation of ZAP-70 sequences resulted in the long-term differentiation of mature and functional thymocytes (Adjali et al., 2005; Irla et al., 2008), thus representing potentially safer alternatives to ex vivo gene-modified HSC gene therapy.

MHC CLASS II DEFICIENCY

Deficit of expression of MHC class II molecules can be caused by defects of several different MHC class II-specific transcription factors including CIITA, RFX5, RFXAP, and RFXANK. MHC class II deficiency is characterized by severe immunodeficiency with low numbers of $CD4^+$ lymphocytes (see Chapter 16). Allogeneic BMT is potentially curative, but its success rate for this disease is very low (Huss et al., 1995; Klein et al., 1995). Alternative forms of therapy are therefore needed, and HSC-directed gene therapy could be beneficial for these patients. Exploring this possibility, Bradley et al. have

shown that retrovirus-mediated gene transfer of the CIITA factor could restore expression of MHC class II in B lymphoblastoid lines and peripheral blood cells from an MHC class II-deficient patient (Bradley et al., 1997). Lentiviral vectors have also been described that express each of the above four MHC class II-specific transcription factors (Matheux et al., 2002); these may prove useful for future gene therapy applications. A cautionary note, however, comes from reports indicating that ectopic expression of MHC class II genes can result in pathological hyperactivity of $CD4^+$ lymphocytes (Bottazzo et al., 1986). Since expression of MHC class II molecules is regulated in important cell types such as T lymphocytes, fibroblasts, and endothelial cells, it will be important to determine whether tissue-specific expression of the therapeutic gene is needed for clinical applications.

IMMUNODEFICIENCY WITH HYPER-IGM

The X-linked hyper-IgM syndrome (X-HIM) is another rare PID caused by genetic mutations in the CD40 ligand molecule (CD40L) expressed on activated $CD4^+$ T lymphocytes (see Chapter 26). X-HIM patients lack functional CD40L on their T cells and have profound impairment of interactions between T cells and B cells. A detailed follow-up of X-HIM patients has made clear that the immunoglobulin substitution did not provide an adequate long-term solution to the severe infectious episodes suffered by these boys. Allogeneic BMT is therefore now indicated as definitive treatment for this disease, which is also a potential candidate for gene therapy.

Unfortunately, however, CD40L expression is highly regulated and restricted to activated $CD4^+$ lymphocytes, thus introducing the need for regulated gene transfer systems. The necessity of strictly regulating the expression of CD40L on gene-corrected cells was stressed by Brown et al., who performed transplantation of retrovirally gene-corrected bone marrow or thymic cells into CD40L knockout mice. Humoral and cellular immune responses of treated mice to influenza virus were partially or fully restored; however, more than 60 percent of these mice developed lymphoproliferative disease in the form of prelymphoma of T-lymphoblastic lymphoma. T-cell proliferation was most likely due to enhanced positive selection driven by the constitutive expression of CD40L on developing thymocytes (Brown et al., 1998). Gene transfer systems allowing effective regulation of CD40L therefore will have to be developed before gene-correction approaches can be proposed for the treatment of humans with X-HIM. One such approach has been proposed by Tahara et al., who aimed at preserving physiological regulation of CD40L by using spliceosome-mediated RNA trans-splicing. Bone marrow from CD40L knockout mice were transduced with a lentiviral vector encoding a pre-trans-splicing molecule containing wild-type CD40L exons 2–5 and transplanted into lethally irradiated recipient animals. Corrected CD40L mRNA, regulated CD40L expression in $CD4^+$ T cells, antigen-specific IgG1 responses, and attenuation of *Pneumocystis carinii* pneumonia were observed in treated mice in the absence of lymphoproliferative complications (Tahara et al., 2004). Although this strategy seems promising, further studies are needed to establish whether the efficacy of RNA trans-splicing will be adequate to correct the human phenotype.

Soluble CD40L is available and could represent an alternative form of therapy for X-HIGM. If proven beneficial, administration of autologous cells or "pseudo-organs" engineered to produce CD40L, but be easily removable, may become a more controllable option. As a more sophisticated approach, a lentiviral vector was recently constructed using the human CD40L proximal promoter to obtain tissue-specific, activation-inducible expression of CD40L. Testing experiments showed that transduced X-HIM T cells expressed CD40L only after stimulation with PMA+Ionomycin (Romero et al., 2011). These encouraging results suggest that CD40L-promoter-driven vectors may be able to be developed for gene therapy of X-HIM.

X-LINKED AGAMMAGLOBULINEMIA

Bruton's disease, X-linked agammaglobulinemia (XLA), is a genetic disorder of B-lymphocyte differentiation that results in absence of mature circulating B cells and undetectable serum immune globulins of all isotypes (Conley et al., 1994; Smith et al., 1994) (see Chapter 25). The molecular defect of XLA has been identified in mutations of the gene encoding Bruton's tyrosine kinase (*BTK*) (Tsukada et al., 1993; Vetrie et al., 1993), normally expressed by developing B and myeloid cells, but not plasma cells or T cells. The current management of XLA is with administration of immunoglobulin, which is generally efficacious in preventing infections. This treatment, however, is expensive, inconvenient, and in some cases insufficient to avoid lethal infections.

XLA patients therefore could benefit from development of gene therapy. The generation of retroviral vectors expressing *BTK* has been attempted since the mid-1990s, but several laboratories failed to produce high-titer retroviral-producing cell lines. These difficulties were explained by the demonstration that expression of *BTK* can mediate apoptosis (Islam et al., 2000). These findings suggest that high levels of *BTK* expression in target cells may induce toxic effects and that vector selection could be critical for the development of successful gene therapy for XLA. On the other hand, progress in vector design and production has made possible preclinical experiments of genetic correction in the X-linked immunodeficiency (xid) mouse, in which *btk* is mutated. Preliminary results showed that gene transfer into xid bone marrow cells can reconstitute B-cell development and production of IgM and IgG_3 antibodies (Conley et al., 2000; Yu et al., 2000). In addition, BTK-expressing B-cell progenitors were found to have a selective advantage over BTK-negative progenitors (Rohrer & Conley, 1999). Mice deficient in both Btk and the related kinase Tec have been corrected by retroviral-mediated gene therapy with a human *BTK* vector (Yu et al., 2004). Treated mice showed restoration of both primary and peripheral B-lineage development, correction of serum IgM and IgG_3 levels, and restoration of T-independent immunity and B-cell proliferative responses.

Following efforts focused on the generation of lentiviral vectors able to obtain B-cell–specific expression of BTK

and avoid potentially detrimental ectopic BTK expression in other lineages that has been shown to result in myeloerythroid proliferation (Kerns et al., 2010; Moreau et al., 2008; Ng et al., 2010). These experiments showed correction of B-cell development and antigen-specific antibody responses in *Btk* knockout mice; overall, the results support the continued development of gene therapy for XLA.

RAG-1 AND RAG-2 DEFICIENCY

Patients with mutations of the recombination-activating genes *RAG1* or *RAG2* suffer from a from of SCID characterized by the lack of both T and B lymphocytes. HSCT is currently the only curative treatment, but it is only partially successful in the absence of an HLA-identical familial donor. Exploring the potential of gene therapy for these diseases is therefore justified. Initial experiments used RAG-2–deficient mice and genetic correction of HSC with a MoMLV-based retroviral vector. Development of T cells and B cells was observed in treated mice, accompanied by a diverse T-cell repertoire, normal proliferative responses to mitogens and alloantigens, and humoral responses to antigenic challenge. A selective advantage for transduced lymphoid cells was demonstrated by comparative provirus quantification in RAG-2 lymphoid and myeloid cells, while there was no evidence of toxicity due to constitutive expression (Yates et al., 2002). The same investigators followed up with similar experiments in the RAG-1–deficient mouse model and showed that retroviral gene transfer into HSCs can restore normal B- and T-cell function, provided that high copy numbers of the transgene (≥5 copies/cell) were achieved in treated mice. These results suggested that a minimum threshold of RAG-1 expression may need to be achieved for efficient lymphoid development. In contrast to the RAG-2 model, however, high transgene copy number in lymphoid organs was associated with the occurrence of a lymphoproliferation event in one mouse, which raised the concern of a delicate balance between efficacy and toxicity for the application of retroviral-mediated gene correction of RAG-1 deficiency (Lagresle-Peyrou et al., 2008).

Additional experiments form the same group used lentiviral gene-corrected bone marrow $CD34^+$ cells obtained from several RAG-1–deficient patients and engrafted them into NOD-SCID mice in xenograft experiments aimed at testing the restoration of human B-cell differentiation following gene correction. Again, the results showed that restoration of B-cell differentiation occurred only after transplantation of samples transduced with the higher vector copy numbers (4 copies/cell) (Lagresle-Peyrou et al., 2008).

More recent experiments used a lentiviral vector designed to provide optimized expression of RAG-1. Treated mice showed normal T- and B-cell development, serum Ig levels, TCR-mediated cell proliferation, and cytokine production. Antigen-specific antibodies were produced after in vivo challenge with trinitrophenyl keyhole limpet haemocyanin TNP-KLH. These results were achieved with less than 1 vector copy/cell in lymphoid organs, and no insertional mutagenesis was observed (Pike-Overzet et al., 2011), which encourages further development of this vector for clinical applications.

CD3 DEFICIENCY

The TcR is constituted by a glycoprotein heterodimeric complex containing TcRα and TcRβ, or TcRγ and TcRδ chains that associate with the CD3 complex composed of CD3γ, CD3δ, CD3ε, and CD3ζ (or CD3η) polypeptides. Selective defects of the expression of CD3γ have been reported in humans, resulting in only partial disorders of cellular immunity (Arnaiz-Villena et al., 1992) (see Chapter 11). Because of the presence of circulating T lymphocytes in these patients, a T-lymphocyte–directed gene therapy approach could be developed. Retroviral-mediated expression of CD3γ in mutant Jurkat T cells resulted in normalization of IL-2 production after TCR/CD3 engagement and TCR/CD3 downmodulation in response to PMA (Sun et al., 1997). Similarly, CD3γ introduction into peripheral blood T lymphocytes from CD3γ-deficient patients corrected the TCR/CD3 expression and downregulation defects but unfortunately also induced constitutive IL-2 synthesis, causing death of nontransduced T lymphocytes. CD3γ gene transfer into postthymic lymphocytes therefore can become detrimental to the host, and regulated expression will be necessary if gene therapy is to be developed for this disease.

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

Mutations or deletions in *SH2D1A/SAP* gene result in the X-linked lymphoproliferative disease (XLP), a combined immunodeficiency associated with severe or fatal outcome after EBV infection (see Chapter 44). The SH2D1A/SAP protein is primarily expressed in T and NK cells (Czar et al., 2001; Parolini et al., 2000; Wu et al., 2001). Among T lymphocytes, cytotoxic T cells (CTLs) play a crucial role in the immune response to EBV. CTLs from XLP patients are characterized by reduced IFN-γ production in response to EBV-mediated stimulation and decreased cytotoxic activity against autologous lymphocytoid cell lines. These defects were restored using retroviral-mediated *SAP* gene transfer, thus opening the way to approaches for corrective gene transfer into CTLs as a potential form of therapy for this disease (Sharifi et al., 2004).

However, a HSC-direct gene therapy approach would likely be more beneficial and can be tested in *SAP* knockout mice that are available and resemble the human condition (Wu et al., 2001; Czar et al., 2001; Yin et al., 2003). A proof-of-principle study used lentiviral-mediated gene transfer to introduce the human SAP cDNA into HSCs from *SAP* knockout mice. This study demonstrated that full correction of NK-cell cytotoxity and partial recovery of NKT-cell development and humoral responses can be obtained with such an approach (Rivat et al., 2013). The lentiviral vector used in this study provided constitutive expression of SAP, which may be problematic as cell types such as HSCs and B cells do not physiologically express SAP. Whether or not enforced expression of SAP was responsible for the incomplete immune recovery seen in treated mice is unclear. However, vectors with

physiologically regulated SAP gene expression are currently under development and will be able to answer this question in the near future.

ARTEMIS DEFICIENCY

Mutations in *Artemis*, a gene critical for VDJ recombination, give rise to a form of SCID originally described in Athabascan-speaking Native Americans. As in other SCIDs, patients present early in life with a typical severe immunodeficient phenotype (viral or *Pneumocystis* pneumonia, persistent viral diarrhea, and growth failure). As a characteristic of this disease, hematopoietic cells and fibroblasts from these patients exhibit increased cellular radiosensitivity (see Chapter 13). HSCT is curative, and preparative regimens including irradiation are usually avoided. The limited availability of ideal donors and the increased frequency of complicating events after the transplant (Neven et al., 2009) justify the development of gene therapy approaches as an alternative treatment for this disease. Preclinical experiments using *Artemis* knockout mouse models and Artemis-expressing lentiviral vectors have been performed by several groups and have demonstrated that genetic correction of HSCs can rescue T- and B-cell development and proliferation responses and serum immunoglobulin and specific antibody production (Benjelloun et al., 2008; Mostoslavsky et al., 2006). A note of caution was raised by studies that demonstrated toxic effects of Artemis overexpression on fibroblasts and 293 cells, including decreased cell viability, increased DNA damage, and increased apoptosis (Multhaup et al., 2010). These results point to a challenge in the clinical development of gene therapy for Artemis deficiency and suggest that future vector design should include endogenous transcriptional elements of the Artemis gene, which would achieve physiological regulation of the transgene in gene-corrected cells.

RETICULAR DYSGENESIS

Reticular dysgenesis, an autosomal recessive from of SCID caused by mutations of the adenylate kinase 2 (*AK2*) gene, accounts for 3 percent of all SCID cases (see Chapter 18). Characteristics of the disease include virtual absence of neutrophils, T lymphocytes, and NK cells, combined with variable decreases in red blood cell, platelet, and B-cell counts. In addition, affected newborns have bilateral sensorineural deafness. Allogeneic HSCT can correct hematopoiesis, but myeloablative conditioning is required to achieve engraftment of myeloid lineages. As for other forms of SCID, treatment options using autologous gene-corrected HSCs would be desirable. Preliminary work toward gene therapy for reticular dysgenesis involved lentiviral vector constructs and transduction of patient-derived bone marrow cells. These experiments showed that AK2 gene transfer can overcome the promyelocyte/myelocyte differentiation arrest in vitro and allow the production of mature neutrophils (Lagresle-Peyrou et al., 2009). Additional experiments will be necessary to verify that, in addition to granulopoiesis, correction of AK2 expression can also rescue lymphocyte development. Unfortunately, these experiments are hampered by the current absence of a mouse model of the disease.

CONCLUSIONS

PIDs fully meet the definition of "experiments of nature" as proposed by Garrod (1924): they provide unique examples of the real consequences of genetic defects in humans, thus shedding light on the physiological role of the missing gene product(s). For this important characteristic, the highly heterogeneous group of extremely rare PIDs has been the focus of extensive clinical and molecular studies and has often been the object of innovative therapeutic approaches.

The first demonstration that allogeneic HSCT could be successfully applied to clinical practice was reported in 1968 following the treatment of a SCID child and a WAS patient (Bach et al., 1968; Gatti et al., 1968). Similarly, successful enzyme replacement therapy was first achieved in a case of SCID (Pahwa et al., 1989). Finally, SCID was also the first disease to be successfully treated by gene therapy (Cavazzana-Calvo et al., 2000). It is not surprising, therefore, that other cutting-edge technologies have continued to be bench-tested on PID models, such as the early demonstrations of the *IL2RG* gene repair with zinc-finger nuclease technology (Urnov et al., 2005) and the more recent development of site-directed gene-addition strategies for CGD in induced pluripotent stem cells (iPSc) (Zou et al., 2011).

With the first clear clinical benefits, the first serious potential complications of gene therapy have unfortunately also become evident (Hacein-Bey-Abina et al., 2003a). This has sparked a revision of the assessment of risks and benefits that will be critical for future development of gene therapy approaches for all PIDs and other genetic disorders.

As HSCT has subsequently emerged as an essential form of treatment for a wide variety of clinical applications, it is likely that the experience acquired from the pioneering gene therapy experiments for immunodeficient patients will constitute a guide for developing and applying gene therapy strategies to an increasing number of congenital and acquired genetic conditions in which conventional therapies have failed or are not a satisfactory long-term option.
