CONTENTS

FOREWORD

The first edition of this masterfully written and edited compendium on the subject of primary immunodeficiency diseases contained descriptions of about 70 entities. The second edition, published 8 years later, described about 120 distinct primary immunodeficiency diseases. The current third edition, in 2013, details about 250 conditions. This exponential increase in the recognition of errors in host defense has occurred in diminishing intervals of time, attesting to the rapid advances in genetics, molecular biology, and cell biology and the equally fast application of basic science in clinical medicine. In examining the recent literature, we have found descriptions of five new immunodeficiencies in one week, so the field continues to grow. Similarly, these advances have begun to move into translational medicine with more frequent, but still early, reports of successful therapies.

It is quite likely that host defense is influenced by hundreds of genes, most of which will be shown to produce disease if altered by mutations, copy number variations, deletions and insertions, or epigenetic phenomena, the latter often caused by environmental influences but still transmissible to future generations. Another pathogenic mechanism is mediated by molecular changes in small RNA species, recently shown to enhance or reduce gene expression. New genetic methods already being applied to the search for causes of Mendelian and complex genetic diseases will permit discovery of new genes influencing the various mechanisms of defense against pathogens. These methods include genome-wide association studies, followed by second- and third-generation sequencing. Specific mutations will be found in patients with frequent infections or autoimmune symptoms by whole-exome and whole-genome sequencing. Other genetic phenomena, such as uniparental disomy and reversion of mutations (first proven in adenosine deaminase deficiency), will also clarify puzzling clinical findings in patients.

A field of importance to further understanding of the development of our normal immune response and its failures is the human microbiome, especially that found in the intestine. It is now clear that the bacterial, viral, and fungal populations in our bodies are several logs higher than the number of cells making up our bodies. The intestinal microbiome is made up of numerous species, many previously unknown and not amenable to culture, but now discoverable by novel genetic methods. These unicellular organisms apparently are critical in the development of our normal host defense, and alterations of their diverse makeup are instrumental in the pathology of autoimmunity and at least some examples of defects in host defense.

All in all, it is becoming clear that immunology and host defenses in general, as is true for perhaps all medical specialties and subspecialties, are controlled and altered by genetics, and that immunodeficiency diseases are but results of the power of the infinite variation and fluidity of our genome. It may be that future editions of this important subject perhaps should be expanded to "Abnormalities of Host Defense," of which immunodeficiency is an important component.

A potentially even more important outcome of the studies so well described in this book and those to come is a greater understanding of immunology and host defense in general. By studying the interaction of the many genes described with the application of system biology, understanding the role of modifiers, enhancers, and inhibitors will lead to possible strategies of therapeutic intervention. The chapters on susceptibility and resistance to specific infectious diseases provide cogent examples of the beginning of such possibilities.

Finally, as already recognized by Drs. Good and Cooper in the forewords of the first two editions, and greatly expanded in this volume, the roles of innate and adaptive immunity, of phagocytes, and of complement in host defense vastly broaden our understanding of this fascinating field.

Kurt Hirschhorn and Rochelle Hirschhorn
New York, August 2012

FOREWORD TO THE FIRST EDITION

Modern immunology can be considered to have been launched in 1952, when Colonel Ogden Bruton described an 8-year old boy who, from 2 years of age, experienced recurrent, life-threatening infections including episodes of bacterial pneumonia and sep-ticemia. Using the newly-introduced technique, serum elec-trophoresis, Bruton found the boy to be agammaglobulinemic. When challenged with antigens, he failed to produce specific antibodies. Upon treatment by passive immunization with large doses of intramuscularly-injected gammaglobulin, his susceptibility to infections was dramatically terminated. Detailed investigations of similar patients, by Charles Janeway in Boston and my group in Minneapolis, demonstrated many similarly affected children, and proved that agammaglobulinemia was often an X-linked, inherited disorder.

In the course of caring for agammaglobulinemic patients, we realized that they were especially susceptible to encapsulated bacterial pathogens, including *Streptococcus pneumoniae, Haemophilus influenzae, Streptococcus pyogenes, Pseudomonas aeruginosa,* and to a lesser extent, *Staphylococcus aureus*. In contrast however, they could impressively resist infections caused by fungi, coliforms, tuberculosis, bacillus Calmette-Guérin (BCG), and many viruses such as measles, chicken pox, rubella, and vaccinia. Thus, the susceptibility profile of agammaglobulinemic patients bisected the microbial universe. As an experiment of nature, patients with X-linked agammaglobulinemia (XLA) introduced us to additional, crucially important concepts concerning how plasma cells and lymph node germinal centers, which are lacking in agammaglobulinemic patients, must be the source of antibodies providing resistance to encapsulated bacterial pathogens. We reasoned that distinct mechanisms of defense that were intact in agammaglobulinemic patients must have been designed to protect against other types of infections. Lymphocytes in the deep paracortical regions of lymph nodes, which appeared normal in XLA patients, were found to mediate this second type of immune protection, cellular immunity, which was later shown to be dependent on the thymus. This conclusion was partially derived from the study of a different group of patients, those with DiGeorge syndrome, who had congenital absence of the thymus.

Thus, it was evident from the beginning that patients with immunodeficiencies, as experiments of nature, helped us to bisect not only the microbial universe, but also the universe of lym-phoid cells and the universe of immunological responses. Further investigations throughout the 1960s, 1970s, and 1980s confirmed that this compartmentalization related to the fundamental lymphocyte dichotomy of B cells versus thymus-dependent T cells. Moreover, patients with different immunodeficiency syndromes helped define the nature and the role in immune responses of other components of the host defense system, such as phagocytes and complement, and to recognize the diseases that occur when these components are absent or not functional.

Over the last decade, advances in molecular biology have allowed for an even greater understanding of the immune system, and the multitude of molecular pathways that regulate growth, differentiation, communication, and effector functions within and between cells. In 1993, two groups of researchers, led by David Vetrie and Satoshi Tsukada, discovered that the difficulties of Bruton's patient and other patients with XLA were due to many different mutations of an X-linked gene that encodes a B-cell specific tyrosine kinase, Btk. In the few years since that discovery, the molecular genetic universe has expanded phenomenally, so that almost every month there is news of the identification of another immune disease gene.

The present volume, edited by Professors H. D. Ochs, C.I.E. Smith, and J. M. Puck, is the first comprehensive guide to this new molecular genetic universe. Herein, diseases of the immune system are presented and analyzed, both in terms of their clinical features and in the context of the impressive molecular and genetic definitions which can be put forward in 1998. Over 90 well-defined primary diseases of the human immune system are listed in the introductory chapter of this book; specific diseases are discussed in later chapters organized by syndrome (Part II). The current understanding of each disorder is outlined, including discussions of clinical issues and clinical presentation, infections, genetic mutations, protein function, cell biology, and management. Framing these discussions of individual diseases are two equally modern presentations—first, a section of seven chapters outlining the essential concepts of immunology and genetics needed to understand primary immunodeficiency diseases, and at the end, a section covering the most current approaches to assessment and treatment of patients with these conditions. Each authoritative chapter is written by a world leader in the field, or in many cases by a pair or group of immunological specialists with complementary perspectives, to present the most up-to-date and complete information available.

This book is an impressive demonstration of how far we have come. Recent studies of primary immunodeficiency diseases have, perhaps more than any other group of diseases, revealed the power of modern molecular genetics to define diseases in precise molecular terms. This approach has already suggested therapeutic possibilities which have proven successful; it has also set the stage for testing gene therapies meant to cure primary immunodeficiency diseases at the molecular level. Just how disruptions of Btk account for all of the morphological and immunological abnormalities and disease susceptibilities of patients with XLA has not yet been elucidated, but future work will show how this molecule interacts with other gene products in the B lymphocyte. Studying XLA will continue to reveal fundamental issues in lymphology and immunobiology.

The knowledge of primary immunodeficiency diseases reflected in this volume continues to grow, based on insights derived from the study of individuals with primary immunodeficiency exemplified by Bruton's original agammaglobulinemic patient. Analysis of each of the immune system diseases in its own way represents the molecular interpretation of an informative experiment of nature. In the aggregate, these analyses help us understand more deeply how man can exist free of infection while living in a veritable sea of microorganisms. This volume constitutes a milestone, marking where we now stand and indicating where we are heading, as we continue to interpret lessons in a most constructive fashion from the greatest teachers of modern immunology: patients with primary immunodeficiency diseases.

St. Petersburg, Florida
July 1998

FOREWORD TO THE SECOND EDITION

The primary immunodeficiency diseases, the first of which were recognized over 50 years ago, are now generally appreciated as major health problems by affected patients, their families, physicians, and even the general public. In 1999, this book was the first comprehensive compendium devoted to primary immunodeficiency diseases. While most are relatively rare, some of these conditions, like IgA deficiency and common variable immunodeficiency, occur with a frequency that makes these patients likely to be seen by most physicians.

The study of patients with these genetically determined immune disorders in conjunction with the study of animal models has led to remarkable progress in our understanding of the interacting components of the complex immune system and how they function in humans. As a consequence, earlier recognition and better treatment options are provided for patients with primary immunodeficiency diseases, as well as for the even larger number of individuals with secondary immune deficiency conditions. This authoritative book, now in its second edition, contains a comprehensive account of currently available information. In the short years since the first publication, the number of known immunodeficiency genes has grown from less than 70 to well over 120, reflecting the tremendous expansion of knowledge in this field. The rich base of information contained in these pages makes it clear that there are few fields in medicine in which laboratory-based research and the study of diseases in patients have been so mutually complementary as for the primary immunodeficiency diseases.

The first immunodeficiency diseases to be identified, namely X-linked agammaglobulinemia, and the more clinically severe congenital lymphopenic syndromes were diseases that are now known to reflect compromised development in the effector limbs of the adaptive immune system. Experimental delineation of the developmentally distinct lineages of lymphocytes, the thymus-dependent population of T cells, and the bone marrow-derived B cells, made possible the recognition of their respective roles in cell-mediated and humoral immunity. Accordingly, the primary immunodeficiency diseases were found to belong to distinct classes, those primarily affecting T cell development, like the thymic underdevelopment seen in the DiGeorge syndrome, and those featuring impaired B cell development and antibody production, as seen in Bruton X-linked agammaglobulinemia. Severe combined immunodeficiency (SCID), recognized first by Glanzmann and Riniker, featured instead a developmental failure of both T and B cells. With the ensuing molecular biology revolution, the pace of the genetic analysis of the immunodeficiency diseases quickened remarkably. As more and more details have been learned about the life history of T and B lineage cells, many of the genetically determined defects in these differentiation pathways can now be identified quite precisely in genetic and molecular terms.

As is indicated in the contents of this book, we currently have sufficient information about the lymphocyte differentiation pathways to categorize primary immunodeficiency diseases into gene mutations that affect (1) DNA transcription factors; (2) rearrangement and expression of the T cell receptor (TCR) and immun-oglobulin genes; (3) signal transducing components of the TCR and B cell receptor (BCR) complexes; (4) essential signaling pathway elements employed by TCR and BCR; (5) coreceptor molecules that are essential for normal function of T and B cells; (6) cytokines and cytokine receptors that promote T and B cell production, proliferation, and differentiation; and (7) cell surface molecules that are necessary for normal lymphocyte homing and intercellular interactions in the peripheral lymphoid tissues, including the spleen, lymph nodes, intestinal Peyer's patches, and appendix. It has also become increasingly evident that the normal function of the effector T and B cell populations depends on other types of cells as well. An especially important cell partner is the dendritic cell, because it responds to potential pathogens by presenting antigen to initiate the T cell response and, in turn, the B cell response. Although few primary immunodeficiency diseases have as yet been attributed to developmental flaws in this cell type, impaired dendritic cell function is an important component of the immunodeficiency caused by gene mutations that prevent CD40 expression or expression of the CD40 ligand on T cells.

The specific adaptive immune responses mediated by T and B cells and their collaborators, although essential, are only a part of the overall host defense strategy. There is an ever-growing awareness that innate immunity is equally important and complex. Disorders of the complement system, abnormal function of phago-cytic cells, and deficiencies of the chemokines and chemokine receptors that influence lymphocyte-phagocytic cell interactions can all result in an impaired ability to eliminate pathogens. Natural killer cells with their diverse array of activating and inhibitory receptors are also beginning to be recognized as one of the dysfunctional cell types in some immunodeficiency disorders.

Infections are the major complications of the immunodeficiency diseases, and, as recognized by the late Robert Good, a true giant in the establishment of the field and author of the original forword to the first edition of this book, the types of infections differ according to the specific gaps in host defense. Primary antibody deficiency states predispose to serious bacterial infections, as do certain complement component and neutrophil deficiencies. Viral and fungal infections are particularly notable in patients with T cell dysfunction. Different infectious disease patterns are seen with other host defense defects. For example, mycobacterial and salmonella infections are common in patients who have mutations in the genes for IL-12 or the receptors for IL-12 and interferon-γ, because these signaling molecules are especially important for normal macrophage activation to kill intracellular pathogens. Characterization of the different patterns of infections has been significantly enhanced by the development of databanks devoted to patients with the relatively rare primary immunodeficiency diseases.

Treatment has advanced in parallel with improved diagnosis of immunodeficiency diseases, understanding of their cellular and molecular basis, and better definition of their clinical consequences. Prophylactic antibiotics can be helpful in reducing the frequency of certain types of infections. Immunoglobulin replacement, employed first by Bruton to treat a boy with congenital agammaglobulinemia, has been refined through the development of safe and efficient preparations of intravenous immunoglobulin. Better ways to perform bone marrow transplantation have made this life-saving mode of cellular engineering safer and available to more patients with severe combined immunodeficiency disease. Enzyme replacement can benefit SCID patients with adenosine deaminase deficiency. Finally, gene therapy has proven effective for the cure of two types of SCID, albeit presently with an attendant risk of lymphoproliferative disease. For all too many patients with primary immunodeficiency diseases, however, a cure is still not yet possible and will come only with improved knowledge that must be gained through continued study. In the meantime, early diagnosis remains the key for a quality life for many patients with an immunodeficiency disease. Toward this end, this newly updated book provides a remarkably comprehensive and clinically useful source of information about this challenging group of disorders.

1.

GENETICALLY DETERMINED IMMUNODEFICIENCY DISEASES: A PERSPECTIVE

C. I. Edvard Smith, Hans D. Ochs, and Jennifer M. Puck

We are in an era of explosive growth in our understanding of the molecular and genetic basis of immune defects. In the early 1990s, only a handful of genes had been associated with primary immunodeficiency disorders (PIDs). By 2000, when the first edition of this book was published, some 60 genes causing PID had been identified. The most recent summary of PID genes (Table 1.1) and their products (Fig. 1.1), with over three times this number, is already incomplete due to the rapid pace of discovery of additional genes that are defective in an ever-broadening spectrum of clinical immune disorders. Advances in basic research in immunology, combined with the increasing ease of determining DNA sequence variants, have greatly facilitated the tasks of finding DNA mutations in PID patients and proving their functional significance. The ability to define genetic diseases of the immune system in molecular terms has made possible improved diagnosis, appreciation of the clinical spectrum, genetic counseling and testing, and, most exciting, new therapeutic strategies including gene therapy. Moreover, the discovery of each previously unknown disease gene feeds back into the pool of scientific knowledge, increasing our understanding of molecular immune networks.

In contrast to many other heritable diseases, PIDs are not obvious at birth but become evident only when the affected individual is exposed to microbes and develops severe infections or responds to self-antigens with autoaggression. Although individually rare, these disorders are treatable and therefore important to detect promptly. The spectrum of diseases is very broad and covers both increased susceptibility to infections and impaired regulation of immune function leading to autoimmunity. The inheritance of PIDs can be recessive or dominant; some produce symptoms early in life, while others are manifested later; and acquired forms of PID associated with somatic mutations are increasingly recognized.

The "classical" PIDs are single gene disorders with either autosomal recessive or X-linked recessive inheritance, such as severe combined immunodeficiency (SCID), Wiskott-Aldrich syndrome (WAS), or X-linked agammaglobulinemia (XLA). In contrast, dominant inheritance is typically seen when a mutation affects a protein that normally functions in a multimeric complex. For example, in autoimmune lymphoproliferative syndrome (ALPS) caused by heterozygous mutations in the genes encoding Fas or Fas-ligand, both the receptor and its ligand are assembled into homotrimers. For a trimer to be functional, all monomeric components need to be unmutated; dominant interference with the function of protein produced by a normal allele results from having one or two mutated monomers in the assembled complex. If normal and mutated protein monomers are produced in equal amounts, only one out of eight trimeric signaling units will be free from any mutated chains and able to function properly (Chapter 29). Because only a single mutation event is needed and a survival advantage is conferred on cells with defective Fas-mediated apoptosis, de novo somatic mutations of a single *FAS* gene allele have been found capable of causing acquired dominant ALPS (Holzelova et al., 2004). Another example is the hyper-IgE syndrome, where missense mutations impair STAT3 dimer formation, reducing the intracellular JAK-STAT signaling by 75 percent (Chapter 37). Dominant inheritance is also seen in some forms of severe congenital neutropenia, in which a mutated, misfolded protein activates the "unfolded protein response," a series of cellular stress responses that are activated by the accumulation of malformed proteins and can ultimately trigger cellular removal by apoptosis (Chapter 50).

As we have pointed out in previous editions of this book, susceptibility versus resistance to infections can depend on inheritance of variant forms of immune system components. HIV typically uses the CCR5 co-receptor to enter human

Table 1.1 PRIMARY IMMUNODEFICIENCY DISEASES

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
	A. Combined B- and T-Cell Immunodeficiencies			
1. Severe combined immunodeficiency (SCID) without T or B cells (T^-B^-)				
a. SCID with leukocyte deficiency. Reticular dysgenesis. *AK2*	**Stem cell defect affecting maturation of leukocytes, including all lymphocytes; associated deafness**	**AR**	**1p34**	**18**
b. SCID with radiosensitivity. Artemis deficiency. *DCLRE1C*	**DNA cross-link repair 1C protein, Artemis; impaired VDJ recombination of B- and T-cell receptor genes**	**AR**	**10p13**	**13**
c. SCID with RAG1 deficiency *RAG1*	**Recombinase-activating protein 1. Impaired VDJ recombination of B- and T-cell receptor genes (*RAG1* and *RAG2* are adjacent genes).**	**AR**	**11p13**	**13**
d. SCID with RAG2 deficiency *RAG2*	**Recombinase-activating protein 2. Impaired VDJ recombination of B and T cell receptor genes (*RAG1* and *RAG2* are adjacent genes).**	**AR**	**11p13**	**13**
2. SCID with nonfunctional T and B cells hypomorphic mutations in genes associated with SCID				
a. Omenn syndrome with				
i. RAG1 deficiency *RAG1*	**RAG1 partially deficient rearrangement of B- and T-cell receptor genes**	**AR**	**11p13**	**13**
ii. RAG2 deficiency *RAG2*	**RAG2 partially deficient rearrangement of B- and T-cell receptor genes**	**AR**	**11p13**	**13**
iii. Artemis deficiency *DCLRE1C*	**Artemis, partially deficient in VDJ rearrangement**	**AR**	**10p13**	**13**
iv. IL-7Rα deficiency *IL-7Rα*	**IL-7 receptor α chain, partially deficient**	**AR**	**5p13**	**11**
v. ADA deficiency *ADA*	**Adenosine deanimase hypomorphic mutation**	**AR**	**20q13.11**	**14**
vi. DNA ligase IV (LIG4) deficiency *LIG4*	**Ligase IV, hypomorphic mutation**	**AR**	**13q33–34**	**13**
vii. RNase MRP complex defi ciency *RMRP*	**Cartilage-hair hypoplasia (CHH). See D.5.**	**AR**	**9p13**	**37**
viii. *22q11.2* deletion	**Complete DiGeorge**	**AD**	**22q11.2**	**45**
b. DNA ligase IV deficiency *LIG4*	**Ligase IV, ATP-dependent, involved in VDJ recombination**	**AR**	**13q22–q34**	**13**
c. SCID with microcephaly and radiosensitivity due to deficiency of non-homologous end-joining factor 1. *NHEJ1*	**DNA repair factor (XRCC4-like factor; XLF; Cernunnos) involved in non-homologous end-joining**	**AR**	**2q35**	**13**
d. SCID due to deficiency of DNA-PKcs *PRKDC*	**DNA activated protein kinase catalytic subunit (defective in SCID mouse)**	**AR**	**8q11.2**	**13**
3. SCID without T cells (T^-B^+)				
a. X-linked SCID (γc-chain deficiency) *IL2RG*	**Common γ (γc) chain protein, a component of receptors for multiple cytokines (IL-2, -4, -7, -9, -15, and -21)**	**XL**	**Xq13.1**	**10**
b. SCID with JAK3 deficiency *JAK3*	**Janus-activating kinase 3 (JAK3), a cytoplasmic tyrosine kinase interacting with γc to transmit signals from extracellular binding of multiple cytokines**	**AR**	**19p13.1**	**10**
c. SCID with IL-7Rα deficiency *IL7R*	**IL-7 receptor α chain**	**AR**	**5p13**	**11**
d. SCID with CD45 deficiency *PTPRC*	**Protein tyrosine phosphatase receptor type C (PTPRC)**	**AR**	**1q31.3–q32.1**	**12**

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
e. SCID with CD3DEZ chain deficiency *CD3 δ/ε/ξ*	CD3δ, ε, or ξ component of CD3 antigen receptor complex. Required for thymic T-cell maturation.	AR	11q23	11
f. Human Nude/SCID *FOXN1*	Forkhead box N1 protein, winged-helix-nude (*Whn*). Transcription factor required for thymus and hair follicle development.	AR	17q11.2	21
g. SCID due to absent coronin-1A *CORO1A*	Required for lymphocyte migration and exit from the thymus	AR	16p11.2	23
4. Deficiencies of purine metabolism				
a. SCID with ADA deficiency *ADA*	Adenosine deaminase (ADA) is required for purine metabolism; elevated purine metabolites are toxic to T and also B and NK cells.	AR	20q13.11	14
b. SCID with PNP deficiency *PNP*	Purine nucleoside phosphorylase (PNP) is required for purine metabolism; elevated purine metabolites are toxic to T and B cells.	AR	14q11.2	14
5. Calcium channel deficiency (normal number of T cells with defective TCR-mediated activation)				
a. ORAI-1 deficiency *ORAI1*	Defect in Ca^{++} release-activated channel (CRAC) modulatory component; autoimmunity, myopathy	AR	12q24.31	20
b. STIM1 deficiency *STIM1*	Defect in stromal interaction molecule Ca^{++} sensor (STIM); autoimmunity, myopathy	AR	12p13.33	20
6. MHC class II (major histocompatiblity complex: class II) deficiency secondary to deficiencies of transcription factors for MHCII expression				
a. CIITA deficiency *MHC2TA*	MHCII transactivator (CIITA) protein, a non-DNA binding component of the MHCII promoter-binding complex; complementation group *A*	AR	16p13	16
b. RFXANK deficiency *RFXANK*	Regulatory factor X-associated ankyrin-containing protein (RFXANK), an MHCII promoter-binding protein; complementation group B	AR	19p12	16
c. RFX-5 deficiency *RFX5*	MHCII promoter X box regulatory factor 5 (RFX5), an MHCII promoter-binding protein; complementation group C	AR	1q21	16
d. RFXAP deficiency *RFXAP*	Regulatory factor X-associated protein (RFXAP), an MHCII promoter-binding protein; complementation group D	AR	13q	16
7. MHC class I deficiency				
a. TAP1 deficiency *TAP1*	Transporter protein associated with antigen presentation 1 (TAP1)	AR	6q21.3	17
b. TAP2 deficiency *TAP2*	Transporter protein associated with antigen presentation 2 (TAP2)	AR	6q21.3	17
c. Tapasin deficiency *TAPBP*	TAP binding protein (tapasin)	AR	6p21.3	17
8. Class-switch recombination defect (hyper-IgM syndromes) affecting both B and T cells; see also B.6.				
a. CD40L deficiency *TNFSF5*	CD40 ligand (CD40L, CD154). Tumor necrosis factor superfamily member 5 (TNFSI5).	XL	Xq26	26
b.CD40 deficiency *TNFRSF5*	CD40. Tumor necrosis factor receptor superfamily member 5 (TNFRS5).	AR	20q13.12	26

(continued)

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
9. Non-SCID CD3 deficiency due to absence of proteins forming the CD3 complex required for T-cell receptor signaling See A.2.e for SCID with CD3δέζ deficiency.				
a. CD3ε deficiency *CD3E*	CD3ε polypeptide	AR	11q23	11
b. CD3γ deficiency *CD3G*	CD3γ polypeptide	AR	11q23	11
c. CD3ζ deficiency *CD3Z*	CD3ζ polypeptide (CD247)	AR	1q242.2	11
10. CD8 deficiency *CD8A*	CD8 antigen, α polypeptide (p32)	AR	2p12	19
11. ZAP-70 deficiency *ZAP-70*	Cytoplasmic tyrosine kinase ZAP-70 (T-cell receptor ζ-chain associated protein kinase, 70kDa). Signaling from the T-cell receptor during T-lineage development.	AR	2q12	15
12. IL-2 R α deficiency *IL2RA*	IL-2 receptor α-chain (IL-2Ra, CD25) is required for regulation and control of autoreactive T cells. Mutations cause an IPEX-like phenotype (see D.3b) with SCID features.	AR	10p15.1	10
13. p56 Lck deficiency *LCK*	Lymphocyte-specific protein tyrosine kinase. Required for T-cell maturation in the thymus.	AR	1p34.3	32; Hauck F et al. JACI 2012;130:1144.
14. IKAROS deficiency *IKAROS*	IKAROS is a hematopoietic specific zinc-finger transcription factor and a regulator of lymphoid development. The only case reported had anemia, neutropenia, and thrombocytopenia and lacked B cells.	AD de novo	7p12.2	Goldman FD et al. Pediatr Blood Cancer 2012;58:591.
15. Cartilage hypoplasia *RMRP*	Abnormal T-cell number and function. See D.5.	AR	9p13	37
RNase MRP complex deficiency *RMRP*	Cartilage-hair hypoplasia (CHH). See D.5.	AR	9p13	36
16. STAT5b deficiency *STAT5b*	Growth hormone insensitive. Dwarfism, lymphopenia, interstitial pneumonia (see F.5), IPEX-like phenotype. See also D.3.b.	AR	17q21	32
17. ITK deficiency *ITK*	Lymphopenia, recurrent EBV infections. See also E.8.i.	AR	5q33.3	Huck K et al. J Clin Invest 2009;119:1350.
18. CD27 deficiency *CD27 (TNFRSF7)*	CD27 is a co-stimulatory molecule that regulates lymphocyte differentiation. Combined immune deficiency and hypogammaglobulinemia (see also B.4.i).	AR	12p13.3	Van Montfrans JM et al. JACI 2012; 129:787.
19. Serine threonine kinase 4 (STK4) deficiency (also known as MST1) *STK4*	Lymphopenia and neutropenia due to enhanced apoptosis of naïve and proliferating T lymphocytes resulting in recurrent bacterial and viral infections, including persistent EBV viremia and EBV+ B-cell lymphoma. See also C.2.	AR	20q13.12	Abdollahpour H et al. Blood 2012;119:3450, 2012; Nehme NT et al. Blood 2012;119:3458.
B. Deficiencies Predominantly Affecting Antibody Production				
1. Agammaglobulinemia				
a. XLA (X-linked agammaglobulinemia) *BTK*	Bruton agammaglobulinemia tyrosine kinase (BTK) required for intracellular signaling in B-cell development	XL	Xq21.3	25
b. X-linked hypogammaglobulinemia with growth hormone deficiency	BTK not affected; gene defect unknown	XL	—	25
c. μ heavy-chain deficiency *IGHM*	μ heavy chain. Part of the pre-B and B-cell receptor complex. Required for development of B cells from B-lineage progenitors.	AR	14q32.3	25
d. λ5 surrogate light-chain deficiency *IGLL1*	λ5 surrogate light chain. Part of receptor complex on pre-B cells required for B-lineage differentiation.	AR	22q11.22	25

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
e. Igα deficiency *CD79A*	Ig-associated α chain signaling component of pre-B and B-cell receptor complex required for B-lineage differentiation and B-cell signaling	AR	19q13.2	25
f. Igβ deficiency *CD79B*	Ig-associated β chain signaling component of pre-B and B-cell receptor complex required for B-lineage differentiation and B-cell signaling	AR	17q23	25
g. BLNK deficiency *BLNK*	B-cell linker/SLP-65/BASH. B-cell signaling protein.	AR	10q24.1	25
h. PI3K deficiency *PIK3R1*	A mutation in *PIK3R1* resulted in absence of p85a, a regulatory subunit of PI3K; absence of pro-B and B cells and reduced numbers of NK cells.		5q13.1	Conley ME et al. J Exp Med 2012;209:463.
i. LRRC8 deficiency *LRRC8*	Leucine-rich repeat containing 8 (LRRC8) transmembrane protein required for B-cell development. Single case.	AD	9q34.2	Sawada et al. J Clin Invest 2003;112:1707.
j. Thymoma with hypogammaglobulinemia	Lack of B lymphocytes and immunoglobulins	Acquired, usually sporadic	—	Good et al. Surgery 1956;40:1010.
2. Selective deficiency of Ig isotypes/subclasses due to isolated or combined deficiencies				
a. IgA deficiency	Failure of IgA B-cell differentiation	Complex	—	28
b. α1 subclass deficiency *IGHA1*	IgA1 is the major IgA subclass.	AR	14q32.33	28
c. α2 subclass deficiency *IGHA2*	IgA2 is mainly found in the gastrointestinal tract.	AR	14q32.33	28
d. γ1 subclass deficiency *IGHG1*	IgG1 constitutes 65 percent of serum IgG.	AR	14q32.33	28
e. γ2 subclass deficiency *IGHG2*	IgG2 constitutes 25 percent of serum IgG.	AR	14q32.33	28
f. γ3 subclass deficiency *IGHG3*	IgG3 constitutes 8 percent of serum IgG. Partial IgG3 deficiency is associated with the "g" allotype and caused by reduced isotype switching.	AR	14q32.33	28
g. γ4 subclass deficiency *IGHG4*	IgG4 constitutes 4 percent of serum IgG.	AR	14q32.33	28
h. IgG subclass deficiency with IgA deficiency	Defect in differentiation of a B lymphocyte subset or in expression of IgG	Unknown	—	28
i. ε isotype deficiency *IGHE*	IgE is encoded by a single gene.	AR	14q32.33	28
3. Light-chain deficiency				
a. κ light-chain deficiency *IGKC*	κ light chain binds to a heavy chain to form immunoglobulins.	AR	2p11	Stavnezer-Nordgren et al. Science 1985;230:458.
4. Common variable immunodeficiency and related disorders (for WHIM see F.8)				
a. Common variable immunodeficiency of unknown origin	Serum IgG low, IgA low or absent, IgM variable. Variable impairment of T-cell function.	Complex	—	28
b. ICOS (inducible T-cell costimulator) deficiency *ICOS*	ICOS is expressed by activated T cells and interacts with ICOSL (B7RP-1). Deficiency results in late-onset B-cell loss.	AR	2q33	28
c. CD19 deficiency *CD19*	CD19 molecule expressed by B cells	AR	16p11.2	28
d. CD20 deficiency *MS4A1*	Membrane-spanning 4 domains, subfamily A, member 1	AR	11q12.2	28

(continued)

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
e. CD81 deficiency *CD81*	CD81 molecule expressed by B cells	AR	11p15.5	28
f. TACI deficiency *TNFRSF13B*	Tumor necrosis factor receptor superfamily member 13B	AD, AR	17p11.2	28
g. BAFF receptor deficiency *TNFRSF13C*	Tumor necrosis factor receptor superfamily member 13C	AR	22q13.2	28
h. CD21 deficiency *CD21/CR2*	CD21/complement component receptor 2 (CR2) is part of the B-cell co-receptor and the EBV receptor.	AR	1q32.2	28
i. CD27 deficiency *CD27 (TNFRSF7)*	CD27, a type I transmembrane protein, belongs to the TNFR family and interacts with its ligand, CD70. CD27 regulates differentiation, survival, and function of lymphocytes. Defective T-cell-dependent antibody responses associated with hypogammaglobulinemia and persistent symptomatic EBV infection.	AR	12p13.3	Van Monfrans JM et al. JACI 2012;129:787.
j. LRBA deficiency *LRBA*	Lipopolysaccharide responsive beige-like anchor protein (LRBA). Early-onset hypogammaglobulinemia due to defective B-cell development/activation and autophagy, and increased apoptosis.	AR	4q13	Lopez-Herrera G et al. AJHG 2012;90:986.
5. Other antibody deficiencies				
a. Antibody deficiency with normal immunoglobulin levels	Defective antigen-specific antibody production	Unknown	—	56
b. Transient hypogammaglobulinemia of infancy	Delayed maturation of T-cell helper function	Unknown	—	Gitlin and Janeway. Prog Hematol 1956;1:318.
6. Defects of class-switch recombination and somatic hypermutation (hyper-IgM syndromes) affecting B cells; see also A.8.				
a. AID deficiency *AICDA*	Activation-induced cytidine deaminase	AR	12p13	27
b. UNG deficiency *UNG*	Uracil-DNA glycosylase	AR	12q24.11	27
c. Selective deficiency in Ig class-switch recombination	Defect downstream of AID, normal somatic hypermutation	Unknown	—	27
d. PMS2 deficiency *PMS2*	DNA repair defect. See G.4	Unknown	—	27
C. Defects in Lymphocyte Apoptosis				
1. Autoimmune lymphoproliferative syndrome (ALPS), characterized by lymphadenopathy, splenomegaly, cytopenias, increased risk of B-cell lymphoma; see also D.3.				
a. ALPS-FAS (defective CD95) *FAS* or *TNFRSF6*	Apoptosis mediator CD95 (Fas/APO-1) required for lymphocyte homeostasis induces apoptosis via engagement of FasL.	AD, AR	10q23.31	30
b. ALPS-FASL (defective CD178) *FASL* or *TNFSF6*	Fas ligand (FasL) induces apoptosis via engagement of Fas.	AD	1q24.3	30
c. ALPS-CASP10 Caspase 10 deficiency *CASP10*	Apoptosis-related cysteine protease. *CASP8* and *CASP10* are adjacent genes.	AR	2q33.1	30
d. CEDS (caspase 8 deficiency state) *CASP8*	Caspase 8; apoptosis-related cysteine protease; in addition to ALPS phenotype, these patients have defective T-, B-, and NK-cell activation and recurrent infections.	AR	2q33.1	30
e. RALD (Ras-associated autoimmune leukoproliferative disorder) *NRAS*	Neuroblastoma Ras viral oncogene homolog (NRAS) sporadic somatic mutations in NRAS	AR	1p13.2	1, 30

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
f. V-KI-RAS2 Kirsten rat sarcoma viral oncogene homolog (KRAS) *KRAS*	Sporadic somatic mutations in KRAS, similar to NRAS	AR	12p12.1	1, 30
2. Increased apoptosis affecting naïve T cells due to MST1 deficiency *STK4*	Serine-threonine protein kinase-4 (STK4) encodes mammalian sterile 20-like 1 (MST1), which phosphorylates FOXO transcription factors. MST1-deficient naïve T cells express decreased amount of FOXO1, IL-7R, and BCL2 and increased FAS expression and are progressively reduced in number. Recurrent bacterial and viral infections, autoimmunity. See also A.19.	AR	20q13.12	Abdollahpour H. et al. Blood 2012;119:3450; Nehme NT et al. Blood 2012;119:3458.
D. Other Well-Defined Immunodeficiency Syndromes				
1. Wiskott-Aldrich syndrome (WAS), X-linked thrombocytopenia (XLT), and X-linked neutropenia (XLN) *WAS*	WAS protein (WASp), expressed only in hematopoietic cells. Classic WAS is characterized by thrombocytopenia, small platelets, eczema, autoimmune diseases, lymphoma; XLT is a mild form of WAS; XLN (only neutropenia) is caused by missense mutations in the GTPase binding domain of WASp.	XL	Xp11.22	43
2. WASp-interacting protein (WIP) deficiency *WIPF1*	WIP is complexed with WASp and stabilizes WASp. If WIP is not expressed, WASp is absent, resulting in a phenotype similar to classic WAS (only a single case reported).	AR	2q31.1	43
3. Autoimmune disorders; see also C.1.				
a. Autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy (APECED) *AIRE*	Autoimmune regulator-1 (AIRE-1) protein is a transcription factor expressed in the thymus. Autoantibodies to IL-17A, IL17-F, IL-22 are often present.	AR	21q22.3	31
b. Immune deficiency/dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) *FOXP3*	Forkhead box P3 transcription factor (FOXP3). Expressed by $CD4^+$ $CD25^+$ regulatory T cells (Treg); multiple autoimmune findings include cytopenias, type 1 diabetes, thyroiditis, villous atrophy, eczema.	XL	Xp11.23	32
4. DiGeorge/velo-cardio-facial syndrome (22q11.2 deletion syndrome)	Multiple congenital anomalies most often due to large deletion (3 Mb) in 22q11.2 (or less frequently a deletion in 10p). Defect in thymic development. May be associated with conotruncal malformation, hypoparathyroidism, and other congenital anomalies.	AD or de novo defect	22q11.2	45
5. CHH (cartilage-hair hypoplasia) *RMRP*	RNA component of mitochondrial RNA-processing endoribonuclease (RMRP). Short-limbed dwarfism, metaphyseal dysostosis, sparse hair, bone marrow failure, autoimmunity, lymphoma or other cancers.	AR	9p13	37
6. Immuno-osseous dysplasia—Schimke syndrome *SMARCAL1*	Short stature, spondyloepiphyseal dysplasia, nephropathy; bacterial, viral, fungal infections, bone marrow failure. May present as SCID.	AR	2q35	Boerkoel CF et al. Eur J Pediatr. 2000;159:1.
7. Hyper-IgE syndromes (HIES)				
a. AD-HIES (Job syndrome) due to STAT3 deficiency *STAT3*	Dominant negative heterozygous mutations in STAT3. Distinct facial features, eczema, osteoporosis and fractures, scoliosis, delayed shedding of primary teeth, hyperextensible joints, abscesses, due to *Staphylococcus aureus*, pneumatoceles, candida infections, elevated IgE, decreased Th17 cell numbers, decreased memory B cells.	AD, or de novo defect	17q21.2	38

(continued)

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
b. AR-HIES due to *DOCK8*-deficiency *DOCK8*	Detection of cytokinesis 8 (Dock8). Recurrent respiratory infections, viral and staphylococcal skin infections, increased risk of cancer. Combined T- and B-cell defects.	AR	9q24.3	38
c. AR-HIES due to TYK2 deficiency *TYK2*	Tyrosine kinase 2 (TYK2). Susceptibility to intracellular bacteria, fungi, viruses.	AR	19p13.2	38
8. Chronic mucocutaneous candidiasis (CMC)				
a. CARD9 deficiency *CARD9*	Chronic mucocutaneous candidiasis (CMC) involving skin and mucous membranes, invasive candidasis and dermatophytosis due to mutations in caspase recruitment domain-containing protein 9 (CARD9).	AR	9q34.4	22
b. IL-17RA deficiency *IL-17RA*	IL-17 signaling pathway in monocytes, epithelial cells, and fibroblast. Cellular responses to IL-17A/F are abolished. CMC.	AR	22q11.1	Puel A et al. Science 2011;332:65.
c. IL-17F deficiency *IL-17F*	IL-17F is expressed as dimers on T cells. CMC.	AD	6p12	Puel A et al. Science 2011;332:65.
d. STAT1 deficiency *STAT1*	Gain-of-function heterozygous mutations of STAT1 interfere with nuclear dephosphorylation of activated STAT1. Impaired development of IL-17-producing T cells. CMC. IPEX-like phenotype (see D.3.b; for loss of function, see F.4).	AD	2q32.2	Liu L et al. J Exp Med 2011;208:1635.
9. Comel-Netherton syndrome *SPINK5* (serine protease inhibitor, Kazal type 5)	Mutations in the serine protease inhibitor LECTI, expressed in epithelial cells. Congenital icthyosis, bamboo hair, allergies, failure to thrive, elevated IgA and IgE, antibody deficiency.	AR	5q32	Renner ED et al. JACI 2009;124:536.
10. Hepatic veno-occlusive disease with immunodeficiency (VODI) *SP110*	Mutations in the nuclear body protein SP110. PCP pneumonia, CMV, Candida, hepatosplenomegaly, thrombocytopenia.	AR	2q37.1	39
11. Dyskeratosis congenita (DKC) 1 (Hoyeraal-Hreidarsson syndrome) *DKC1*	Mutations in dyskerin 1 (DKC1). Nail dystrophy, recurrent infections, ulcerative lesions of mucous membranes, pancytopenia (myelodysplastic), cancer.	XL	Xq28	Jyonouchi S et al. Pediatr Allergy Immunol 2001;22:313.
	E. Defects of Phagocyte Development and Function			
1. Defects of neutrophil differentiation				
a. Severe congenital neutropenia 1 (SCN1) due to ELANE deficiency *ELANE*	Myeloid differentiation	AD	19p13.3	51
b. Severe congenital neutropenia 2 (SCN2) due to GFL1 deficiency *GFL1*	Loss of expression of ELANE (rare), thus interfering with myeloid differentiation	AD	1p22.1	Person RE et al. Nat Genet 2003;34:308.
c. Severe congenital neutropenia 3 (SCN3), Kotsmann *HAX1*	HAX1 regulates apoptosis.	AR	1q21.3	
d. Severe congenital neutropenia 4 (SCN4) due to G6PC3 deficiency *G6PC3*	Glucose-6-phosphatase (G6PC3), myeloid differentiation, enhanced apoptosis of neutrophils		17q21.31	51
e. Glycogen storage disease type 1b *G6PT1*	Glucose-6-phosphate transporter 1 (G6PT1)	AR	11q23.3	51

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
f. Cyclic neutropenia due to ELANE deficiency *ELANE*	Oscillation in all leukocyte and platelet numbers	AD	19p13.3	51
g. X-linked neutropenia due to WASp deficiency *WAS*	Release of myeloid cells from bone marrow. See D.2.	XL	Xp11.22	43
h. LAMTOR2 deficiency *LAMTOR2* (also known as *MAPBPIP*)	Late endosomal/lysosomal adaptor, MAPK and MTOR activator 2. Mutations in P14 cause neutropenia, hypogammaglobulinemia, partial albinism.	AR	1q22	51
i. Shwachman-Bodian Diamond syndrome *SBDS*	Highly conserved protein of unknown function. Pancreatic insufficiency and bone marrow dysfunction, including neutropenia.	AR	7q11.21	Boocock GR et al. Nat Genet 2003;33:97.
j. Warts, hypogammaglobulinemia, recurrent bacterial infections, and "myelokathexis" (WHIM) *CXCR4*	Chemokine C-X-C motif receptor 4 (CXCR4), gain-of-function mutations, hypogammaglobulinemia, reduced B-cell number, severe neutropenia, warts/HPV infections	AD	2q21	40
2. Defects of the intracellular oxidative burst (chronic granulomatous disease [CGD])				
a. X-linked CGD due to cytochrome b beta (CYBB) deficiency *CYBB*	Cytochrome phagocytic oxidase (phox) gp91^{phox}. Together with p22^{phox} forms the heterodimer cytochrome b-245 beta-polypeptide.	XL	Xp11.4	52
b. AR-CGD due to cytochrome b alpha (CYBA) deficiency *CYBA*	Cytochrome oxidase p22^{phox}	AR	16q24	52
c. AR-CGD due to neutrophil cytosol factor 1 (NCF1) deficiency *NCF1*	Cytochrome oxidase p47^{phox}	AR	7q11.23	52
d. AR-CGD due to neutrophil cytosol factor 2 (NCF2) deficiency. *NCF2*	Cytochrome oxidase p67^{phox}	AR	1q25	52
3. Glucose 6-phosphate dehydrogenase deficiency *G6PD*	Granulocyte intracellular killing defect associated with complete absence of G6PD in phagocytes	XL	Xq28	50
4. Myeloperoxidase (MPO) deficiency *MPO*	MPO is required to convert H_2O_2 to hypohalous acid. Intracellular killing of fungi is impaired.	AR	17q23.1	Lehrer RI, Cline MY. J Clin Invest 1969;48:1478; Nauseef WM et al. J Biol Chem 1994;269:1212.
5. Leukocyte adhesion defects (LAD)				
a. LAD1 due to beta-2 integrin deficiency *ITGB2*	Lack of the CD18 cell surface protein leads to defective cell adherence and chemotaxis. Cell surface adhesion complex (CD11a, b, c/CD18) requires integrin β2 (CD18) to be stably expressed. Patients present with leukocytosis, skin ulcers, peridontitis.	AR	21q22.3	53
b. LAD2 due to fucose transporter 1 deficiency *SLC35C1*	Fucose transporter required for proper carbohydrate addition; patients cells lack sialyl-Lewis X and have the Bombay RBC phenotype. Mild LAD1 phenotype with mental retardation, defective neutrophil rolling, and chemotaxis.	AR	11q11.2	53
c. LAD3 *KINDLIN3*	Defect in Rap 1- activation of β 1–3 integrins, mild LAD1 phenotype with bleeding tendency	AR	11q13.1	53

(continued)

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
d. LAD with RAC2 (regulation of actin polymerization) deficiency *RAC2*	RAS-related, Rho family small GTP-binding protein RAC2. Predominant in neutrophils, involved in $O2^-$ production, actin cytoskeleton. Abnormal adherence and chemotaxis.	AR	22q13.1	53
6. Immunodeficiency with hypopigmentation				
a. Chediak-Higashi syndrome *LYST*	Lysomal trafficking (LYST) regulator. Required for formation of lysosomes and cytoplasmic granules. Partial albinism, recurrent infections, encephalopathy, neutropenia, low NK and CTL activity.	AR	1q42.3	54
b. Griscelli syndrome type 1 *MYO5A*	Myosin-VA (5A) (MY05A) is involved in organelle transport. Partial albinism, neurologic impairment.	AR	15q21.2	54
c. Griscelli syndrome type 2 *RAB27A*	Rab27A is a GTPase that promotes docking of cytotoxic vesicles to the cell membrane. Myosin-VA (5A) and Rab27A are closely linked on chromosome 15q21. Partial albinism, encephalopathy, low NK and CTL activity.	AR	15q21.3	54
d. Hermansky-Pudlak syndrome type 2 *AP3B1*	β subunit of the AP-3 complex (AP3B1). Partial albinism, neutropenia, low NK and CTL activity.	AR	5q14.1	51
7. Glycogen storage disease type Ib *SLC37A4*	Solute carrier family 37 (glycerol-6-phosphate transporter), member 4. Neutropenia, impaired neutrophil migration due to defective glucose 6-phosphate translocase.	AR	11q23.3	Hiraiwa H et al. J Biol Chem 1999;274:5532.
8. Familial hemophagocytic lymphohistiocytosis (FHL) and lymphoproliferative syndromes				
a. FHL1	FHL with unknown gene defect	AR	—	54
b. FHL2 due to perforin deficiency *PRF1*	Perforin 1 (pore-forming protein), a major cytolytic protein	AR	10q22	54
c. FHL3 UNC13D (Munc 13-4) deficiency *UNC13D*	Vesicle priming protein unc-13 homolog D (*C. elegans*). Required to prime vesicles for fusion.	AR	17q25.3	54
d. FHL4 due to syntaxin11 deficiency *STX11*	STX11 is required for fusion of secretory vesicles with the cell membrane.	AR	6q24.2	54
e. FHL5 due to syntaxin11 binding protein 2 (Munc 18-2) deficiency *STXBP2*	STXBP2 has similar functions as STX11.	AR	19p13.2	54
f. X-linked lymphoproliferative syndrome (type 1, XLP1) *SH2D1A*	SH2 domain 1A protein (also called SLAM-associated protein, SAP) is involved in intracellular signaling of T and NK cells. Symptoms, triggered by EBV and other viral infections, include hepatitis, hemophagocytic syndrome, lymphoma, hypogammaglobulinemia, low NKT cells.	XL	Xq25	44
g. X-linked lymphoproliferative syndrome type 2 (XLP2) *XIAP*	Inhibitor of apoptosis, X-linked (XIAP); symptoms are similar to XLP11 and triggred by EBV infections; include splenomegaly, hepatitis, hemophagocytic syndrome, colitis.	XL	Xq25	44
h. Immunodeficiency X-linked, with magnesium defect, EBV infection and neoplasm (XMEN) *MAGT1*	Magnesium transported 1 susceptibility to EBV and other viral infections, respiratory and gastrointestinal infections, lymphoma	XL	Xq21.1	Li FY et al. Nature 2011;475:471.
i. IL2 inducible T-cell kinase (ITK) deficiency *ITK*	EBV-associated lymphoproliferation	AR	5q33.3	Huck K et al.. J Clin Invest 2009;119:1350.

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
j. CD16 deficiency *FCGR3A*	CD16 plays a role in NK cell-mediated cytotoxicity in association with CD2. Persistent herpes virus and human papillomavirus infections; EBV-driven Castleman disease.	AR		Grier JT et al. J Clin Invest 2012;122:3769.
	F. Defects of the Innate Immune System: Receptors and Signaling Components			
1. Interferon-γ receptor deficiency.				
a. IFNγ receptor 1 deficiency *IFNGR1*	IFNγ-receptor 1 (or α-chain) is required for binding IFNγ as well as signaling by associating with JAK1. Susceptibility to mycobacteria and salmonella.	AR, AD	6q23.3	35
b. IFNγ receptor 2 deficiency *IFNGR2*	IFNγ-receptor 2 (or β-chain) is required for signaling by associating with JAK2. Susceptibility to mycobacteria and salmonella.	AR	21q22.11	35
2. IL-12p40 deficiency *ILI2B*	Interleukin-12, 40 KD subunit of IL-12 and IL-23, which is required for the production of IFNγ by T, monocytes, and NK cells. Susceptibility to mycobacteria and salmonella.	AR	5q33.3	35
3. IL-12 and IL-23 receptor β1 chain deficiency *ILI2RB*	Receptor β 1 chain of IL-12 and IL-23, required for IFNγ production. Susceptibility to mycobacteria and salmonella.	AR	19p13.1	35
4. STAT1 deficiency *STAT1*	Signal transducer and activator of transcription 1, 91 KDa. Loss of function mutations involved in IFNγ signaling. Susceptibility to mycobacteria and salmonella. For gain of function, see D.3.b (IPEX-like) and D.8.d (CMC).	AD	2q32.2	35
5. STAT5b deficiency *STAT5B*	Signal transducer and activator of transcription 56, 80 KDa. Immunodeficiency and growth hormone insensitivity. Involved in FOXP3 expression (may present as IPEX-like phenotype).	AR	17q21	32
6. IRAK-4 deficiency *IRAK4*	Interleukin-1 receptor-associated kinase 4, a component of TLR and IL-1R pathway. Recurrent pyrogenic infections.	AR	12ql2	36
7. MYD88 deficiency *MYD88*	Myeloid differentiation primary response gene 88 (MYD88) is a component of the TLR and IL-1R pathway. Recurrent pyrogenic infections.	AR	3p22.2	36
8. X-linked anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) *IKBKG*	NF-κB essential modulator (NEMO), a regulator of NF- κB activation. Anhidrotic ectodermal dysplasia, mycobacterial and pyogenic infections, antibody deficiency.	XL	Xq28	36
9. Anhidrotic ectodermal dysplasia with (T-cell) immune deficiency (EDA-ID) *NFKBIA*	IKBα is an inhibitor of NF-κB activation. Anhydrotic ectodermal dysplasia with T-cell deficiency, mycobacterial and pyogenic infections.	AD	14q13	36
10. WHIM syndrome *CXCR4*	See E.1.j for details.	AD	2q21	40
11. GATA2 deficiency *GATA2*	Lack of dendritic cells, monocytes, B and NK lymphocytes (DCML). Susceptibility to mycobacteria (MonoMAC syndrome), papillomaviruses, histoplasmosis, lymphedema.	AD	3q21.3	Hsu AP et al. 2011;118:2653.

12. Pulmonary alveolar proteinosis (PAP) *CSF2RA*	Mutations in the colony-stimulating factor 2 receptor alpha (CSF2RA) impair GMCSF signaling, resulting in surfactant-derived lipoprotein accumulation in the lungs. Biallelic mutations within the X-Y pseudoautosomal region-1 (PAR-1).	AR	Xp22.33	41
13. Epidermodysplasia verruciformis				
a. Ever1 deficiency *TMC6*	Transmembrane channel-like 6 expressed in keratinocytes conferring resitance to HPV	AR	17q25.3	42
b. Ever2 deficiency *TMC8*	Transmembrane channel-like 8 expressed in keratinocytes conferring resitance to HPV	AR	17q25.3	42
G. *DNA Breakage-Associated and DNA Epigenetic Modification Syndromes* (*for Artemis, Ligase IV, and NHEJ1 deficiency, see A.2*)				
1. DNA breakage-associated syndromes				
a. Ataxia-telangiectasia (A-T) mutated (ATM) *ATM*	Cell cycle checkpoint ATM protein kinase	AR	11q22.3	47
b. Nijmegen breakage syndrome protein 1 (Nibrin) *NBS1*	Nibrin participates in DNA repair together with RAD50 and MRE11.	AR	8q21	48
c. Bloom syndrome *BLM*	DNA repair protein BLM	AR	15q26.1	48
d. A-T like disease (ATLD) *MRE11A*	DNA damage-response protein	AR	11q21	48
e. DNA ligase deficiency I *LIG1*	DNA ligase I is ATP-dependent.	AR	19	48
2. Immunodeficiency, centromere instability and facial abnormalities syndrome 1 (ICF1) *DNMT3B*	DNA (cytosine-5)-methyltransferase 3b	AR	20q11.2	49
3. Immunodeficiency, centromere instability and facial abnormalities syndrome 2 (ICF2) *ZBTB24*	Zinc finger and BTB domain-containing protein 24 (ZBTB24) is involved in DNA methylation. Same phenotype as ICF1.	AR	6q21	49
4. PMS2 deficiency *PMS2*	Class-switch recombination deficiency due to impaired mismatch repair resulting in CSR-induced DNA double-strand breaks in Ig switch regions. May present as hyper-IgM syndrome.	AR	7q22.1	27
5. RIDDLE (radiosensitivity, immunodeficiency, dysmorphic features, learning difficulties) syndrome *RNF168* (Ring finger protein 168)	Defective DNA double-strand break repair	AR	3q29	Blundred M. Stewart GS. Expert Rev Clin Immunol 2011;7:169.
H. Defects of the Classical Complement Cascade Proteins				
1. C1q deficiency	SLE-like syndrome			
a. *C1QA*	Subcomponent A chain. C1qA chain.	AR	1p36.12	55
b. *C1QB*	C1qB chain	AR	1p36.12	55
c. *C1QC*	C1qC chain	AR	1p36.12	55
2. C1 deficiency				
a. C1r deficiency *C1R*	C1r subcomponent. Often combined with C1s defect.	AR	12p13	55
b. C1s deficiency *C1S*	C1s subcomponent. Often combined with C1r defect.	AR	12p13	55
3. C2 deficiency *C2*	*C2* gene is located within the MHC cluster. SLE, infections.	AR	6p21.3	55

Table 1.1 (CONTINUED)

DESIGNATION, GENE NAME*	DEFECTIVE PROTEIN, PATHOGENESIS	INHERITANCE	LOCUS	REFERENCE OR BOOK CHAPTER
4. C3 deficiency *C3*	Major factor for both classical and alternative complement pathways. Severe pyogenic infections, SLE.	AR	19p.13.3	55
5. C4 deficiency	SLE, infections			
a. *C4A*	C4A subunit deficiency	AR	6p21.3	55
b. *C4B*	C4B subunit. *C4A* and *C4B* are adjacent genes within the MHC cluster.	AR	6p21.3	55
6. C5 deficiency *C5*	C5 peptide. Initiates formation of the membrane attack complex (MAC). *Neisseria* infections.	AR	9q34.1	55
7. C6 deficiency *C6*	C6 peptide. Part of MAC. *Neisseria* infections.	AR	5p13	55
8. C7 deficiency *C7*	C7 peptide. Part of MAC. *Neisseria* infections.	AR	5p13	55
9. C8 deficiency (*Neisseria* infections)				
a. *C8A*	C8α-polypeptide	AR	1p32	55
b. *C8B*	C8β-polypeptide	AR	1p32	55
c. *C8G*	C8γ-polypeptide, binds covalently to the C8α-chain; C8 is part of MAC	AR	9q	55
10. C9 deficiency *C9*	C9 peptide. Part of MAC. *C6*, *C7*, and *C9* genes are clustered on chromosome 5p. *Neisseria* infections.	AR	5p13	55
	I. *Defects of the Alternative Complement Pathway*			
1. Factor B deficiency *CFB*	Factor B serine protease. Interacts with factor D. The gene is encoded within the MHC cluster.	AR	6p21.33	55
2. Factor D deficiency *CFD*	Factor D interacts with factor B.	AR	19p13.3	55
3. Factor H1 deficiency *CFH1*	Factor H deficiency leads to uncontrolled activation of the alternative C pathway. A polymorphism (Y402H) is responsible for ~50 percent of age-related macular degeneration.	AR	1q231.3	55
4. Properdin factor C deficiency *PFC*	Contributes to activation of C3 via the alternative pathway	XL	Xp11.23	55
	J. *Complement Regulatory Proteins*			
1. C1 inhibitor deficiency *C1NH*	C1 inhibitor, a serine protease inhibitor. Haploinsufficiency results in hereditary angioedema.	AD	11q12.1	55
2. C4-binding protein deficiency. Presumed defect in C4 binding; dissociates and degrades C4 (classical C pathway).				
a. *C4BPA*	C4 binding protein α	AR	1q32.2	55
b. *C4BPB*	C4 binding protein β	AR	1q32.2	55
3. Decay-accelerating factor (DAF) (CD55) deficiency *CD55*	Impairs C killing by controlling both pathways via inhibition of C3 convertase	AR	1q32.2	55
4. Factor I deficiency *CFI*	C3-inactivator	AR	4q25	55
5. CD59 (antigen P18-20) or protectin deficiency *CD59*	20 kDa GPI-anchored antigen. Inhibits lysis by classical C pathway.	AR	11p13	55

6. Mannose-binding lectin deficiency				
a. Mannose-binding lectin deficiency *MBL2*	Mannose-binding lectin activates a distinct, antibody-independent complement pathway.	AR and AD	10q21.1	55
b. Mannan-binding lectin serine protease 1 *MASP1*	Activates C3 and C2. Developmental facial syndrome; 3MC syndrome has been proposed as a unifying term encompassing the overlapping Carnevale, Mingarelli, Malpuech, and Michels syndromes.	AR	3q27.3	55
c. Collectin subfamily member 11 *COLEC11*	Developmental facial syndrome; 3MC syndrome has been proposed as a unifying term encompassing the overlapping Carnevale, Mingarelli, Malpuech, and Michels syndromes.	AR	2p25.3	55
d. Mannan-binding lectin serine protease 2 deficiency *MASP2*	Mannan-binding serine peptidase 2. Activates complement pathway via C4 and C2 by cleaving mannose-binding lectin.	AR	1p36..22	55
7. Miscellaneous complement defects				
a. Complement receptor 3 (CR3) deficiency, integrin, alpha M (ITGAM) *ITGAM*	*ITGAM* encodes the α-subunit of LFA-1 (Mac1), SLE.	AR	16p11.2	53
b. CD46 molecule *CD46*	Complement regulatory protein	AR	1q32	55
c. CD59 molecule *CD59*	Membrane attack complex inhibitor	AR	11p13	55
d. Ficolin deficiency *FCN3*	Ficolin (collagen/fibrinogen domain containing) 3 (Hakata antigen)	AR	1p36.11	55
e. Paroxysmal nocturnal hemoglobinuria *PIGA*		Acquired mutation (XL)	Xp22.2	55
	K. Periodic Fever Syndromes			
1. Familial Mediterranean fever (FMF) *MEFV*	The *MEFV* gene product, pyrin, controls ASC (apoptosis-associated speck-like protein)-induced IL1-caspase-1 cascade.	AR	16p13.3	33
2. Hyper-IgD with periodic fever syndrome *MVK*	Mevalonate kinase (MVK) regulates mevalonic acid and isoprenoid metabolism.	AR	12q24.11	33
3. Cold autoinflammatory syndrome due to cryopyrin deficiency. Mutations in NLR family pyrin domain containing 3 *NLRP3* (also called *CIAS1, NALP3* or *PYPAF1),* including:	Cryopyrin/Nacht domain-, leucine-rich repair and PYD-containing protein 3 (NALP3)/pyrin domain-containing Apaf1-like protein 1(PYPAF1) deficiency	AD	1q44	33
a. Familial cold autoinflammatory syndrome 1 (FCAS1)	Maculopapular rash, arthralgia, fever in response to cold			
b. Muckle-Wells syndrome (MWS)	Similar to FCAS1, progressive deafness, amyloidosis			
c. Chronic infantile neurological, cutaneous, and articular (CINCA) syndrome	Neonatal rash, chronic meningitis, anthropathy, recurrent fever			
4. Cold urticaria due to phospholipase Cγ2 (PLCγ2) deficiency *PLCG2*	Cold urticaria persistently present. Variable manifestations of atopy, granulomatous rash, autoimmune thyroiditis, ANA positive, sinopulmonary infections.	AD		Ombrello MJ et al. *N Engl J Med* 2012;366:330.
5. Tumor necrosis factor receptor-associated periodic syndrome (TRAPS) *TNFRSF1A*	TNF receptor 1 (CD120a) mutations result in impaired TNF removal. Serositis, rash, arthritis.	AD	12p13.31	33

Table 1.1 (CONTINUED)

6.	Blau syndrome due to defective nucleotide-binding oligomerization domain protein 2 NOD2 (also called CARD15) *NOD2*	Granulomatous polyarthritis, uveitis and cranial neuropathies; 30 percent develop Crohn's disease.	AD	16q12.1	33
7.	Early-onset inflammatory bowel disease				
	a. Due to IL-10Rα mutations *IL10RA*	IL-10 receptor, alpha	AR	11q23.3	33
	b. Due to IL-10Rβ mutations *IL10RB*	IL-10 receptor, beta	AR	21q22.11	33
	c. Due to IL-10 mutations *IL-10*		AR	1q32.1	33
8.	PAPA syndrome due to proline-serine-threonine phosphatase interacting protein 1 deficiency *PSTPIP1*	Pyogenic (sterile) arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome	AR	15q24.3	33
9.	Majeed syndrome lipin 2-deficiency *LPIN2*	Chronic recurrent multifocal osteomyelitis, congenital dyserythropoietic anemia, transient inflammatory dermatosis with neutrophil infiltration	AR	18p11.31	33
10.	Deficiency of the IL-1 receptor antagonist (DIRA) *IL1RN*	Skin and bone inflammation in the newborn period	AR	2q14.2	33

AD, autosomal dominant; AR, autosomal recessive; EBV, Epstein-Barr virus; NK, natural killer; XL, X-linked.

*Gene names, in italics, according to the Human Genome Organization, http://www.gene.ucl.ac.uk/nomenclature/; Wai Man, http://www.nebi.nlm.nih.gov/omim/.

CD4 T lymphocytes, and individuals with homozygous variants of this receptor have decreased HIV susceptibility. Thus, one could make the extreme argument that the majority of humans are immunodeficient with respect to HIV, while those lacking the CCR5 receptor constitute a rarer, resistant population. The dominantly inherited immune defect caused by the expression of fully functional CCR5 is manifested only upon HIV infection, with development over time of a generalized secondary immunodeficiency as HIV-infected cells are lysed and the T-lymphocyte count decreases. This example illustrates that the definition of what is actually a primary immunodeficiency is not always straightforward. Similar to many other PIDs, this CCR5 sufficiency "defect" can be treated by a transplant of hematopoietic stem cells from a donor lacking CCR5 expression (Hütter et al., 2009).

THE INCREASED RATE OF DISEASE GENE IDENTIFICATION AND MUTATION NUMBER

The number of identified genes and individual mutations causing PIDs is steadily increasing. With the unprecedented development of very high-throughput DNA sequencing technologies, it is likely that we will witness a truly dramatic increase in the diagnosis of PID over the next few years. Deep sequencing approaches to detect disease-causing mutations have already begun (Bolze et al., 2010; Puel et al., 2011). Historically, molecular disease mechanisms were first identified when an affected protein was recognized by coincidence. This was the case for adenosine deaminase (ADA) deficiency, discovered serendipitously in 1972 in an infant with SCID, who lacked the ADA protein (Chapter 13). Next followed the era when disease genes were mapped by linkage analysis in multiplex families, or in some instances by cytogenetic abnormalities, to certain chromosomal regions, whose content then needed to be ascertained. A causative gene and corresponding deleterious mutations were subsequently deciphered by painstaking molecular analysis. The first example of this approach was the discovery in 1986 of the *CYBB* gene underlying the X-linked form of chronic granulomatous disease. A patient with an intracellular oxidative bacterial killing defect as well as other phenotypes had a contiguous gene deletion including *CYBB* (Chapter 51).

X-linked immunodeficiency genes were among the first to be found because pedigree analysis restricted the proportion of the genome that needed to be tested and hemizygous males were affected; autosomal recessive genes, in contrast, were often found by studying consanguineous families in whom a disease gene could be sought in a limited region of DNA inherited from a common ancestor. Before the human genome was fully sequenced, identifying mutated genes by finding linkage regions was tedious. However, once a dense map of highly polymorphic markers and even more numerous single nucleotide polymorphisms (SNPs) was available, it became much easier to trace and identify disease-causing genes. Subsequently, having the complete human genome sequence and catalogs of known and predicted genes further facilitated PID gene discovery. Now new methods enabling high-throughput sequencing of targeted DNA regions or of

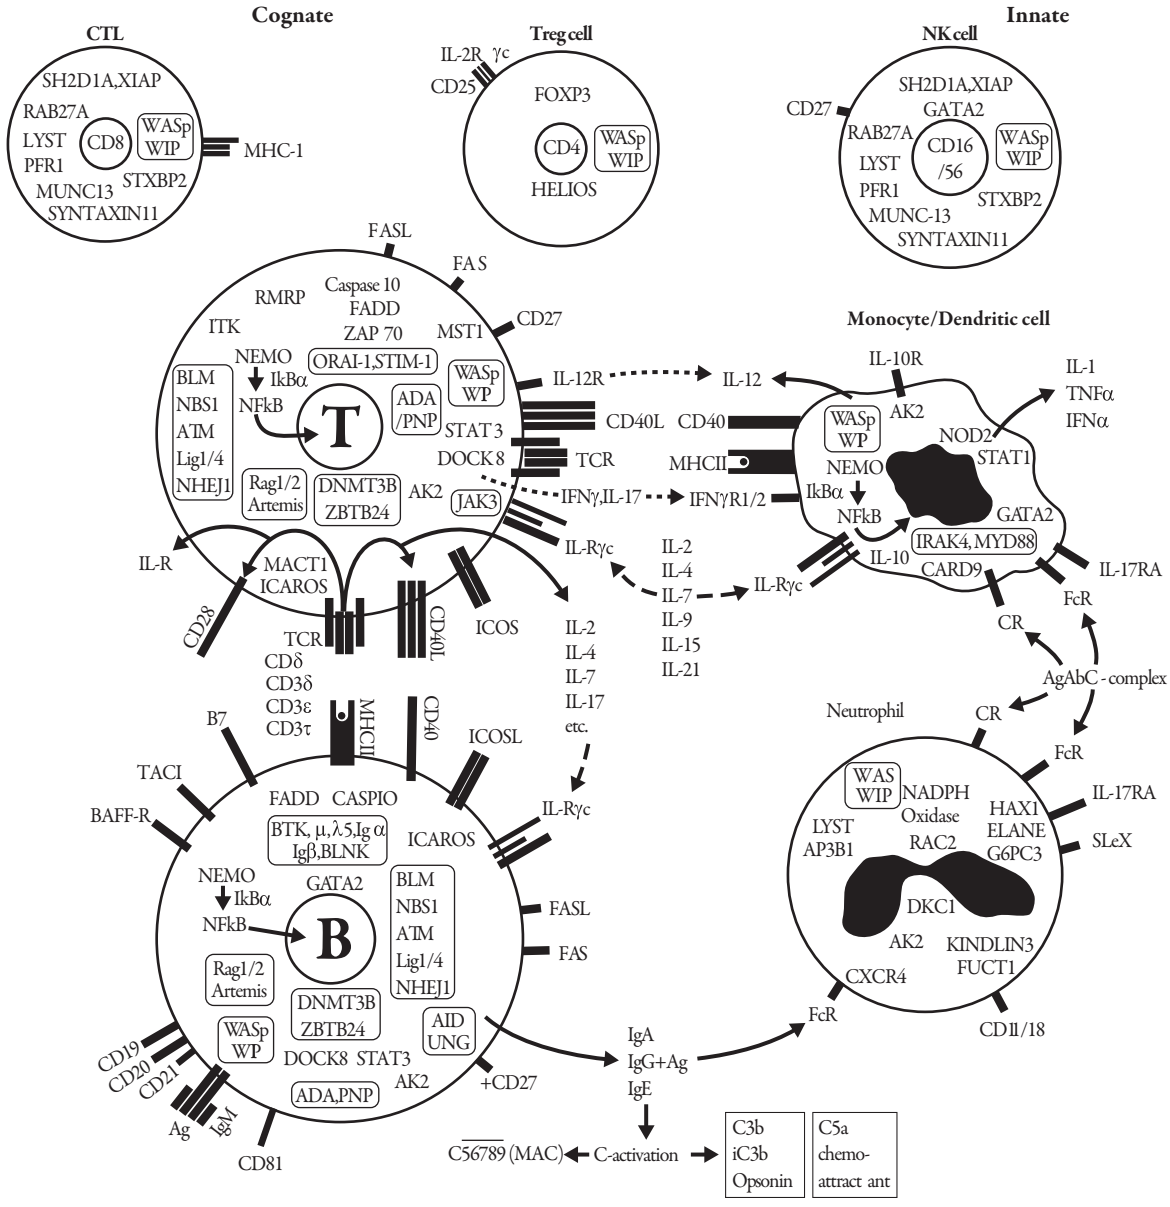

Figure 1.1 Simplified schematic diagram of mediators of leukocyte activation and interactions between T and B cells, macrophages, and neutrophils. IL-2Ryc [this lowercase y should be Greek symbol gamma], common chain of IL-2, 4, 7, 9, and 15 receptors; TCR, T cell receptor; SLeX, S-Lewis X receptor. For other abbreviations, see Table 1.1.

the entire exome (defined as the coding and immediate adjacent regions of genes) further assist direct searches for disease-associated sequence variants. With reduction of sequencing costs, detection of sequence variants throughout the entire genome will be increasingly affordable, although bioinformatics analysis remains a major challenge at present. In the future whole genome sequencing of newborns may identify many PIDs even prior to clinical manifestation. This will have a major impact on patient care.

For these reasons, future editions of this book are likely to contain many more disease genes, and individual gene mutations are already too numerous to catalog in print. In this volume there are so many new disease genes that the editors have decided to make some changes compared to the second edition. We have grouped related diseases into single chapters and introduced a new, short-chapter format for rare PID genes that do not belong to a functionally related group but rather form unique disease paradigms.

DISORDERS WITH FINDINGS OUTSIDE THE IMMUNE SYSTEM AS THE MAIN PRESENTATION

There are several multisystem disorders in which variable degrees of immunodeficiency may occur but are not the most severe or widely recognized feature. Although immune compromise may be severe in rare cases, it is more often mild or even inapparent. Such disorders include centromere instability syndromes (Chapter 48), ataxia-telangiectasia (Chapter 46), DiGeorge syndrome (Chapter 44) and cartilage-hair hypoplasia (Chapter 36). A recent addition is the hepatic veno-occlu-

sive disease with immunodeficiency described in Chapter 38. The reader is cautioned to consider the contribution of underlying immune pathology to both the frequent infections and the autoimmune phenomena that may accompany multisystem syndromes such as trisomy 21 and others beyond the scope of this book, for which the immune features are not predominant and malfunctions in other organ systems prevail.

MULTIPLE-MICROBE VERSUS SINGLE-MICROBE SUSCEPTIBILITY

Several excellent recent reviews have dealt with the distinction between patients in whom the infectious panorama involves multiple agents versus those whose susceptibility is limited to one or a few microbes (Alcaïs et al., 2009; Quintana-Murci et al., 2007). Traditionally, most PIDs belong to the group of multiple-microbe susceptibility. Thus, reticular dysgenesis and SCID patients are highly prone to most, if not all, infectious agents. However, retrospective analysis shows that when children born with such defects have succumbed to an infection, a limited number of pathogens have been implicated. This reflects common environmental exposure and lack of effective treatment, as well as the potential of certain agents such as adenovirus to cause lethal disease in a short period of time. Similarly, patients with less profound defects limited to B lymphocytes, complement or granulocytes, while being susceptible to a multitude of infectious agents, nevertheless show a more restricted infectious pattern than found in SCID. As expected, the more profound and global the immune defect, the wider is the range of infectious pathogens in the phenotype.

The other end of the multiple-microbe susceptibility spectrum can be exemplified by individuals with failure to make a specific immune system component. Those with low levels of IgG4 are not recognized to be particularly prone to infections, while only about one in three people lacking IgA, which is targeted to mucosal surfaces, show increased susceptibility to respiratory and gastrointestinal infections. However, even without an overt history of mucosal infections, those who lack IgA have increased susceptibility to infections caused by microbial species such as Giardia and also show an increased propensity for autoimmune disease (Chapter 27). These patients may demonstrate underlying disease mechanisms not directly related to their lack of IgA, as autoimmunity is generally uncommon in patients with XLA, who lack B lymphocytes and thus all classes of immunoglobulins (Chapter 24).

The above PIDs contrast strongly with the lymphoproliferative syndromes, disorders in which a single infectious agent, Epstein-Barr virus (EBV), is the cause of nearly all fatal outcomes (Chapter 43). Individuals with defects in the X-linked genes *SH2D1A* and *XIAP* or the autosomal genes *ITK* (Huck et al., 2009) and *CD27* (van Montfrans et al., 2012) may be completely healthy until exposed to EBV but develop life-threatening complications following infection with this virus. Thus, it appears that humans are endowed with several gene products that are essential for protection against lethal EBV infections. This is an important message, demonstrating the co-evolution of a human pathogen and host defenses. The proteins involved in the defense against EBV appear nonredundant, since there seems to be full penetrance of the defect in each genotype. Additional components of the innate immune system are postulated whose contribution to defense against severe EBV disease may be more nuanced or nonspecific. Such genes have yet to be identified.

EBV is not a unique example. Over the past decade hundreds of patients with defects in components involved in Th1 cytokine responses have been identified (Quintana-Murci et al., 2007; Chapter 34). In these disorders, infections due to mycobacteria, salmonella, and fungi are overrepresented. Thus, the lack of a particular immunocyte product results in a more selective phenotype as compared to the absence of an entire lymphocyte subpopulation. Surprisingly, results from experimental animal models suggest a defect that is more profound than the observed human infections, when the γ-interferon response is abrogated. These differences may be due to the large dose of infectious agents used in animal studies, as well as the route of administration, calling into question the relevance of these models for human disease.

Given the enormous number of microbial species, it seems quite possible that each and every one of us will have holes in the repertoire of humoral and cellular elements involved in protecting us against infections. To this end, a particular genetically determined variant of a single molecule could potentially protect us against one microbe while at the same time increase susceptibility to infection with another. The best example of such polymorphism is the major histocompatibility (MHC) locus, where certain HLA molecules efficiently present one antigen at the expense of another. Because each individual expresses only a limited number of MHC antigens, there must be important differences in how antigens are presented to T lymphocytes. In addition to HLA molecules, other components of the adaptive immune system not yet identified may be critical for determining susceptibility to individual infectious agents, but environmental factors such as age at exposure are also important.

CONTROLLING INFECTIONS: FROM ADAPTIVE TO INNATE IMMUNITY, TO FACTORS UNRELATED TO THE IMMUNE SYSTEM

Although anticipated, it became evident only recently that large numbers of autosomal recessive diseases exist, where the endogenous defense mechanism is mainly directed against single, or a few, infectious agents. A recent example is the increased susceptibility to herpes simplex virus (HSV), caused by mutations in *TLR3* encoding Toll-like receptor 3, *UNC-93B1* or *TRAF3*, encoding tumor necrosis factor receptor-associated factor 3 (Quintana-Murci et al., 2007, Perez de Diego et al., 2010, Chapter 35). The TLR3 defect causing susceptibility to HSV does not seem to primarily affect the adaptive immunity, but rather the innate immunity as manifested in cells of the central nervous system, where the mutation permits HSV to replicate and cause tissue damage. Very few affected individuals have been identified to date, and it appears that not all individuals carrying the mutation will develop severe HSV infection. The reason for this is not known.

The TLR3 defect resembles another disease, namely selective susceptibility to human papillomavirus (HPV), in that the affected cell does not belong to immunocytes. While TLR3 is still recognized as a representative of the innate immune system, the situation is different for epidermodysplasia verruciformis (Chapter 41) caused by mutations in the *EVER1* and *EVER2* genes, whose function is not known, but whose products have features of integral membrane proteins and are localized in the endoplasmic reticulum. It may well be that these proteins have no relationship to innate immunity.

Thus, one can easily imagine gene products whose primary functions are completely unrelated to innate or adaptive immunity, but when defective, clearly contribute to the propensity for infections. Whether such genes should be classified as immunodeficiency genes is debatable. At any rate, there will be many difficult future distinctions and definitions to be made, since certain gene products may remotely contribute to immune functions while other products may not.

NEW GENES FOR OLD SYNDROMES

Since the second edition was published, disease genes have been discovered for numerous long-recognized PID phenotypes. An example is chronic mucocutaneous candidiasis (CMM), for which Puel et al. (2011) have identified two disease mechanisms, both affecting interleukin-17. Mutations in the gene for IL-17F produce autosomal dominant disease, whereas defective interleukin-17 receptor A causes autosomal recessive disease. Importantly, the defective interleukin-17 signaling pathway results in susceptibility to infections with *Candida albicans* but not to infections with other pathogens. However, the most common cause for CMM seems to be gain-of-function mutations in the *STAT1* gene (Liu et al., 2011, van de Veerdonk, 2011). In this disease with autosomal dominant inheritance the increased STAT1-signaling seems to impair the induction of IL-17 immunity.

ACQUIRED SYNDROMES RESEMBLING PID

As mentioned above, ALPS can be caused not only by heterozygous germline *FAS* mutations but also by somatic ("acquired") mutations (Holzelova et. al, 2004) detected in the circulating double-negative T cells (CD3+CD4−CD8−, TCR αβ+). In a recent report, more than one third of ALPS patients had somatic mutations of the intracellular domain of *FAS*, resulting in loss of Fas-mediated apoptosis and selective survival (Dowdell et al., 2010). Somatic ALPS patients had elevated serum concentrations of vitamin B12, IL-10, and soluble Fas ligand, similar to ALPS patients with germline *FAS* mutations. A subset of ALPS (type IV) has been found to be caused by somatic mutations in RAS family genes (*NRAS*, *KRAS*); two unrelated infants with ALPS-like symptoms had the same heterozygous point mutation in the *KRAS* gene affecting hematopoietic cell lineages (Takagi et al., 2011).

Anticytokine autoantibodies have also emerged as a cause of susceptibility to infections. Neutralizing antibodies that target a particular cytokine known to participate in host defense against specific organisms have been observed in several unique patient populations: autoantibodies to granulocyte macrophage colony-stimulating factor (GM–CSF) cause pulmonary alveolar proteinosis (Chapter 40); anti-interferon (IFN)-γ autoantibodies have been associated with disseminated nontuberculous mycobacteria (Patel et al., 2005); and antibodies to IL-17A, IL-17F, and IL-22 have been found to explain the mucocutaneous candidiasis associated with autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) syndrome (Puel et al., 2010; Kisand et al., 2010). Anti-IL-6 autoantibody was observed in a boy with severe staphylococcal cellulitis and subcutaneous abscesses (Puel et al., 2008). It is possible that these and other autoantibody-mediated infectious disease susceptibilities may be controlled with therapy to eliminate B cells.

REVERSION OF MUTATIONS CAUSING PID

Pathologic mutations that have reverted to wild type have been known previously but are now firmly established in several PIDs, including ADA-deficient, X-linked SCID and WAS. In these disorders, the spontaneous reversion or second-site mutations restored function and thus ensured a selective survival or growth advantage for the corrected cells (Liu et al., 2009; Stephan et al., 1996; Wada et al., 2001). Less obvious are reversion mutations in CD8 T cells of three patients with leukocyte adhesion deficiency type I (LAD-1) reported by Uzel et al. (2008). It is unclear if these CD8+CD18+ T lymphocytes were functionally active.

PROGRESS IN DIAGNOSIS AND TREATMENT

Progress in immunology, genetics, and molecular biology has changed the way we diagnose and treat PID patients. This is illustrated by the histories of families with multiple generations of affected members. Figure 1.2 represents a kindred now known to carry XLA (Chapter 25). Inspection of the pedigree reveals that individual III-3, born in 1918, was an obligate carrier of this condition. It is interesting that she had two brothers who died early in life; although definitive information is lacking, they may have been affected with XLA. Her oldest son, IV-3, suffered from recurrent upper and lower respiratory tract infections and died of pneumonia in 1948 at the age of 4 years. Her two younger sons, IV-4 and IV-6, were able to receive the newly available antibiotic penicillin. They survived multiple episodes of pneumonia and were diagnosed with XLA in the mid-1950s, shortly after Bruton's discovery of agammaglobulinemia (Bruton,

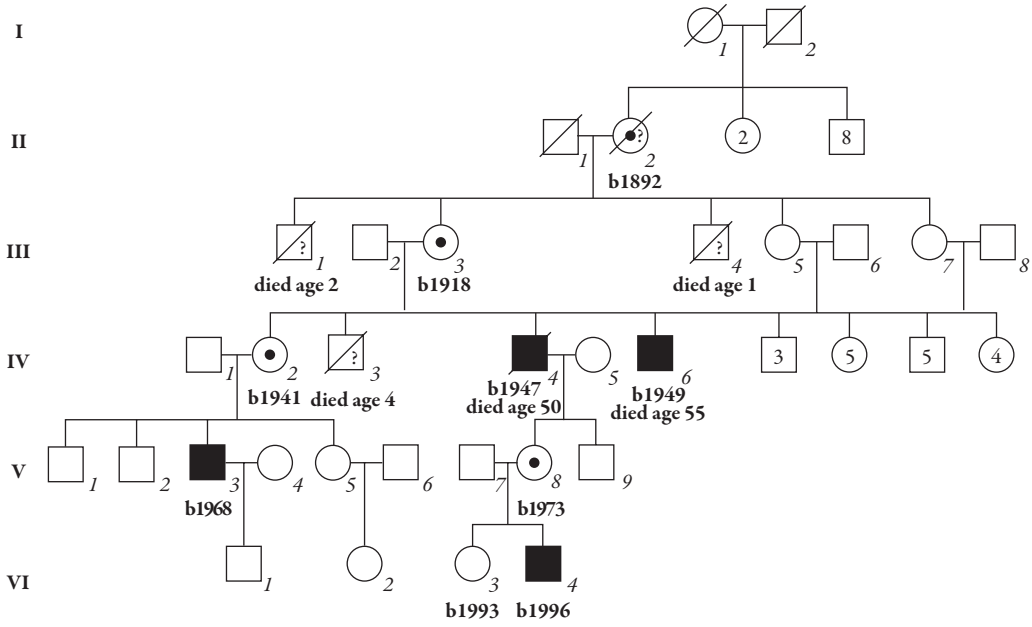

Figure 1.2 Pedigree of a family with X-linked agammaglobulinemia (XLA), illustrating medical progress in diagnosing and treating affected males. Males, squares; males diagnosed with XLA, filled squares. Females, circles; mutation carriers, circles with filled center. Slash, deceased. Individuals who may have had the XLA mutation are indicated with a question mark. Year of birth (b) and age of death are indicated for selected individuals. Individuals III-1, III-4, and IV-3 died of pneumonia. IV-4 died of pulmonary insufficiency, having suffered many bouts of pneumonia from early childhood until diagnosis at age 7.

1952). By the time intramuscular immunoglobulin treatment was instituted, both boys had developed chronic lung disease and bronchiectasis. IV-4 was one of the first patients treated with high doses of intravenous immunoglobulin (IVIG) for echovirus infection with dermatomyositis, fasciitis, and meningitis (Mease et al., 1981). He died of chronic respiratory failure at the age of 50; his younger brother (IV-6) died at the age of 55.

The younger generations of this family have a much more hopeful prognosis. When individual V-3 developed his first pneumonia at the age of 2, he was referred to a university center, where the diagnosis of XLA was confirmed and treatment with immunoglobulin initiated. He has remained healthy with regular immunoglobulin replacement, now by subcutaneous self-infusion, and at present has a full-time job and no chronic disease. XLA was diagnosed in the youngest member of this kindred, VI-3, at the time of birth by documentation of absent B cells in cord blood and sequence analysis of *BTK*. He was immediately started on immunoglobulin treatment and has remained completely healthy.

2.

GENETIC PRINCIPLES AND TECHNOLOGIES IN THE STUDY OF IMMUNE DISORDERS

Jennifer M. Puck and Robert L. Nussbaum

INTRODUCTION

Medical genetics is concerned with the investigation, diagnosis, treatment, counseling, and management of patients and families with inherited disease. Research in medical genetics focuses on identifying the genes involved in human hereditary diseases and the changes in DNA sequence that cause or predispose to these diseases; elucidating disease pathogenesis, including both genetic and environmental factors; understanding the inheritance patterns of diseases in families; developing new treatments or cures for hereditary disorders; and helping patients and families make reproductive decisions and cope with the impact of genetic disorders on the health of family members. Although a complete discussion of medical genetics is beyond the scope of this book and can be reviewed in several texts (Nussbaum et al., 2007; Scriver et al., 2001; Speicher et al., 2010), we present here an overview of the terminology, concepts, and methods of molecular genetics. This introduction will outline the approaches that have led to the identification of the genes involved in over 200 specific disorders of the immune system. Newer and more powerful methods of deep "next-generation" sequencing and genomic analysis will make possible further revolutionary changes, not only in the discovery of additional disease genes, but also in understanding the pathogenesis of defects in host defenses. Using this understanding has led to and will continue to lead to effective new therapies.

The normal complement of 46 chromosomes in a human cell consists of 23 pairs of homologous chromosomes (Fig. 2.1). Twenty-two of the 23 pairs are *autosomes* and are the same in men and women; the remaining pair, the *sex chromosomes*, consist of two X chromosomes in females or one X and one Y (carrying the male-determining genes) in males. The two homologous chromosomes that make up each of the 22 pairs (23 pairs in females) are identical in size, centromere placement, and arrangement of genes.

The location of a particular gene on a chromosome is known as the *locus* for that gene. The DNA sequence in and around a gene (such as in introns or flanking regions or even within coding regions) may vary among the individuals in the population, so the *reference sequence* of the human genome is defined as our best approximation of frequently found sequences in a large collection of individuals (http://genome.ucsc.edu; Fujita et al., 2011). The term *allele* is used to describe the DNA sequence at a locus, which may be identical to or different from the reference sequence, and the particular pair of alleles an individual possesses for a given gene is called his or her *genotype*. Alleles can be rare, deleterious mutations that cause disease or frequent normal variants of no known significance. If greater than 1 percent of the alleles in the population have a DNA sequence at a locus that differs from the reference DNA sequence, the locus is said to be polymorphic. A polymorphism can be a single nucleotide change (*single nucleotide polymorphism* or *SNP*), a small deletion or insertion of a few nucleotides (*indel*), a difference in the number of repeated of di-, tri-, or tetra-nucleotide units contained in a short tandem repeat (*STR*), or a deletion or duplication of segments containing hundreds to millions of nucleotides, known as a *copy number variant* (*CNV*). A group of polymorphic alleles at a set of loci close together in a row on a single chromosome is called a *haplotype*. When the alleles in a particular haplotype are found to remain together over many generations, the alleles are said to be in *linkage disequilibrium* (LD). LD is a measurable quantity and ranges from 0 (no LD) to 1 (complete LD).

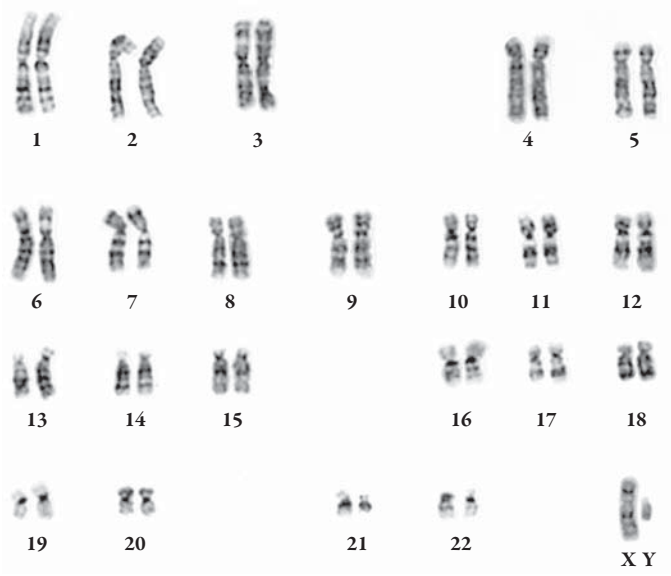

Figure 2.1 Normal human metaphase chromosomes from a male, aligned to show the 22 pairs of autosomes, one X, and one Y. The banding pattern is revealed by Giemsa staining. Giemsa-dark regions are particularly rich in genes. (Kindly provided by Amalia Dutra.)

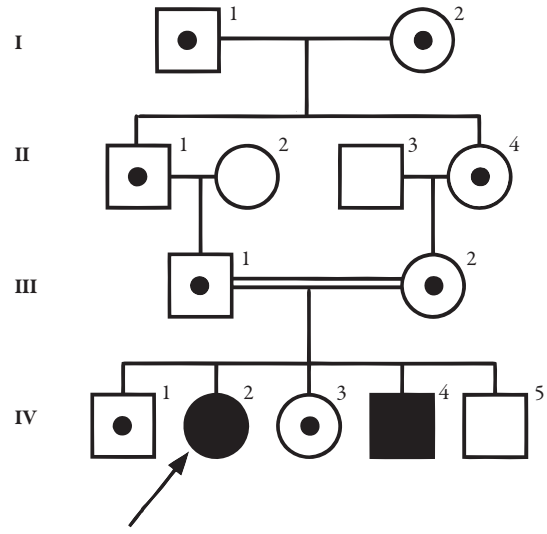

Figure 2.2 Autosomal recessive inheritance. Circles, females; squares, males; filled symbol, affected; symbol with dot, silent carrier. Roman numerals designate generations, with each individual within a generation identified by an integer. This pedigree demonstrates a consanguineous mating, double horizontal line, between cousins III-1 and III-2 (a typical but not required characteristic of autosomal recessive disease pedigrees). An arrow marks the proband, the first person in the family to come to medical attention. For updated conventions for pedigree drawing, see Bennett et al. (1995).

MECHANISMS OF INHERITANCE

MENDELIAN VERSUS COMPLEX INHERITANCE

Mendelian inheritance describes the hereditary patterns in diseases caused by DNA mutations of big effect in single genes inherited from parents by their offspring. Thus, Mendelian disorders include most of the rare primary immunodeficiency diseases described in this book. An increasing awareness of a genetic contribution to other diseases has led to the designation *non-Mendelian* or *complex inheritance* to refer to instances in which an individual's genetic makeup has a more variable and more complex role in disease causation. Examples of complex diseases include multifactorial diseases in which one or more gene mutations must interact with each other and/or environmental factors in order for a disease to be manifest.

AUTOSOMAL RECESSIVE INHERITANCE

In autosomal recessive inheritance (Fig. 2.2), disease usually results when a person inherits two defective copies of the same autosomal gene; the affected individual can be either a homozygote, if two identically defective copies of the same gene are inherited, or a compound heterozygote, if each gene copy has a different deleterious mutation. The parents are unaffected heterozygotes, who carry one normal copy and one abnormal copy of the gene. By definition, heterozygous carriers of recessive disorders are not affected because the normal copy of the gene compensates for the defective copy. The typical familial inheritance pattern in autosomal recessive illness is for disease to occur in one or more full brothers and sisters, with both genders affected equally and both parents unaffected. Recessive disorders are seen with increased frequency in children of consanguineous marriages, in which the parents are related to each other (Fig. 2.2), share ancestry, or come from genetically isolated populations. The underlying mutations carried by the parents are presumed to have arisen in a single common founder. The genotypes of affected individuals in such instances are expected to show homozygous mutations. A lack of a family history of affected relatives is not an argument against autosomal recessive inheritance because many contemporary families have small sibship sizes, making a single affected child born to unaffected parents the rule rather than the exception.

Recessive illness usually results from loss of function of a gene whose product is normally present in excess, so that even a half-normal amount of the gene product is adequate to prevent disease. For example, homozygotes with deletion of the first exon of the gene encoding adenosine deaminase (ADA) have a profound deficiency of the enzyme, resulting in early onset of severe combined immunodeficiency (SCID) (see Chapter 13). In contrast, heterozygotes, with one deleted and one functional copy of the gene, have an amount of enzyme activity in between that found in normals and that in patients with ADA-deficient SCID; however, even a reduced amount of the normal enzyme is sufficient to remove purines toxic to lymphocytes and thus protect a heterozygous individual from expressing any immunological defect.

AUTOSOMAL DOMINANT INHERITANCE

In pure autosomal dominant inheritance (Fig. 2.3), an individual needs only one copy of a gene alteration for disease to occur, and homozygotes for the alteration have the same severity of disease as do heterozygotes. The parent from whom the genetic alteration was inherited may himself or herself be affected or may be a silent, or *nonpenetrant*, carrier. In humans,

very few dominantly inherited disorders are truly dominant. Instead, they are usually incompletely dominant, which means an individual heterozygous for the mutation is affected but homozygotes for the mutation are far more severely affected. The typical inheritance pattern in autosomal dominant illness is to see multiple affected individuals, both genders affected equally, with transmission of the disease from one generation to the next.

If a dominantly inherited condition requires the presence of an alteration on only one chromosome, it would seem contradictory that some individuals whose position in the pedigree implies they must be heterozygotes for the disease-causing mutation (*obligate heterozygotes*) show no evidence of the disease (lack of penetrance), as illustrated for individual II-4 in Figure 2.3. However, such lack of penetrance is a well-described phenomenon in autosomal dominant disorders. It is seen if the onset of the disorder is age-dependent, or if an additional factor or factors, such as a second spontaneous somatic mutation or an environmental agent or influence, must be superimposed on the underlying genetic defect in order for the disease to become clinically evident. An example of an autosomal dominant primary immune disorder is autoimmune lymphoproliferative disease (ALPS, see below and Chapter 30).

A lack of family history is not a strong argument against autosomal dominant inheritance because a nonpenetrant carrier parent makes the affected individual appear as a sporadic case of the disease in the family. Alternatively, it is possible that neither parent harbors the alteration if the child's mutation arose spontaneously after separation of the germline of one of the parents from somatic cell progenitors, a situation known as *germline mosaicism*. With germline mosaicism, a parent can make gametes carrying the mutation and pass the mutation one or more times to a child without the germline mosaic parent demonstrating the mutation in the somatic tissues (blood, buccal cells, fibroblasts) that are readily available for mutation testing. New mutations may also occur in an embryo after conception and may be present in the germline but also in some, but not all, somatic tissues. In this situation, known as *somatic mosaicism*, the mutation in the child may or may not be detectable in somatic tissues available for mutation testing.

The rate at which new mutations occur per gamete was previously estimated by measuring the incidence of completely penetrant autosomal dominant or X-linked diseases, such as achondroplasia or Duchenne muscular dystrophy, in a large cohort of newborns. The measured rate of gene mutations per gamete that resulted in a detectable clinical phenotype ranged over nearly two orders of magnitude, from 10^{-6} to 10^{-4}. With the availability of whole-genome sequencing, we now have an unbiased estimate of mutation rate of 1.1×10^{-8} per base (95 percent confidence interval, 0.68 to 1.7×10^{-8}), or approximately 33 new mutations among the ~3 billion base pairs of DNA in a gamete.

Mutations can cause dominantly inherited diseases through a number of different mechanisms. In the most straightforward situation, abnormal amounts of the gene product may be inadequate. For example, deficiency of one copy of a gene contained within microdeletions of chromosome 22 can be responsible for DiGeorge syndrome (see Chapter 45). This model for dominant inheritance is called *haploinsufficiency*. In contrast, more than two copies of a gene may also cause disease inherited in an autosomal dominant manner, as is seen with duplication of the *PMP22* gene in Charcot-Marie-Tooth IA peripheral neuropathy (Boerkoel et al., 2002) or triplication of the α-synuclein gene in familial Parkinson's disease (Singleton et al., 2003).

A second pathogenetic mechanism for dominant genetic disease is a *gain of novel function*, in which a new or altered protein produced from the mutated allele is endowed with a novel or toxic activity not found in the normal gene product. An example is multiple endocrine adenomatosis type 2, in which activating mutations in the *RET* oncogene lead to medullary thyroid carcinoma, hyperparathyroidism, and pheochromocytoma.

A mechanism for a single mutation causing dominant disease is *dominant negative* mutation, as is seen in most patients with ALPS (see Chapter 30). Patients with heterozygous mutations in the gene encoding the apoptosis mediator CD95/Fas have defective programmed cell death, normally initiated through the homotrimeric Fas receptor complex. In vitro studies show not only failure of the mutant protein to transmit a death signal itself, but also interference by mutant Fas molecules when associated with normal Fas molecules in the death-inducing signal complex (Fisher et al., 1995). The mutated Fas proteins produce steric interference when incorporated into the normal trimeric Fas receptor complex.

Finally, in some dominantly inherited cancer syndromes there is a *two-hit* mechanism (Knudson, 1971). The first hit is a mutation inherited through the germ line that inactivates one allele of a *tumor suppressor gene*, thus rendering an individual heterozygous for the mutated gene. One defective allele, however, is not sufficient to cause disease until a single somatic cell undergoes a second event inactivating the remaining normal allele. After this second hit, the cell may undergo

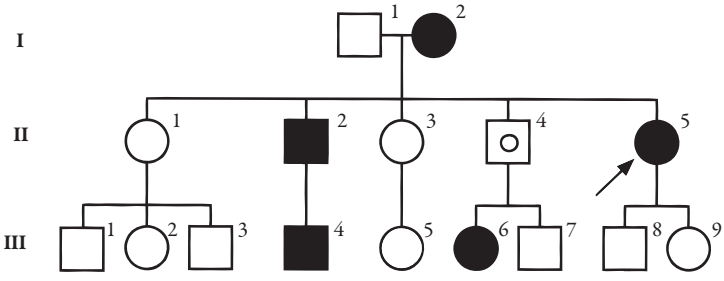

Figure 2.3 Autosomal dominant inheritance. Note male-to-male transmission from subject II-2 to III-4, strongly suggesting dominant inheritance. II-4 is a nonpenetrant carrier. Circles, females; squares, males; filled symbol, affected; symbol with circle, at risk but currently unaffected carrier; arrow, proband.

pathological, unregulated growth to produce a clonal cancer. Second hits may be large genomic deletions in a single cell as it divides, resulting in *loss of heterozygosity* for SNPs in the vicinity of the disease locus in the tumor cells. On the other hand, the second hit may be an epigenetic change (such as abnormal DNA methylation) of the remaining normal allele, resulting in inactivation without any alteration of the primary nucleotide sequence. Accumulation of multiple somatic hits after the initial two hits increases pathogenic features of many cancers. The Lynch syndrome of hereditary colon and endometrial cancer caused by mutations in genes responsible for DNA mismatch repair is a classic example of an autosomal dominant syndrome that satisfies a two-hit model.

X-LINKED INHERITANCE

Mutations in X-linked genes have strikingly different consequences in males and females and cause diseases with a distinctive X-linked pattern of inheritance (Fig. 2.4). Males have only one copy of genes on their single X chromosome, while women have two. To provide dosage compensation and equalize gene expression for X-linked genes in males and females, one of the two X chromosomes in a female's somatic cells is chosen at random, early in embryonic life, to undergo a near-total and irreversible inactivation (Lyon, 1966). In a male carrying a defective X-linked gene, clinically apparent abnormality always occurs because his only copy of the gene is disrupted. Male *hemizygosity* for the X chromosome explains the large number of X-linked immunodeficiencies (Fig. 2.5) and the high proportion of males diagnosed with inherited immunodeficiency.

In females with X-linked gene defects, the situation is more complex. In contrast to the situation with a heterozygote for an autosomal gene mutation, a female heterozygous for an X-linked gene mutation does not have a uniform population of cells, each of which expresses both the normal and abnormal gene. Instead, the somatic tissues of a female are made of a mixture of cells, some of which have an active X chromosome carrying the normal gene, while the rest have an active X chromosome carrying the abnormal gene. The relative proportion of cells with one or the other X chromosome active in any one tissue averages 50 percent but may differ substantially depending on chance and the number of precursor cells for that tissue that were present in the embryo when X inactivation took place. The fraction of cells in a tissue that have an active X chromosome carrying the normal gene is usually sufficient for normal function of the tissue, so female heterozygotes for X-linked disorders are usually silent carriers. If, however, the cells that have inactivated the X chromosome carrying the normal gene predominate in a tissue, a female heterozygote may be symptomatic. Thus, the terms "dominant" and "recessive" as applied to autosomal disorders are not strictly applicable to X-linked conditions.

In female carriers of some X-linked diseases, such as X-linked SCID due to defects in the IL-2 receptor γ chain (see Chapter 10) or X-linked agammaglobulinemia (XLA) due to defects in the Bruton (or B-cell) tyrosine kinase Btk (see Chapter 25), the expected random X inactivation in the lymphocyte population targeted by the gene defect is not seen (Puck, 1993). In these situations, a female carrier of X-linked

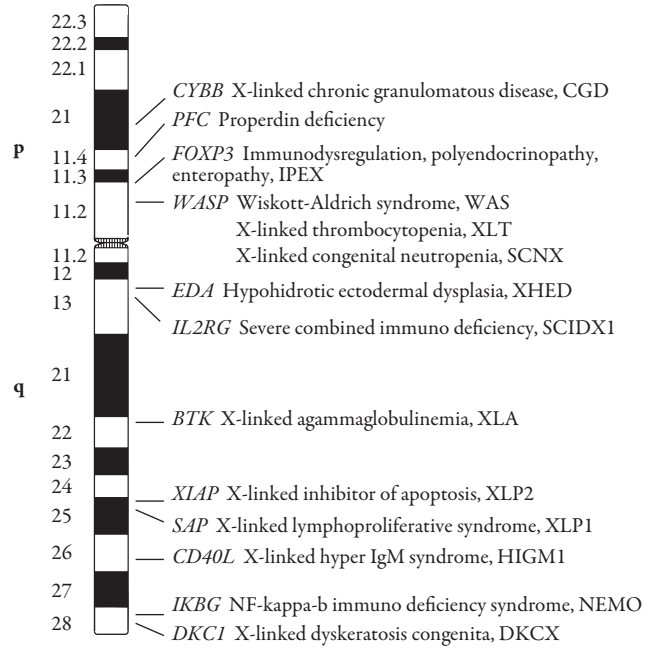

Figure 2.5 Idiogram of human chromosome X, illustrating the major Giemsa bands and conventional cytogenetic nomenclature, including p (short) arm and q (long) arm, integers denoting major bands increasing from centromere to telomere, and additional digits to the right of the decimal point denoting sub-bands. The loci on the X chromosome of 12 known human immune disease genes are indicated.

SCID (or of XLA) will have no lymphocytes in the case of SCID (or no B cells in XLA) whose active X chromosome carries the mutation because the fraction of the lymphocyte precursors that have inactivated the X chromosome carrying the normal version of the gene cannot develop and survive normally. As a result, the target lymphocyte population for each disease will show marked "skewing" of X inactivation. The abnormal X-inactivation pattern seen in X-linked immunodeficiencies has been useful for carrier identification in the past but has largely been replaced by direct mutation assessment.

A typical X-linked inheritance pattern (Fig. 2.4) is characterized by affected male siblings and cousins as well as affected males in additional generations, all affected members of the kindred being related through unaffected female relatives. However, a lack of family history does not rule out an X-linked inheritance mechanism for immune deficiency. As with autosomal dominant disorders, a spontaneous new mutation in an X-linked gene can result in somatic or germline mosaicism for a mutation and cause the disease to appear in the family, either directly in a male or by the creation of a silent female carrier who passes the mutation on to her sons. One third of the cases of X-linked diseases severe enough to prevent reproduction by affected males are expected to be the first manifestation in their family of a new mutation (Haldane, 1935). Because males donate a Y chromosome and not an X chromosome to their sons, documenting male-to-male transmission of any trait in any pedigree rules out X-linked inheritance.

HETEROGENEITY

Genetic heterogeneity is a broad term used to describe departures from the simple models of "one gene—one enzyme" or "one mutation—one disease." Diseases can show *allelic heterogeneity*, in which different mutations in the same gene cause disease, as is the rule in single-gene immunodeficiency diseases. *Locus heterogeneity* occurs in diseases such as SCID in which a similar phenotype of absent cellular and humoral immunity leading to opportunistic infections can arise from mutations in a number of different genes; the diseases caused by mutations at these different loci are termed *genocopies*. In contrast, a *phenocopy* is an acquired, not a genetic, disease that resembles genetic forms of the disease.

Still more complicated models of inheritance appear to be operating in disorders such as common variable immune deficiency and IgA deficiency (see Chapter 28) or in atopic disease. In these disorders one can observe a clearly increased incidence within families; however, an obvious Mendelian pattern of inheritance is absent. A genetic contribution to such diseases is suspected when there is greater concordance of the disease in monozygotic (identical) twins as compared to dizygotic (fraternal) twins, and when there is an increased risk for the disease in relatives of affected individuals as compared to the population at large. The risk of a second affected person in a family is greater the closer the blood relationship with the proband. Such complex inheritance patterns, well described in asthma and insulin-dependent diabetes mellitus, are the result of interactions between genes at different loci combined with unidentified but substantial environmental effects.

HOW TO IDENTIFY DISEASE GENE LOCI

ABNORMAL PROTEIN PRODUCTS

The first disease genes to be recognized as mutated in immune disorders were identified by defining abnormalities in their protein products. ADA was originally identified as a purine metabolic enzyme, and subsequently the absence of ADA activity was noted to occur in patients who lacked lymphocytes and had immune defects (see Chapter 14; Giblett et al., 1972). This approach was fruitful in ADA-deficient SCID because the enzyme encoded by the disease gene turned out to be a "housekeeping" gene, expressed in all normal cells. The general method of first identifying protein abnormalities in immune disorders and then documenting gene lesions has been less successful for disease genes that have restricted tissue expression or are active only in an early stage of differentiation of the target cell type. For these, positional cloning and identifying mutations in candidate genes have been essential.

CYTOGENETIC ABNORMALITIES

When clinical disorders are associated with abnormalities in the number or structure of an individual's chromosome complement, cytogenetic techniques can lead to the identification of disease genes. Metaphase chromosomes from dividing cells can be stained with Giemsa dye to reveal segmental banding patterns that uniquely characterize each human chromosome (Fig. 2.1). Cytogenetic analysis involves comparison of each chromosome to the standard karyotype idiogram, as illustrated for the X chromosome in Figure 2.5, and can identify translocations and show deletions or duplications large enough to be visible under the microscope (>2 to 5 Mb, depending on location). Hybridization of labeled DNA probes to denatured chromosomes, known as fluorescent in situ hybridization (FISH; Plate 2.I), can pinpoint much smaller regions of the genome to indicate the chromosomal location of a disease-associated microdeletion, duplication, or rearrangement. Comparative genome hybridization (CGH) is a powerful newer technique that reveals much smaller, cytogenetically invisible deletions or duplications. In CGH, the patient's DNA, labeled with a fluorescent dye that emits at a "green" wavelength, is mixed in equal proportions with a standard DNA labeled with a dye that emits in the "red" spectrum. The mixture is then denatured and hybridized to an array of hundreds of thousands of oligonucleotides corresponding to DNA sequences throughout the genome. If the number of copies of DNA in the patient and reference sam-

ples containing a particular nucleotide sequence are equal, the spot on the array corresponding to that sequence will fluoresce yellow, representing equal contributions of DNA labeled with green and red. If the patient has a deletion of a segment, the DNA in the mixture representing that segment will have less green and more red and the spot will fluoresce more toward the red; if the patient has a duplication of a segment, that spot will demonstrate excess fluoresce in the green part of the spectrum. The resolution of array CGH depends on the density and loci of the oligonucleotides on the array. While perfectly balanced translocations are not detected by CGH, this technique has become the preferred way, rather than karyotype analysis or FISH, to diagnose copy number variations such as the interstitial deletions in DiGeorge syndrome.

Aneuploidy, or abnormal chromosome number, is associated with immune defects. Trisomy 21, or Down syndrome, the most common genetic cause of human mental retardation, is accompanied by depressed in vitro immune responses and by an increased incidence of autoimmunity and infections, the leading cause of death in Down syndrome (Epstein, 2001; Ram and Chinen, 2011). In addition, some infants with trisomy 21 have sufficiently low T cell numbers to be flagged as abnormal in population-based newborn screening for SCID (Kwan et al, 2013).

At the subchromosomal level, *contiguous gene deletion syndromes* are collections of consistently observed clinical manifestations resulting from deletions spanning multiple neighboring genes. An example is the chromosome 11p13 deletion syndrome associated with Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (Haber, 2001; Schaffer et al, 2001). Larger deletions produce the complete phenotype, while smaller disruptions involving single genes within the region produce limited phenotypes, such as isolated aniridia.

Rare or unique cytogenetic abnormalities are occasionally found in the context of genetic disorders. Coexistence of a chromosomal translocation, duplication, or deletion with an abnormal phenotype in a patient is unlikely to be a coincidence; rather, the cytogenetic lesion may provide evidence for the genetic localization of a disease. One of the best examples is the contiguous gene deletion syndrome produced by interstitial deletion of chromosome Xp21 in male patients suffering from multiple disorders, including chronic granulomatous disease as well as Duchenne muscular dystrophy, retinitis pigmentosa, and McLeod hemolytic anemia (see Chapter 52; Schaffer et al, 2001).

DISEASE GENE LOCALIZATION BY LINKAGE MAPPING

DNA Polymorphisms

Each child inherits one of each pair of homologous chromosomes from one parent and the other chromosome of the homologous pair from the other parent. The parent of origin of each chromosome can be identified by tracing the inheritance of different polymorphic alleles. The most common polymorphisms are SNPs, which occur approximately every 1,000 base pairs and are therefore useful not only for linkage but also for association studies (see below).

Meiotic Crossing Over

In the absence of abnormal cytogenetic findings to point to the chromosomal locus for a genetic disorder, a disease gene may be mapped by *linkage analysis* in kindreds in which the disorder affects multiple individuals. Linkage analysis relies on the normal phenomenon of *meiotic recombination*, or crossing over during gametogenesis. During the first meiotic division, each pair of homologous chromosomes lines up randomly on the spindle and then separates in the course of the first reduction division of meiosis I. This independent assortment of chromosomes during meiosis I is responsible for randomly distributing one member of each pair of homologous chromosomes into each gamete. It is also in meiosis I that homologous segments of two chromatids form a pair of homologous chromosomes that interchange their genetic material by crossing over at points of contact, known as chiasmata (Fig. 2.6). On average, between two and four chiasmata develop between every pair of homologous chromosomes during each meiosis.

Suppose two polymorphic loci are situated at locus 1 and locus 2 on the same chromosome, as shown in Figure 2.6, and there are polymorphic alleles "A" and "a" at locus 1 and alleles "B" and "b" at locus 2. Also suppose that a parent is heterozygous at both loci (genotype Aa Bb), and, in addition, allele A at locus 1 happens to be on the same chromosome (same DNA molecule) as allele B at locus 2, while alleles a and b are both on the other chromosome. If no crossing over occurs in

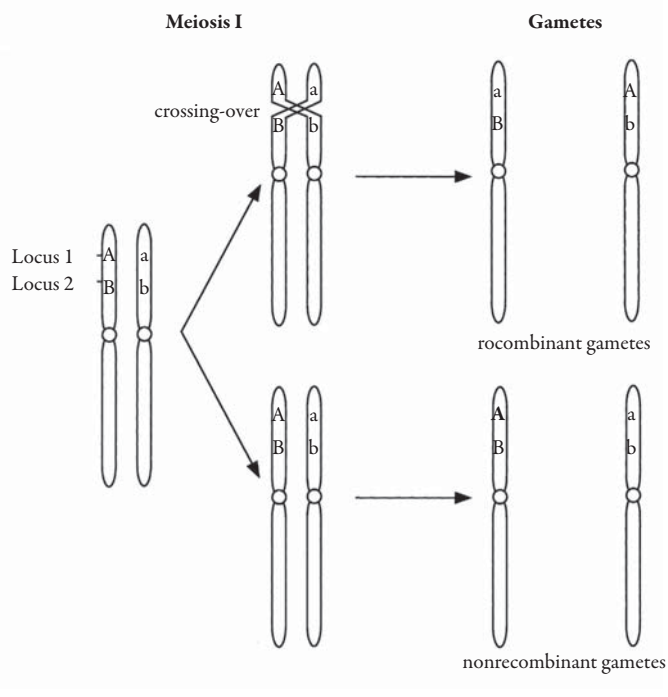

Figure 2.6 Diagram of meiotic crossing over involving two hypothetical loci, 1 and 2. Alleles at locus 1 are A and a; alleles at locus 2 are B and b. Recombinant gametes are products of a crossover event between locus 1 and locus 2.

the interval between locus 1 and locus 2 during meiosis, each gamete will receive either the chromosome containing alleles A and B or the one carrying alleles a and b (*nonrecombinant*). If, however, crossing over occurs between the two loci in the Aa/Bb individual, the resulting gametes will have a chromosome with a new (*recombinant*) combination of alleles, either alleles Ab or aB. From a knowledge of the genotypes of parents and their offspring, one can count the number of offspring resulting from a gamete carrying a crossover between locus 1 and locus 2 and determine the observed *recombination frequency* with which crossing-over events happen between the two loci during gametogenesis.

Because crossing over occurs approximately uniformly along a chromosome, the chance of a crossing-over event between two loci reflects how far apart they are on that chromosome. The further apart the loci are physically, the greater the chance that at least one crossover will occur between them; if they are very close to each other, the chance of crossing over will be small. If two loci are so far apart that at least one crossover will always occur in the chromosomal interval between locus 1 and 2 during gamete formation, then 50 percent of all the offspring will have the nonrecombinant and 50 percent the recombinant genotype. At the other extreme, when two loci are so close together that crossovers almost never occur, the observed recombination frequency will approach zero. Between these two extremes loci are *linked* on a chromosome. For such loci, the frequency of recombinant offspring will be between 0 percent and 50 percent, and one can correlate recombination frequency with the actual distance between two loci. When two loci have a recombination frequency less than 10 percent, recombination frequency translates directly into a theoretical *genetic distance*, in units called centiMorgans (cM), where 1 percent recombination is equal to 1 cM. This relationship does not hold when loci are loosely linked (recombination frequencies >10 to 20 percent) because of the chance that two independent crossovers, rather than just one, will occur between the two loci. A double crossover will not be detected as a recombination between the two loosely linked markers and, thus, the measured recombination frequency will always be less than the genetic distance in cM. In physical terms, the average recombination rate across the entire genome is 1.2 cM per megabase of DNA, which means that 1 cM of genetic distance holds around 830,000 base pairs of DNA (Kong et al., 2002).

Model-Based Linkage Analysis

Linkage analysis is used to map genes responsible for diseases that are inherited in a classical Mendelian pattern (Borecki and Suarez, 2001). Affected and unaffected members of families in which the disease is being inherited are studied by determining their genotypes at a large number of polymorphic genetic marker loci whose positions are known along each chromosome. Linkage analysis depends on looking in families for co-inheritance of a disease allele and alleles at polymorphic loci located in the chromosomal region near the disease gene. Recombination events between the disease locus and all of the genetic markers are tabulated. If the inheritance pattern is known by inspection of the pedigree (model-based analysis), one can score each affected and unaffected individual as either showing or not showing a crossover between the disease locus and each marker locus tested to determine the recombination frequency. Most markers will show a 50 percent recombination frequency because they are not linked to the disease locus, indeed not even on the same chromosome as the disease locus. If a marker seems to show less than a 50 percent frequency of offspring carrying chromosomes with a recombination between the marker locus and the disease locus, this marker may be linked to the disease locus. Model-based linkage works best when one or a few loci of reasonably high penetrance are responsible for a disease and, therefore, demonstrate a Mendelian inheritance pattern in families.

The statistical method used to measure the recombination frequency between genetic loci is called the maximum logarithm-of-odds (*LOD*) score method, and its features are summarized in Table 2.1. The result of a LOD score analysis consists of two parts. The first part, called θ_{max}, is the best estimate (in a statistical sense) of the recombination frequency between the disease locus and a polymorphic marker locus in a set of families. The value of θ_{max} is, therefore, a measure of genetic distance between two loci. The second parameter, Z_{max}, is a measure of how good that estimate of θ_{max} actually is. When Z_{max} is greater than 1.5, linkage is strongly suggested. If Z_{max} is larger than 3, the likelihood that the loci are linked is a thousand times (10^3) greater than the likelihood that the linkage data are purely the result of chance. Thus, LOD scores with Z_{max} of 3 or greater are taken as nearly definitive proof that two loci are linked.

LOD score analysis will demonstrate which polymorphic loci of known location are linked to the disease by finding the smallest value of θ_{max} with the largest Z_{max}, preferably 3 or greater. Linkage of the disease gene to a marker of known location on a chromosome thereby places the disease gene in the same general location as the marker on that chromosome.

ASSOCIATION STUDIES

In contrast to linkage analysis, association studies are usually done in populations, not families (Borecki and Suarez, 2001).

Table 2.1 **CHARACTERISTICS OF THE LOD SCORE**

1. The LOD score is a measure of the degree of linkage between two genetic markers.
2. The LOD score information comes in two parts: θ**, the recombination fraction** ***z*****, the logarithm of the odds that the markers are linked rather than unlinked**
3. θ **measures how frequently recombination occurs between two genetic markers. It is a statistical average derived from observing how often a recombination is seen in actual families.** ***The smaller*** θ ***is, the closer two markers are to each other.***
4. z is a logarithmic measure of how good the estimate of θ **really is. Every integer increase in z is a 10-fold improvement in certainty that** θ **"really" is what it has been measured to be.** ***The higher the z, the more significant is the measurement of*** θ***.***

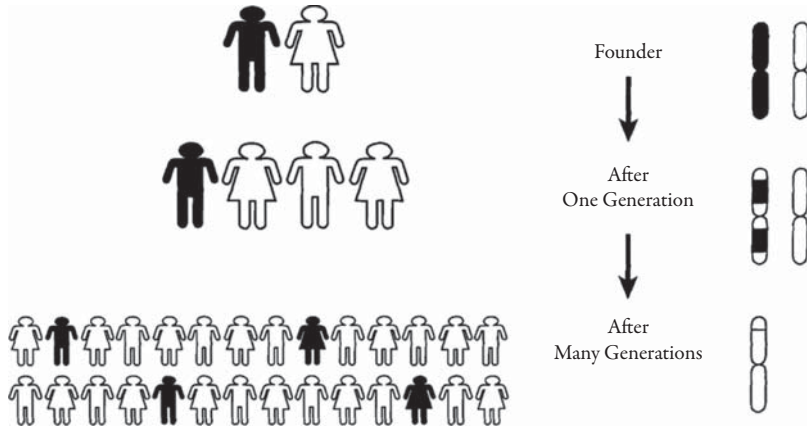

Figure 2.7 Linkage by descent in a hypothetical population in which a disease mutation can be traced to a founder. Marker alleles very close to the disease gene are unlikely to be separated by crossing over and constitute a disease-associated haplotype, which is preserved over many generations. (Kindly provided by Dennis Drayna.)

Association studies are particularly useful for common diseases with complex inheritance, as opposed to rarer diseases with Mendelian inheritance. In diseases with complex inheritance, the genetic contributions to a disease are subtle and involve alleles at many different loci, as well as environmental influences, that increase disease susceptibility. As a result, we see an increase in disease prevalence in close relatives compared to the general population because relatives tend to share more of the disease-susceptibility alleles than do unrelated population controls. Another characteristic of diseases with complex inheritance is that when one identical (monozygotic) twin has the disease, the other twin, who shares all of the disease susceptibility alleles with the affected twin, is more likely to develop the disease than would a dizygotic twin who shares only half the alleles. In diseases with complex inheritance, a Mendelian inheritance pattern is absent and standard linkage analysis cannot be applied. Instead, association studies can be used to find the genetic variants responsible for increasing disease susceptibility.

Suppose a disease-susceptibility allele arose many generations ago (Fig. 2.7), in a region of a chromosome with a particular haplotype defined by a particular set of alleles at nearby loci (Todd, 2001). An association between the disease-susceptibility allele and this haplotype is likely to be preserved through many generations because the loci containing the alleles that define the haplotype are so close to the disease locus that they are unlikely to recombine during the meioses that occurred as the disease gene was passed down through the generations; thus, the disease and haplotype will be in linkage disequilibrium, which means that the haplotype on which the disease allele originated will be found with increased frequency among affected individuals as compared to the population in general. Such increased frequency can be assessed using standard epidemiological tools such as case-control, cross-sectional, or longitudinal cohort studies.

In cross-sectional or cohort studies, in which all the affected individuals in a population are ascertained, an under- or over-representation of a genetic variant (an allele, a single-locus genotype, or a haplotype involving multiple loci) among affected individuals is measured using the *relative risk ratio* (RR ratio) in a two-by-two table (Table 2.2). The RR ratio is calculated as

$$\frac{\frac{a}{(a+b)}}{\frac{c}{(c+d)}}$$

i.e., RR is the *fraction* of individuals with a given genotype who have the disease divided by the *fraction* of individuals without that genotype who have the disease. A RR ratio of more than 1 indicates an association between the genotype and the disease in the population, while a ratio less than 1 suggests the genotype is protective. The significance of any deviation from 1 must of course be assessed by an appropriate statistical test.

In case-control studies, the relative risk has no meaning because the number of case and controls are chosen arbitrarily, independent of the prevalence of the condition in the population. For case-control studies, the *odds ratio* (OR) is calculated instead from a two-by-two table. The OR is the *odds* that an individual with a particular genotype has the disease versus the *odds* that an individual without the genotype has the disease:

Table 2.2 **RELATIVE RISK RATIO ANALYSIS**

The relative risk (RR) ratio describes the risk of having a disease with versus without a given genetic determinant:

	DISEASE PRESENT	DISEASE ABSENT
Haplotype present	**a**	**B**
Haplotype absent	**c**	**D**

RR ratio = [a/(a + b)]/[c/(c + d)].

$$\frac{\frac{a}{(b)}}{\frac{c}{(d)}} = ad/bc$$

Note that when the disease is rare (i.e., a<b and c<<d), the RR ≈ OR.

Association studies can be powerful tools for identifying alleles that appear to increase or decrease susceptibility to various diseases. Suppose, however, we do not know the relevant variants and genes for which we wish to test for association and want to assess association between a disease and *every* genetic variant throughout the genome. This approach, known as a genome-wide association study (GWAS), has been heavily exploited over the past 10 years, due primarily to the identification of many millions of variants resulting from the haplotype mapping (HapMap) project. This project, the second major effort of the Human Genome Project to be undertaken once the first sequence of a human genome was completed, revealed $\sim 8 \times 10^6$ alleles as of 2010. The alleles discovered through the HapMap project have been used to define haplotypes that are in linkage disequilibrium (LD blocks). Finding an association with any of the alleles within an LD block means it is likely that some allele(s) within the LD block, either known or unknown, are responsible for the association.

Association studies must be interpreted with care (Nussbaum, 2013). First, poor study design or inadequate numbers of cases and controls can lead to false-positive or false-negative results. Second, even when a study has been done properly and with appropriate quality-control standards, an association by itself does not prove a causal relationship between the variant alleles and the disease phenotype. All alleles in linkage disequilibrium with a variant found to be associated with a disease will also show an association without being directly, causally related, although documentation of linkage of a risk factor to all such alleles (a risk-associated haplotype) would provide important information. For example, the iron-overload disease hemochromatosis and certain alleles at the HLA-A locus are closely associated, but the HLA-A alleles themselves do not actually cause hemochromatosis. Instead, there is significant linkage disequilibrium between particular HLA-A alleles and mutations at the closely linked *HFE* gene that is actually responsible for the disease (Gandon et al., 1996).

The variants in the HapMap project are for the most part polymorphic variants, meaning they are fairly common, occurring in more than 1 percent of alleles in at least one, and usually most, human populations. Thus, using the HapMap variants to do genome-wide association assumes that complex diseases will have their major genetic contributions from relatively common alleles, an assumption referred to as the "common disease—common variant" hypothesis. This hypothesis has now been tested in hundreds of common diseases with complex inheritance, with mixed results. In some cases, such as in macular degeneration or Crohn's disease, variants have been found in genes that are functionally related to the disease process and are responsible for a substantial fraction of the genetic susceptibility to these diseases. In most cases, however, such as coronary artery disease or type 2 diabetes mellitus, the genetic contribution of common alleles to complex diseases is very modest, with relative risks or odds ratios ranging from just over 1 up to 2. Furthermore, the fraction of the total genetic susceptibility conferred by these alleles is quite small.

POSITIONAL CLONING

The availability of the entire sequence of the human genome has revolutionized disease gene identification once linkage or association to a specific genetic region has been established. The entire complement of genes in any region of human DNA is now readily ascertained by searching public databases containing the complete human genome sequence deposited by the Human Genome Project (Baxevanis, 2001), and all the genes located in this region can be evaluated as candidates for alterations responsible for the disease phenotype. In addition to genomic sequences, mRNA sequences from all the expressed genes in a wide variety of tissues are also available (Riggins and Strausberg, 2001) (Table 2.3).

SCREENING OF CANDIDATE GENES

Once the set of candidate genes in the critical region of linkage or association is obtained through mining genomic DNA and mRNA sequence databases, candidates can be evaluated to determine which one is likely to be the disease gene. Northern blots or reverse transcriptase PCR (rt-PCR) help to determine the tissue expression pattern and to test for alterations in mRNA size or quantity in patients affected with the disease. Ultimately, sequence comparison must reveal mutations in the alleles of affected patients that are not present in the alleles of healthy controls, and studies of mutant gene function may be required to prove that the mutations are deleterious.

The changes in DNA that constitute deleterious mutations in genes are extremely heterogeneous. In some cases, deletion of part or all of the DNA encoding the gene has occurred, resulting in production of no mRNA or a defective mRNA transcript lacking important portions of the gene sequence. Small insertions or deletions of a few base pairs may shift the triplet reading frame and create mRNA carrying incorrect codons and, often, a premature termination downstream of the small insertion or deletion. In other cases, single point mutations can interfere with normal RNA processing, such as splicing of exons, resulting in mRNAs that either retain noncoding intron sequences in the transcript or lack all or part of a coding exon. Some point mutations within coding regions change an amino acid codon into a stop codon (*nonsense mutation*), thereby inserting a premature termination into the mRNA. Still other point mutations may alter a codon from that of one amino acid to another (*missense mutation*). Regardless of which of the above mutation mechanisms has occurred, mutant mRNAs are frequently poorly transcribed or highly unstable; cells carrying such mutations may appear to lack mRNA entirely rather than producing abnormal mRNA.

Mutations that occur over and over again on independent genetic backgrounds are known as *hot-spot mutations*. The most frequent is the alteration of the dinucleotide cytosine-guanine (CG) to thymidine-guanine (TG) either on the coding or anticoding strand; this particular mutation occurs approximately 11 times more frequently than any other single-base mutation in the genome. It is believed that the cytosine within a CG dinucleotide is at high risk for undergoing C-to-T transition because such cytosines are frequently covalently modified by methylation at the 5 position of the pyrimidine ring. Spontaneous deamination of a methylcytosine results in a thymidine, which may not be repaired promptly by the cell because it is not recognized as an abnormal base within DNA. Hypotheses for the mechanisms of these mutations and data on their frequency, as well as a lexicon of mutations observed in human genetic disease, were first compiled by Cooper and Krawczak (1995).

The impact of any particular mutation depends on the effect of that mutation on the transcription of the gene into mRNA, the translation of the mRNA into a protein product, and the post-translational processing and stability of any mutant protein that is made. Moreover, the functional consequences of mutations also depend on the physiological and environmental context of the cell, tissue, and individual carrying the mutation. In many diseases, a myriad of different mutations can lead to the same final common pathway: the loss of a functional gene product. In the inherited immune disorders as a rule, there are dozens or hundreds of different mutations that can disrupt function of the gene product and bring about the disease. However, in certain types of genetic disease, a particular mutation may affect the function of a protein in a subtle and unique way and thereby cause a highly specific phenotype. For example, only a few, highly specific missense mutations in the β-globin gene result in a protein with the physicochemical properties that cause the hemoglobin to form crystals under low oxygen conditions, as seen in sickle cell anemia. Thus, the mutation repertoire for sickle cell disease is severely restricted. Similarly, a restricted type of mutation in the Wiskott-Aldrich protein gene causes neutropenia rather than the typical phenotype of thrombocytopenia (see Chapter 43).

By means of positional cloning, human disease genes have been identified solely on the basis of their genomic location with little or no knowledge of the nature of the pathophysiological process responsible for the disease. These mutations overwhelmingly affect the coding portions of genes or occur at highly conserved regions of introns immediately adjacent to exons. The coding portions of genes, however, constitute only 4 to 5 percent of the sequence of a gene, and thus constitute a mere 1 to 2 percent of the genome. With detailed information on the sequence of the human genome, we are discovering further alterations in noncoding regions that contribute to disease. In such cases, linkage mapping or association studies are only the beginning of the study of pathogenesis of genetic disease and correlations between genotype and phenotype. Such variants may be in 5' or 3' regulatory sequences or introns and may alter expression or function only to a limited degree. Variants affecting levels of gene expression are not always adjoining the coding sequence; examples are known of locus control regions, enhancers, and other sequences altering expression that are 10 to 100 or more kilobases distant from the coding sequences they influence. There are also small interfering RNA (siRNA) molecules encoded throughout the genome that recognize and target specific transcripts for degradation and an increasingly appreciated array of epigenetic modifications of gene expression. Finding such mechanisms and proving they contribute to human disease is a major challenge to current and future genetics research.

After the completion of the first human genome sequences in 2003, predictions of great improvements in technology

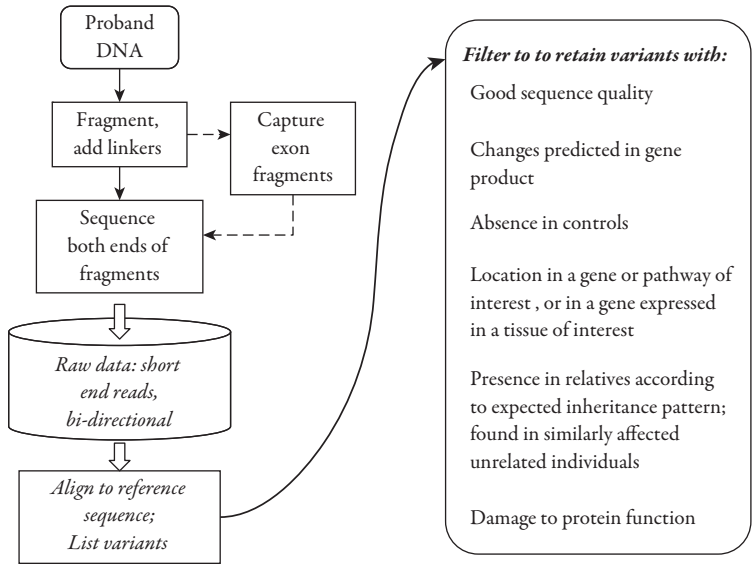

Figure 2.8 Schema for whole-exome sequencing. Input genomic DNA is fragmented, linkers are attached that carry signatures similar to barcodes for tracking, and hybridization to a fixed set of exome reference oligonucleotides is carried out with the remaining DNA washed away. After exon capture, the DNA is submitted to high-throughput sequencing, and short sequence reads are assembled and mapped to the human genome. Variants from the reference genome can then be analyzed.

with corresponding reduction in cost were made, including that a full genome sequence for any individual would eventually be obtainable for merely $1,000. The era of deep sequencing has arrived even ahead of predictions, with many reports of disease-gene identification through sequencing all of the coding DNA (whole exome) or even the whole genome of affected individuals (Bamshad et al., 2011; Bick and Dimmock, 2011; Cirulli and Goldstein, 2011; Teer and Mullikin, 2010). Methodologies are rapidly evolving, but Figure 2.8 shows how whole-exome or whole-genome sequencing and analysis are done, starting with fragmentation of genomic DNA, selective capture of sequences containing exons and immediate surrounding DNA (for exome sequencing), and generation of short "reads" of sequence, each around 100 bp, by high-throughput methodology. Next, the short sequences are aligned to the reference human genome, removing nonmatching sequences as presumed artifacts. Variants that do not match the reference sequence are listed, and this list can be subjected to further filtering, as shown in Figure 2.8, to remove nonsynonymous changes and common population variants from consideration, such as those in the dbSNP database. Further prioritization is based on absence in control individuals, tissue expression or involvement in a particular pathway or network (if known), and hypothesized mode of inheritance. Generation of whole-genome sequencing may become more prevalent, and even routine, but efficient analysis still represents a major challenge.

ETHICAL ISSUES IN GENETIC TESTING

There are numerous ethical issues surrounding human genetics as scientific knowledge and medical technology come to grips with the four central tenets of medical ethics: *beneficence* (doing good for the patient), *nonmaleficence* (doing no harm), *autonomy* (safeguarding the individual's rights to control his or her medical care and be free of coercion), and *equity* (ensuring that all individuals are treated equally and fairly). A full discussion of these issues is beyond the scope of this chapter, but a few examples arising in immunodeficiency diseases serve to illustrate some of these aspects of medical ethics and genetics.

As more and more genes are identified and found to be involved in human genetic disease, our ability to diagnose them will continue to increase dramatically. An inescapable consequence of this rapidly accelerating knowledge is the time lag between acquiring the ability to diagnose genetic disease and developing effective interventions to prevent diseases or treat them once they are diagnosed. For the immunodeficiency diseases, recent advances in therapy, from new antibiotics to immunoglobulin replacement to bone marrow transplantation and gene therapy, have placed clinical immunologists at the forefront of developing the tools to close the gap between diagnosis and treatment. How such tools are used, and whether they are readily available to all who need them, is clearly an issue of fairness in the application of scientific knowledge.

The ability to perform population-based newborn screening for SCID and other conditions with low T-lymphocyte levels has raised the possibility of making preinfectious diagnosis, but at this writing not all states in the United States have committed to adding this testing to their newborn screening panels, nor is the optimal treatment for newborns with SCID established (see Chapters 9, 59, and 60).

An additional aspect of the growth of genetic knowledge is in the area of disease predisposition. Increasingly, whole-exome sequencing and whole-genome sequencing allow for identification of individuals and their relatives who are at risk for disease that may have an onset much later in life than when the testing is being done. Testing healthy individuals for disease predispo-

sitions encoded in their genomes has obvious benefits in identifying people at risk who may be able to modify their lifestyles and/or begin appropriate preventive therapy, but it also carries the risk of serious adverse psychological damage and stigmatization in society. Discrimination in insurance and employment was also a serious issue, but the passage of laws such as the Genetic Information Nondiscrimination Act (GINA) in the United States and similar laws in other countries has reduced, but not eliminated, these concerns. Ethical problems with genetic testing are especially acute when the testing identifies a predisposition for a disorder for which current medical technology provides little or no treatment when clinical disease actually develops. The issue of beneficence becomes central in this setting. Is knowing that one carries such a gene doing more good than harm, or more harm than good?

The ethics of genetic testing is also an issue when testing children for the carrier state of diseases, such as X-linked immunodeficiencies, that pose no threat to a female child's own health but identify a substantial risk for having affected offspring. The autonomy of children, including their right to make decisions for themselves about learning about their own genetic constitution, must be balanced against the desire of parents to obtain such information and transmit it to their children in the manner they believe best. As the amount of available genetic information increases, there is an increasingly greater need to educate health-care providers, patients, their families, and society at large to make informed decisions about using genetic information wisely and for maximum benefit.

3.

MAMMALIAN HEMATOPOIETIC DEVELOPMENT AND FUNCTION

Gerald J. Spangrude

The origins of the mammalian immune response are found in hematopoiesis. The primary immunodeficiency diseases discussed in this book are mediated by mutations in genes that function during the course of hematopoietic development at the level of the progenitors for specific cell lineages (severe combined immunodeficiencies), or at the level of the expression of signaling molecules that promote differentiation (major histocompatibility complex class II deficiency), or at the level of the functional potential of mature effector cells (leukocyte adhesion deficiency, chronic granulomatous disease). The common theme underlying the primary immunodeficiency diseases is the origin of the cellular components of specific and nonspecific immunity, the hematopoietic stem cell (HSC). While specific mutations in particular genes can result in defective function of highly specialized mature cell populations, the resulting immunodeficiencies are distinguished by the biochemical result of the disrupting mutation manifested at a stage of development much later than the HSC. This presents a unique opportunity in the design of HSC replacement therapies for some of these diseases.

Bone marrow transplantation (today mainly in the form of mobilized HSCs collected from the blood) is one avenue of HSC replacement therapy for a number of immunodeficiencies, as discussed in Chapter 60. Complications due to graft-versus-host disease often mean that in the absence of a related, genetically matched donor, the risks inherent in allotransplantation can outweigh the potential benefits. An exception to this generalization is severe combined immunodeficiency (SCID), which is 100 percent fatal without marrow transplantation (excluding adenosine deaminase and purine nucleoside phosphorylase deficiencies, which can be treated by enzyme replacement therapy). Transplantation of gene-corrected autologous cells can overcome the allotransplantation issue, as demonstrated by gene therapy trials for a variety of immunodeficiencies discussed in Chapter 61. While a number of immunodeficiencies can be corrected by gene therapy, it is important to recognize that inserting and inducing expression of an exogenous gene in order to correct a developmental defect may be accompanied by an equally disruptive alteration in hematopoietic function as a result of expressing the corrected gene in cell lineages where it is not normally found. Further, insertional mutagenesis is a valid concern, as shown by the recent experience in gene therapy for X-linked SCID. These obstacles to effective gene therapy for primary immunodeficiency diseases are the focus of current research in vector design, regulation of gene expression, and targeted insertion of genetic elements into the genome.

This chapter will provide an overview of our current understanding of hematopoiesis, specifically focusing on the transplantable HSC, to provide a basis for considering the common origin of primary immunodeficiency diseases and the prospects for bone marrow transplantation and gene therapy as therapeutic interventions.

OVERVIEW OF HEMATOPOIETIC STEM CELLS

Because of the relatively short lifespan of most blood cells, a high rate of production is necessary throughout life to maintain normal numbers. In adult mammals, the major source of blood is the bone marrow. It is here that the HSC is found, represented at a frequency of less than 1 cell per 10^4 marrow cells (Neben et al., 1993).

The HSC is now known to represent a heterogeneous mixture of cells with various degrees of functional activity in transplant and culture assays (Kiel et al., 2005). The identification and physical isolation of discrete stages of hematopoietic development has provided insight into the hierarchical nature of the hematopoietic lineages and has generated controversy regarding the developmental potential of cells at specific stages of development (Ceredig et al., 2009). Fundamentally, the HSC compartment can be considered as comprising two components, a dormant population and a proliferating population (Fig. 3.1). Various lines of experimental evidence indicate that these primitive HSCs enter the cell cycle only infrequently (Bradford et al., 1997, Cheshier et al., 1999), and they are generally thought of as being metabolically quiescent (Hodgson and Bradley, 1984). These conclusions were based on in vivo labeling studies using bromodeoxyuridine (BrdU), a nucleoside analog that is incorporated into DNA during cell division and can subsequently be detected by immunostaining. Cells that retain the BrdU label for a prolonged period of time after a pulse labeling period are termed "label-retaining cells," and their presence indicates cell cycle dormancy. However, truly dormant cells would not be expected to incorporate the BrdU label unless the pulse labeling time is extended to encompass the rare cell divisions that occur during the dormant state. A recent study has demonstrated that BrdU actually induces proliferation of HSC, likely by inducing a mild genotoxic injury sufficient to promote DNA repair (Wilson et al., 2008). Using a unique approach of inducible fluorescent labeling of histone proteins, Wilson et al. were able to characterize the dormant and activated subsets of HSC in the absence of proliferation induced by the labeling method. These experiments demonstrate that a two-way interconversion between the dormant and activated states occurs depending upon hematopoietic demand (Fig. 3.1). Cells making up the dormant subset replicate roughly once every 145 days in the mouse, suggesting that these cells do not contribute to ongoing hematopoiesis. However, this small subset of cells, estimated to be about 600 cells per mouse or about 1 per 2×10^4 bone marrow cells, includes the most potent cells for long-term reconstitution following transplantation into irradiated recipients. The HSC compartment is maintained to ensure lifelong blood production through a process known as *self-renewal*, defined as cell division cycles to replace HSCs that are lost due to differentiation into the multipotent progenitor compartment (Fig. 3.1). The pool of expanding multipotent progenitors retains developmental potential for all hematopoietic lineages but has largely lost the ability to self-renew. After an undefined number of cell divisions, these cells differentiate as various types of mature cells, depending on the cytokines available in the specific areas of the marrow where they mature. Recent studies utilizing prospective isolation of progenitor cell populations have demonstrated that one of the initial lineage specification events in normal hematopoiesis is the separation of the megakaryocyte and erythroid lineages from the myeloid and lymphoid lineages (Adolfsson et al., 2005). However, whether this segregation of lineages is absolute remains controversial (Forsberg et al., 2006), and the subsequent cellular intermediates in the pathways of differentiation that lead to the mature blood cells continue to be debated (Ceredig et al., 2009).

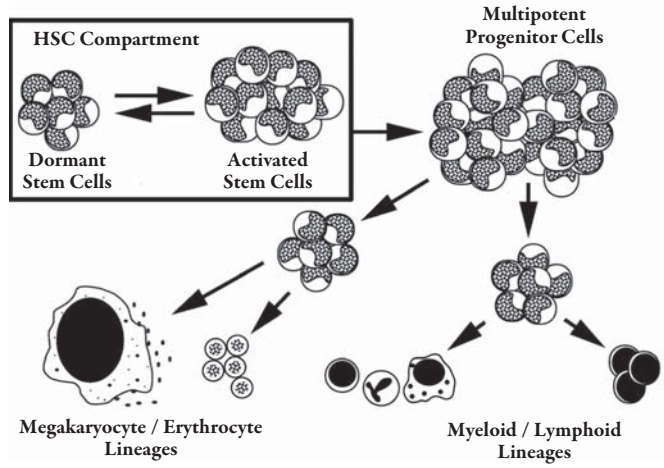

Figure 3.1 A model of the hierarchy of primitive hematopoietic stem cells (HSCs) and progenitor cells. Dormant stem cells are representative of the pluripotent HSCs, with both self-renewing potential and the ability to differentiate as any type of blood cell. These HSCs occasionally enter the cell cycle and replicate, during which time they are considered activated. Activated stem cells can return to dormancy (Wilson et al., 2008), effectively self-renewing the dormant pool, or may continue to proliferate and differentiate into the expanding multipotent progenitor cell pool, with a concomitant loss of the potential to self-renew. The expanding multipotent pool can differentiate as lymphoid or myeloerythroid progeny, and although the intermediate steps in this process are controversial (Ceredig et al., 2009) the process includes an early segregation of the megakaryocyte and erythroid lineages from the remaining lineages. Commitment to the lymphoid or myeloerythroid lineages results in further expansion of these progenitors during differentiation, and subsequent restriction to specific lineages results in precursor cells with limited proliferative potential.

EMBRYOLOGY OF HEMATOPOIESIS

Blood cells develop in essentially the same manner in embryos of all mammals. Embryonic mammalian hematopoiesis can be divided into three distinct phases: mesoblastic, hepatic, and myeloid (Wintrobe, 1967). The *mesoblastic phase* (also known as the *vitelline phase* because of the predominance of morphologically recognizable hematopoietic cells in the yolk sac) persists for about 10 weeks in human embryos (about 12 days in the mouse). During this time, the predominant blood cell type observed morphologically is the primitive (nucleated) erythrocyte in the yolk sac, which can be detected as early as 18 days of gestation in humans. During the *hepatic period* (beginning at 6 to 8 gestational weeks in the human or 10 to 12 days in the mouse), the fetal liver assumes the major responsibility for blood formation and continues to be hematopoietic until shortly before birth. In humans, a transient period of splenic hematopoiesis precedes the *myeloid phase*, which initiates in marrow cavities at 10 to 12 weeks of gestation (15 to 16 days in the mouse), and by 20 weeks the majority of blood formation in human embryos occurs in the bone marrow. While splenic hematopoiesis is only a transient stage during human development, the spleen remains

hematopoietically active throughout the adult life of the mouse. Despite this, the bone marrow remains the primary site of blood formation, as it contains at least 10-fold higher levels of assayable progenitors compared to the spleen.

As discussed above, the primary anatomical site where hematopoiesis is first observed in mammalian embryos is extra-embryonic, in the numerous blood islands of the yolk sac. The liver primordium is subsequently seeded by migrating HSCs and rapidly becomes the predominant site of embryonic blood production. Recent experimental evidence suggests that a separate origin of hematopoiesis is also present intra-embryonically in mammals, as is the case in lower vertebrates. Intra-embryonic hematopoiesis in mammals is localized in a specialized splanchnopleural region of mesoderm that includes the dorsal aorta and the mesonephros and genital ridge (AGM region, Fig. 3.2; Muller et al., 1994). Although morphologically recognizable hematopoietic elements are present only in the yolk sac during early embryogenesis, progenitor assays can detect hematopoietic activity in the AGM region prior to the appearance of progenitors in the fetal liver (Medvinsky and Dzierzak, 1996). It is currently unclear whether the fetal liver is colonized by HSCs deriving from the yolk sac, the AGM, or both. One series of experiments demonstrated lymphoid and multipotent myeloid generative activity in the region of the dorsal aorta prior to establishment of circulation in the mouse embryo (Cumano et al., 1996). Other studies question the presence of HSC function within the embryo prior to the onset of circulation, when yolk sac-derived cells are rapidly distributed within the embryo (Ghiaur et al., 2008; Lux et al., 2008). However, the biomechanical forces associated with blood flow have also been shown to promote hematopoiesis (Adamo et al., 2009; North et al., 2009), leading to a caveat in the interpretation of studies that rely on interruption of circulation to prevent the distribution of yolk sac-derived blood progenitors (Lux et al., 2008; Rhodes et al., 2008). A recent study utilized inducible labeling in vivo to demonstrate that the yolk sac contributes to the adult HSC pool, without ruling out the AGM as an additional source of HSCs (Samokhvalov et al., 2007). Finally, the endothelial cell origin of HSCs has been demonstrated in a number of studies (Chen et al., 2009; Eilken et al., 2009; Lancrin et al., 2009; Rhodes et al., 2008; Zovein et al., 2008). Therefore, it seems clear that mammalian hematopoiesis initiates within the developing embryo as well as in the yolk sac and placenta. The relative contributions of each of these sites of HSC generation to the adult HSC pool remains to be definitively determined.

Transplantation of yolk sac cells into irradiated adult animals does not result in engraftment. However, HSC activity has been demonstrated in early (day 10) mouse yolk sac after transplantation into neonatal recipient animals, possibly because of an obligate localization of these cells in the hematopoietic liver for further maturation into HSCs prior to marrow colonization (Yoder and Hiatt, 1997). It is likely that the yolk sac promotes primarily primitive hematopoiesis (nucleated red cells that transiently

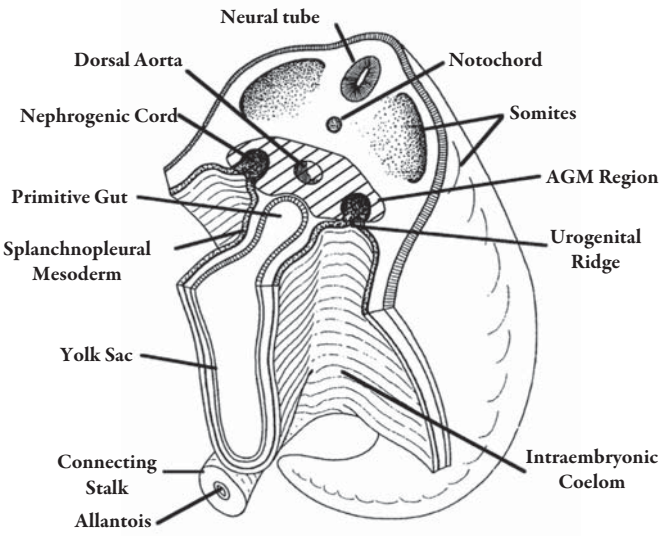

Figure 3.2 Morphology of early mammalian embryogenesis and the origins of the blood-forming cells. The embryo depicted here is human and at the beginning of the fourth week of gestation, just prior to differentiation of the mesonephros and genital ridge from the nephrogenic cord. While morphologically distinct blood cells are already present in the blood islands (not depicted here) of the yolk sac, no blood production is evident in the body of the embryo. Surgical dissection of the AGM region (hatched area in the figure) followed by specific assays for hematopoietic function has demonstrated that primitive hematopoietic stem and progenitor cells are also present in the AGM, even though no morphologically identifiable blood cells can be detected. (Adapted from *Illustrated Human Embryology*, *Volume 1*: *Embryogenesis*, by Tuchmann-Duplessis et al. [translated by L. S. Hurley], 1975, figure 1, page 38. © 1971 by Masson and Company. Used with kind permission of Springer Science and Business Media.)

function during embryogenesis) while the embryonic sources of hematopoiesis are predominantly definitive (the stable, long-term source of hematopoiesis). However, after the onset of blood circulation both types of hematopoietic function are present in both anatomical locations during subsequent development.

The AGM and the yolk sac are both mesodermally derived. The primordial cells that initiate formation of the hematopoietic system migrate to the AGM and yolk sac from the caudal portion of the early primitive streak during gastrulation (Bloom, 1938; Huber et al., 2004). The proliferating cells of the blood islands differentiate along two distinct pathways: one to form the endothelial cell boundaries of the first blood vessels at the periphery of the blood islands, and the other to give rise to primitive blood cells in the center of the islands. Thus, the common mesenchymal ancestry of endothelium and blood cells can be traced to a relatively late period during their ontogeny. Within the mammalian embryo, clusters of hematopoietic cells are not observed in the AGM region but rather are seen intravascularly as clumps of cells attached to the aortic endothelium (Dzierzak and Medvinsky, 1995; Oberlin et al., 2002). In birds, the onset of intra-embryonic hematopoiesis is morphologically obvious, and for many years this was generally felt to be a fundamental difference between mammalian hematopoiesis and that of lower vertebrates.

BONE MARROW AND THE NICHE

Bone is a calcified extracellular matrix of collagen and glycosaminoglycans that is synthesized by osteoblasts—bone-forming cells. The medullary cavity of bone may be hematopoietically active and contain so-called red marrow, or it may be predominantly inactive and filled with fat cells (white marrow). During the process of aging in humans, the anatomical sites of medullary hematopoiesis are progressively limited, beginning at birth, when hematopoietic activity is distributed throughout the skeleton. By 18 years of age, most hematopoietically active marrow is found in central locations such as the pelvis, sternum, and ribs (Amos and Gordon, 1995). The medullary cavity and Haversian canals of bone, which house blood vessels, are lined with a membrane called the *endosteum*. Occasional osteoclasts, which destroy bone, are found in the walls of the medullary cavity and are associated with areas of bone resorption.

The endosteum and its associated osteoblasts are of particular interest because the most primitive HSCs for blood formation appear to be localized near the walls of the medullary cavity (Askenasy et al., 2002). The process of hematopoiesis depends on HSCs in an intimate association with nonhematopoietic tissue cells in the medullary cavity of bone and, in some rodents, in the spleen. These tissue cells are generally termed *stromal cells*, a generic term that may be applied to any of a wide variety of nonmobile cells. The matrix of the medullary cavity includes structural elements of the blood vascular system, nerve fibers, and a system of reticular cells and fibers. This matrix is established during embryogenesis before the initiation of hematopoiesis. Thus, it provides a specialized microenvironment that supports hematopoietic cells within the parenchyma.

The distinct functions of HSCs and the microenvironments that support them are clearly seen in two mutant mouse strains that were selected after mutations at the "dominant spotting" (W) and "steel" (Sl) loci on chromosomes 5 and 10, respectively (Shultz and Sidman, 1987). The products of these two loci interact to result in normal hematopoietic development and function; the Sl gene product is expressed by the microenvironment, while the W gene product is expressed by the hematopoietic cells (Witte, 1990).

The bone marrow microenvironment has several distinct functions with regard to hematopoiesis (Fig. 3.3). First, it must provide conditions to maintain pluripotent HSCs in a primitive state throughout an animal's lifetime, thus ensuring an adequate supply of the seeds of hematopoiesis. Second, it must provide appropriate inductive signals for primitive HSCs to direct regulated development of erythroid, myelomonocytic, and B-lymphoid lineages. The processes of maintenance and differentiation of HSCs must be balanced to sustain a regulated frequency of functionally mature blood cell populations without depleting the HSC pool. The role of regulating the maintenance and differentiation of HSCs is filled by the stromal-cell elements of the marrow microenvironment, although in the case of erythropoiesis the kidney is also intimately involved in an endocrine manner through the production of erythropoietin. In addition to producing cytokines, marrow stromal cells also mediate proliferation and differentiation of hematopoietic progenitors via direct cell–cell interactions, using both common and specialized cell adhesion molecules.

Over the past few years, the characteristics of the bone marrow niche critical for HSC maintenance have been defined experimentally. Two distinct niches in the marrow have been proposed, one associated with the vascular sinuses (Kiel et al., 2005) and the other associated with the

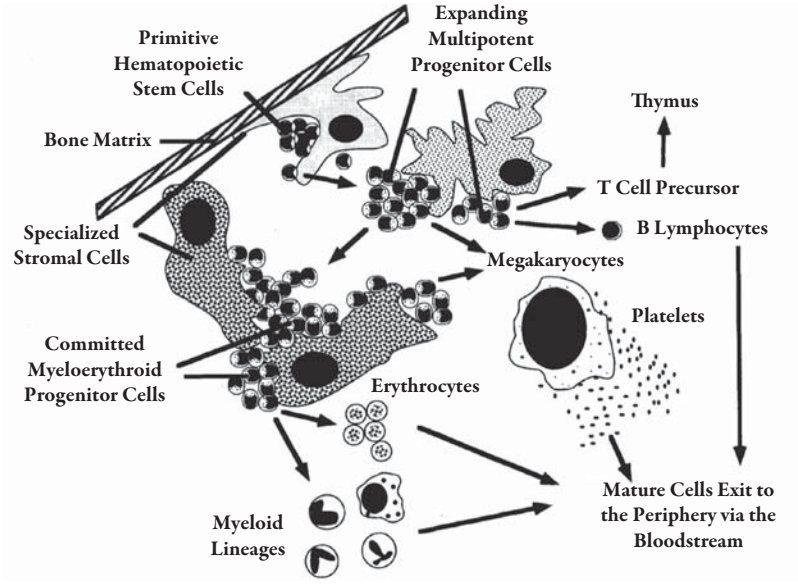

Figure 3.3 The bone marrow microenvironment includes a complex mixture of parenchymal cells that support maintenance and differentiation of hematopoietic cells by secretion of cytokines as well as via cell–cell interactions. The associations between developing hematopoietic cells and their supportive microenvironment are largely uncharacterized; this diagram is strictly a generalized representation of the notion that interactions with stromal cells are thought to regulate various stages of hematopoietic development in specific manners.

endosteum. Osteoblasts have been shown to be an integral part of the endosteal niche (Calvi et al., 2003; Zhang et al., 2003). Moreover, the frequency of HSCs seems to be dependent on the number of osteoblasts (Visnjic et al., 2004; Zhang et al., 2003). Parathyroid hormone was reported to increase hematopoiesis by inducing the synthesis of jagged 1, which serves as a ligand for notch signaling (Calvi et al., 2003). Calcium receptor expression by HSCs facilitates engraftment of transplanted HSCs in response to extracellular calcium concentration (Adams et al., 2006). Conversely, osteopontin serves as a negative regulator, with defective mice showing increased jagged 1 and angiopoietin 1 expression (Stier et al., 2005). Of particular interest to the field of primary immunodeficiencies, the ATM protein, defective in ataxia-telangiectasia, was recently reported to regulate the reconstitutive capacity of HSCs (Ito et al., 2004). Recent insights into the specific hematopoietic microenvironments with the bone marrow have also been provided by vital microscopy studies and by antibodies that detect HSCs and their stromal environments (Calvi et al., 2003; Chan et al., 2009; Kiel et al., 2005; Kohler et al., 2009; Xie et al., 2009; Zhang et al., 2003).

SPLEEN

Another example of the importance of HSC–stromal cell interactions in regulating hematopoietic growth is provided by the mouse spleen. In mice, hematopoietic activity is maintained in the spleen throughout adult life. Although both the bone marrow and spleen support erythropoiesis and granulopoiesis, the spleen is dominantly erythropoietic, whereas granulopoiesis exceeds erythropoiesis in the bone marrow. Implantation of bone fragments into irradiated spleens allows the two types of microenvironments to exist in juxtaposition. In such cases, individual colonies of hematopoietic cells that arise at the border of the two microenvironments are frequently granulocytic in the vicinity of the bone fragment and erythroid in the splenic area (Wolf and Trentin, 1968). Results from these experiments argue that microenvironmental differences can dictate the developmental pathways followed by individual multipotent cells.

Other examples of microenvironments that induce specialized hematopoietic growth include the B- and T-lymphocyte lineages, which develop predominantly in bone marrow and thymus, respectively. These observations are consistent with an "instructive" role for microenvironments in directing lineage commitment (Metcalf, 1998). An equally compelling case can be made for a stochastic model of hematopoietic differentiation (Enver et al., 1998), and it is likely that both mechanisms function in various lineages and stages of development.

HEMATOPOIESIS IN CULTURE

The establishment of long-term cultures of bone marrow stromal elements has provided further evidence that specialized stromal cells contribute to microenvironments that support hematopoiesis. In addition, culture systems have been developed that selectively support HSC maintenance with myeloid and erythroid development (Dexter and Lajtha, 1974), B-cell development (Whitlock and Witte, 1982), or T-cell development (Schmitt and Zuniga-Pflucker, 2002). These culture systems involve the establishment in vitro of specialized stromal cell monolayers or reaggregation of stromal cells and progenitors into a three-dimensional structure to mimic the organ culture of the intact thymus. Stromal cell monolayers may be heterogeneous, consisting of fibroblasts, endothelial cells, adipocytes, and mononuclear-derived macrophages and dendritic cells, or they may be established in vitro as cell lines of clonal origin that have been screened and selected to optimally support hematopoietic development.

Early observations of the myeloid cultures developed by Dexter et al. indicated that adipocytes were most closely associated with hematopoiesis in vitro. The subsequent development of stromal cell lines (Hunt et al., 1987; Kodama et al., 1992) has strengthened these findings in that the stromal cell lines that support in vitro growth of early lymphoid and myeloid cells and maintain spleen colony-forming cells are adipocyte-like and resemble adventitial reticular cells. These latter cells are fibroblastoid cells that form a cellular network, or reticulum, within the bone marrow cavity. They accumulate neutral lipid deposits under certain conditions and are secretory, producing collagen and other proteins (Hunt et al., 1987). A recent study characterized cell populations within developing fetal bone and found that cells co-expressing α_v (an adhesion molecule), CD105 (an endothelial cell marker), and CD90 (a marker useful for identifying HSCs) in the absence of a series of other antigens were capable of establishing hematopoietic niches when implanted under the kidney capsule of adult animals (Chan et al., 2009). This and other model systems promise to provide clues that will clarify the roles of cell–cell interactions and of soluble growth factors in regulating hematopoiesis in general and the development of the immune system in particular.

ISOLATING MOUSE HEMATOPOIETIC STEM CELLS

Because of the important biological and medical implications inherent in the concept of a rare population of primitive cells being responsible for continuous replenishment of all circulating blood cells, efforts to identify and isolate HSCs date back to the first quantitative assays of hematopoietic development (reviewed in Spangrude, 1989). After description of the in vivo spleen colony-forming assay (Till and McCulloch, 1961), development of an in vitro colony assay followed a few years later (Bradley and Metcalf, 1966). Although early efforts to enrich primitive hematopoietic cells relied on these assays, the limitations of the assays in reflecting the self-renewal potential of HSC were recognized early on. Velocity and equilibrium centrifugation studies demonstrated that bone marrow cells with an inherent capacity to produce splenic colonies could be separated from those capable of in vitro colony formation (Worton et al., 1969a, 1969b) and that self-renewal potential, as indicated by the content of splenic colony-forming units

(CFU-S) within individual spleen colonies, could be separated from the bulk of the CFU-S in normal bone marrow (Worton et al., 1969a). These observations indicated that CFU-S activity might not directly correlate with self-renewal potential, a problem that has not been conclusively resolved. However, the early separation studies demonstrated that cell-separation methods could indeed be applied to dissect the hierarchy of primitive hematopoietic cells.

Mouse HSCs can be enriched from adult bone marrow by use of a number of methods. In one approach to the identification and enrichment of mouse HSCs, monoclonal antibodies specific for antigens that characterize cells belonging to specific mature and committed hematolymphoid lineages are used to identify these cells in bone marrow suspensions (Müller-Sieburg et al., 1986). The marked cells can be depleted by a solid-phase immunological method such as panning (Jordan and Lemischka, 1990) or by the use of immunomagnetic particles (Bertoncello et al., 1989; Ikuta et al., 1990). The remaining population of cells, termed *lineage-negative* (Lin^{neg}), contains approximately 5 percent of the initial number of bone marrow cells and consists of a mixed population of multipotent HSCs, early progenitors, and late progenitors. Lin^{neg} cells can be further fractionated with specific monoclonal antibodies that recognize antigens expressed by a variety of hematopoietic and nonhematopoietic cells—for example, Thy-1 (Müller-Sieburg et al., 1986), Sca-1 or Ly-6A/E (Spangrude and Brooks, 1992), c-kit (Okada et al., 1991), and major histocompatibility complex class I molecules (Mulder et al., 1984). The lectin wheat germ agglutinin has also been useful in discriminating multipotent HSCs from early- and late-stage progenitors due to a relatively high number of binding sites for the lectin on multipotent HSCs compared to that on later-stage progenitors (Visser et al., 1984). When combined with a depletion of cells expressing high levels of lineage differentiation antigens, any one of these markers alone, or in combination, will identify a group of primitive hematopoietic cells in adult bone marrow or fetal liver. This multiparameter approach is helpful because few cell-surface antigens are unique to HSCs (Kiel et al., 2005), and most currently defined HSC markers continue to be expressed as the cells differentiate and new, lineage-specific markers appear.

HETEROGENEITY OF THE HEMATOPOIETIC STEM CELL COMPARTMENT

Cell populations resulting from antibody selection techniques are heterogeneous in function, suggesting a complex organizational structure within the HSC compartment (Fig. 3.1). The heterogeneity is mostly with respect to self-renewal potential, since a high frequency of cells isolated by antibody enrichment are multipotent for both lymphoid and myeloid lineages (Spangrude and Johnson, 1990). The subset of multipotent cells possessing extensive self-renewal potential is resistant to killing by 5-fluorouracil and other cell-cycle–active agents (Hodgson and Bradley, 1979). This finding suggests that these cells are metabolically quiescent or that they possess elevated levels of a multidrug-resistance mechanism (Chaudhary and Roninson, 1991).

Several methods have been used to select for long-term repopulating HSCs from antibody-enriched stem/progenitor-cell populations. The vital mitochondrial dye rhodamine-123 can be used to distinguish cell populations on the basis of metabolic activity, and self-renewing HSCs are predominantly recovered from the group of cells exhibiting low mitochondrial staining (Bertoncello et al., 1985). Rhodamine-123 is also a substrate for multidrug efflux pumps. However, it is likely that the discrimination between the self-renewing and non–self-renewing HSC subsets by rhodamine-123 is due to differences in mitochondrial content and activity (Kim et al., 1998). In a second strategy, vital nucleic acid dyes such as Hoescht 33342 are used to identify quiescent cells based on cell-cycle position (Neben et al., 1991; Wolf et al., 1993) or dye efflux that defines a "side population" of cells by flow cytometry (Goodell et al., 1997). Finally, specific combinations of antibody markers can select for self-renewing HSCs (Morrison and Weissman, 1994). The combination of cell-surface and metabolic markers allows the recovery of a population of cells capable of long-term repopulation of irradiated animals after transplantation of less than 10 cells (Ema et al., 2005; Spangrude et al., 1995; Wolf et al., 1993). In contrast, over 10^5 normal bone marrow cells are required to produce a similar level of reconstitution.

The published methods for enriching populations of HSCs from mouse bone marrow and fetal tissues have dramatically improved the ability of researchers to explore the early events in normal mammalian hematopoiesis. As more enriched populations have become available for experimental use, it has become possible to critically test these cells for their ability to respond to recombinant cytokines by proliferating (Li and Johnson, 1992; Sitnicka et al., 1996), to assess the developmental pathways that the cells will follow under defined conditions in vitro (Yamazaki and Nakauchi, 2009), and to explore the ability of purified cells to home to marrow niches in vivo (Adams et al., 2009).

CHARACTERISTICS OF HUMAN HEMATOPOIETIC STEM CELLS

The demonstration that the CD34 antigen is expressed by progenitor cells in human bone marrow (Civin et al., 1984) has allowed many investigators to explore the HSC compartment in humans. Applying the same general approach that was successful in the mouse, several groups have combined negative selection for lineage markers; positive selection for CD34 (Andrews et al., 1986), Thy-1 (Baum et al., 1992), or c-kit (Briddell et al., 1992); and selection for low staining with rhodamine-123 (Srour et al., 1991) to achieve high enrichments of human hematopoietic progenitor cells. Positive selection for CD34 alone has been used as a method to enrich for progenitors prior to bone marrow transplantation after chemotherapy for a number of malignancies (Berenson et al., 1991; Shpall et al., 1994).

Highly purified $CD34^+$ $Thy\text{-}1^+$ Lin^{neg} cells have also been used clinically for transplants after myeloablative chemotherapy (Michallet et al., 2000). In allograft transplants for treatment of immunodeficiencies, selection for HSCs by specific antigen expression may decrease the potential for graft-versus-host disease (Flake et al., 1996). In addition, the introduction of normal counterparts of defective endogenous genes into the hematopoietic system for treatment of immunodeficiencies (see Chapters 60 and 61 of this volume) requires that the target population be relatively enriched for self-renewing HSCs.

In recent years, a great deal of attention has been focused on augmentation and acceleration of engraftment in bone marrow transplant settings by cytokine therapy in the recovery phase, and on the use of peripheral blood-derived stem/progenitor cells as a source of hematopoietic stem cells for human transplantation. While hematopoietic progenitors are rarely found circulating in peripheral blood under normal circumstances (Micklem et al., 1975), cytotoxic drug treatment, the administration of hematopoietic cytokines (Bodine et al., 1993), or both treatments in sequence (Siena et al., 1989) induce a rapid peripheralization of hematopoietic stem/progenitor cells. These cells can be harvested by multiple leukopheresis sessions over several days, frozen for storage, and infused to mediate hematopoietic recovery following marrow ablative therapy. There is a significant effect of peripheral blood-derived stem and progenitor cells on the kinetics of recovery during the pancytopenic phase, when infection and hemorrhage can result in significant patient morbidity and mortality. A variety of studies have documented dramatic effects on both neutrophil and platelet recovery when peripheral blood stem cells, with or without supplemental cytokines, were used to mediate hematopoietic recovery following high-dose chemotherapy (Basser et al., 1996; Benjamin et al., 1995). Enrichment of HSCs from normal donor peripheralized blood progenitor products (Murray et al., 1995; Weaver et al., 1995) may enable efficient allotransplantation without graft-versus-host disease in the treatment of many immunodeficiencies (Flake et al., 1996).

ASSAYS FOR HEMATOPOIETIC STEM CELLS

A great deal of attention has been focused on the development of assay systems that specifically detect the activity of the most primitive of HSCs for hematopoiesis (Fig. 3.4). One approach to an in vivo clonal assay for long-term repopulation is limiting dilution competitive repopulation to derive a measure of competitive repopulating units (CRUs) (Szilvassy et al., 1990). In this assay, very small numbers of genetically marked cells are transferred into anemic W/Wv mice (Boggs et al., 1982) or irradiated animals. In the latter case, a radioprotective dose of normal marrow cells is also provided to mediate radioprotection, and the development of donor-derived populations is followed over long periods of time. This approach has been used to estimate the frequency of long-term repopulating cells in normal marrow suspensions (Boggs et al., 1982; Micklem et al., 1987). Enrichment of mouse HSCs from bone marrow resulted in repopulation of recipient animals after transfer of single injected cells (Osawa et al., 1996; Smith et al., 1991; Spangrude and Weissman, 1988).

Because it is very difficult to determine what the seeding efficiency of this assay is—that is, how frequently an intravenously injected cell seeds to a microenvironment such as the spleen or bone marrow where hematopoiesis is supported—it

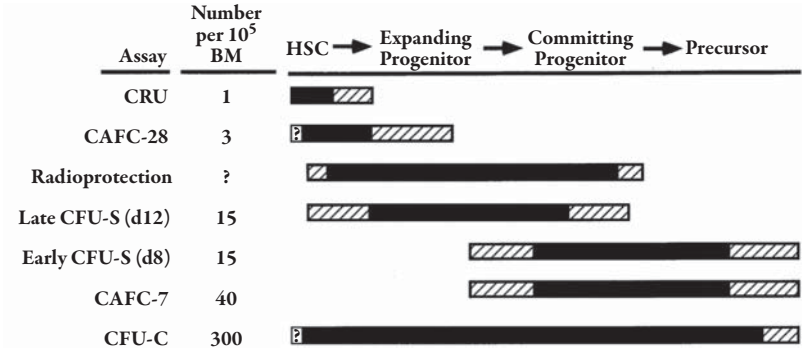

Figure 3.4 Assays that detect various members of the hematopoietic hierarchy. A number of assays currently used to detect hematopoietic stem and progenitor cells are listed along with the approximate frequency of the normal mouse bone marrow cells detected by these assays and a general indication of the level of the hematopoietic hierarchy detected by each assay. The black and shaped portions of the bars indicate strong and weak activity, respectively, in the indicated assay. The assays are abbreviated as follows: CRU, competitive repopulating unit, a transplantation assay that measures the clonal frequency of cells able to contribute long term to blood formation in a transplant recipient. CAFC, cobblestone-area-forming cell, a cell culture assay that measures the ability of stem and progenitor cells to form within 7 to 28 days a morphologically distinct colony of cells in association with a monolayer of cultured stromal cells; Radioprotection, the potential of transplanted stem and progenitor cells to mediate hematological rescue of lethally irradiated animals; CFU-S, colony-forming units (spleen), a transplant assay that measures the formation of clonally derived colonies of proliferating hematopoietic cells in the spleens of irradiated animals 8 or 12 days after transplant; CFU-C, colony-forming units (culture), a culture assay that measures the expansion of clones of cells in a semisolid culture medium in response to soluble growth-factor stimulation. This assay can also be performed by seeding single cells into culture wells. The frequency of responding cells in each assay has been taken from Neben et al. (1993) and Szilvassy et al. (1996); these numbers will vary depending on specific assay conditions and the age and strain of the donor mouse from which bone marrow cells are obtained.

is not possible to know how frequent the long-term repopulating cell was in the original population; only a minimum frequency can be determined based on the measured seeding efficiency of about 35 percent (Camargo et al., 2006). Further, since there is ample evidence that long-term repopulation is usually quasi-clonal in radiation-reconstitution models, the absence of progeny in the long term may indicate that the single injected HSC is one of many in a quiescent state, rather than supporting the idea that the cell was unable to self-renew and give rise to progeny over a long period of time (Van Zant et al., 1992; Wilson et al., 2008). The quasi-clonal repopulation problem compounds the difficulty of measuring the frequency of long-term repopulating cells in transplant models, even when a remarkable level of enrichment for the activity has been achieved.

Very soon after the description of the CFU-S assay by Till and McCulloch in 1961, the question of whether splenic colonies truly represent the proliferation of primitive HSCs became an important issue. Since the criteria for defining HSCs at that time included multilineage potential and a capacity for self-renewal, it naturally followed that one should be able to demonstrate the presence of new colony-forming cells within spleen colonies. This hypothesis was tested in a double transplant experiment by either excising individual spleen colonies (Siminovitch et al., 1963) or pooling the entire spleen from a CFU-S experiment (Siminovitch et al., 1964) for transplant into secondary irradiated recipients. The results revealed a broad heterogeneity in the ability of splenic colonies to initiate new splenic colonies. Also, when a longer period of time was allowed to elapse prior to harvesting spleen colonies for secondary transplant, the number of colonies containing secondary CFU-S increased. Many more colonies harvested 14 days after injection contained CFU-S compared to colonies harvested after 8 days. While a reasonable interpretation at the time invoked an extended timeframe necessary for the self-renewal process within spleen colonies (Lewis and Trobaugh, 1964), later work revealed that the majority of early (day 8) CFU-S disappeared a few days later and that at least half of the late (days 11 to 13) colonies arose from a separate group of hematopoietic cells (Magli et al., 1982; Wolf and Priestley, 1986). These intrinsic differences in CFU-S hinted at the limited utility of the CFU-S assay to detect HSCs; only after a secondary transplant could one be assured of the self-renewing potential inherent in the original spleen colony.

Refinements in HSC characterization and enrichment have strengthened the concept that many types of hematopoietic cells that form spleen colonies lack the ability to reconstitute long-term hematopoiesis in irradiated animals (Ploemacher and Brons, 1988). Conversely, several groups have demonstrated long-term repopulating potential in the apparent absence of splenic colony-forming potential (Jones et al., 1990; Ploemacher and Brons, 1989; Wolf et al., 1993). While it is not yet clear whether inhibitory cytokines (Graham et al., 1990) or splenic seeding considerations (Spangrude and Johnson, 1990) may explain the failure of certain HSC preparations to form spleen colonies, it is very clear that spleen colony formation is not a unique characteristic of primitive HSCs (Hodgson and Bradley, 1979; Magli et al., 1982). Further, the inability to use such an assay in the investigation of human hematopoiesis, with the possible exception of chimeric human-mouse model systems (McCune et al., 1988), dictates the need to develop specific in vitro assays for HSCs.

Many recent attempts to develop specific in vitro assays for HSCs have relied on co-culture of candidate HSC populations with feeder layers of bone marrow-derived stromal cells. A number of laboratories have used this approach to analyze hematopoiesis with mouse and human models (Ploemacher et al., 1989; Sutherland et al., 1990). In this assay there are two phases: an expansion phase, in which the primitive HSC number is increased without a large degree of differentiation, and a detection phase, when the products of the initial expansion are read out. In the expansion phase, self-renewal must be favored over differentiation, and the typical approach is to use a stromal cell feeder layer under the conditions originally defined by Dexter et al. (Dexter and Lajtha, 1974) to culture HSC populations. In most cases, the second phase of the assay involves harvesting the cells that differentiate in the cultures and testing these progeny cells for the ability to produce macroscopic colonies in semisolid medium under the influence of a variety of cytokines (the culture colony-forming unit, or CFU-C assay). While the readout of colony formation is not an activity uniquely associated with HSCs, the differentiation of HSCs in these stromal cell co-cultures is thought to result in the production and thus a net increase in the number of colony-forming cells. The results of such an assay are fairly quantitative, but the assay is not clonal because individual colonies in the second phase of the assay do not reflect single-input HSCs. However, if the co-culture is initiated under limiting dilution conditions, an estimate of the frequency of the HSCs in any given cell population is possible. Furthermore, a higher absolute number of colony-forming cells produced in any one culture is interpreted as an indicator of a more primitive initiating HSC. This culture system, and variants thereof, is usually termed the *long-term culture initiating cell* (LT-CIC) assay.

Co-cultures of HSC and supportive bone marrow stroma evolve to generate unique associations between the two cell types. The mobile HSC interdigitates between and beneath the stromal monolayer, resulting in HSCs with a characteristic nonrefractile appearance by phase-contrast microscopy. These stromal-covered cells proliferate to form clusters of tightly packed cells that have been referred to as *cobblestone areas*, and the assay to detect such events is known as the *cobblestone-area-forming cell* (CAFC) assay (Neben et al., 1993; Ploemacher et al., 1989). The frequency of formation of cobblestone areas can be correlated to hematopoietic repopulating activity in vivo, and the kinetics of cobblestone area formation reflects the relative maturation stage of the initiating cells, with more primitive cells requiring a longer period of time to establish a cobblestone area. These observations have been incorporated into the CAFC assay, which does not rely on a readout of CFU-C, but rather quantitates the frequency of cobblestone areas as a function of time (Neben et al., 1993; Ploemacher et al., 1991; Weilbaecher et al., 1991). There is currently no strong evidence that stromal cell systems effectively reproduce the bone marrow environment in terms of self-renewal of HSCs (Spooncer et al., 1985). The stromal co-cultures can

produce CFU-C from input HSCs over prolonged periods of time (van der Sluijs et al., 1990), but it is unclear to what extent HSCs can actually self-renew in these cultures relative to the in vivo environment.

While some correlation has been made between long-term reconstitution of lethally irradiated animals and some in vitro culture systems (Ploemacher et al., 1991), in fact the only definitive method available to define the self-renewing characteristics of HSCs is by transplantation in vivo (Orlic and Bodine, 1994). The availability of genetically defined strains of mice that allow easy identification of donor-derived cells in the peripheral blood of recipient animals in an otherwise syngeneic transplant (Harrison, 1980, Spangrude et al., 1988) provides a valuable model system for HSC function that has not yet been entirely duplicated by in vitro culture systems (van der Sluijs et al., 1993). The major limitation of the in vitro systems is that, in general, the development of only one or a few hematopoietic lineages is supported. Also, sole reliance on long-term culture initiation as an indicator of HSC function ignores the known capacity of mammalian cells to adapt to tissue culture conditions. A variety of immunodeficient strains of mice have been widely used as an in vivo model for engraftment of both normal and leukemic hematopoietic cells from human sources (Pearson et al., 2008). This assay allows detailed study of stem cell homing to bone marrow and multilineage differentiation in the context of a normal microenvironment.

SELF-RENEWAL OF HEMATOPOIETIC STEM CELLS

A major advantage of using a mouse model system to define basic characteristics of the HSC is that this model can be used to demonstrate the most critical of HSC functions, self-renewal. The concept of self-renewal in hematopoiesis can be interpreted in several ways. One possibility is that self-renewal of HSCs occurs at each cell division, which requires that HSCs divide in the complete absence of differentiation. This leads to the conclusion that one HSC may contribute indefinitely to hematopoiesis, a critical assumption for the application of gene therapy protocols in immunodeficiencies. If, however, one envisions a heterogeneous compartment of HSCs, all of which share the ability to initiate development in multiple hematopoietic lineages but differ in ability to give rise to more multipotent cells, the conclusion is consistent with the clonal succession model as proposed by Kay (1965), and there is less optimism for prolonged correction of genetic defects by gene therapy. An intermediate situation consisting of essential elements from both extremes produces a further variation. It will be difficult to prove or disprove the proposal that one HSC can divide to produce progeny of identical proliferative and developmental potential; however, many experiments have demonstrated the reality of clonal succession and of the heterogeneous nature of the HSC compartment (McKenzie et al., 2006). Sequential activation of HSC clones leads to clonal or quasi-clonal contributions to hematopoiesis, as demonstrated by transplantation experiments between animals differing at isoenzyme loci (Abkowitz et al., 1995; Micklem et al., 1987) or by transplants of bone marrow cells carrying unique retrovirally induced genetic markers (Jordan and Lemischka, 1990). Serial transplantation of bone marrow, which eventually leads to a loss of repopulating activity (Harrison et al., 1990), can demonstrate two distinct phases of engraftment in recipient animals. The first phase is unsustained, apparently because more committed members of the HSC compartment are unable to maintain hematopoiesis in the long term. The second phase is sustained and is due to very primitive HSCs (Jones et al., 1989). These observations are compatible with clonal succession and with the generation-age hypothesis (Rosendaal et al., 1976), which extends the clonal succession model to predict that the number of generations an HSC is removed from its initial progenitor is inversely proportional to its proliferation potential (and hence hematopoietic-repopulating potential) and directly proportional to its state of activation. This means that the ability of any individual HSC to self-renew is limited, but the compartment of multipotent cells possesses the self-renewing ability of the sum of all individual HSCs.

Application of transplantation pressure in hematopoiesis results in exhaustion of HSCs (Harrison et al., 1990). In a very intriguing study, allophenic chimeras, made by aggregating embryos of two inbred mouse strains, were used to show that HSC exhaustion can be observed under normal developmental pressure (Van Zant et al., 1990). In these experiments, one partner mouse strain (DBA/2) has spleen colony-forming cells, of which 24 percent are normally in cell cycle, whereas in the other partner strain (C57BL/6) only 2.6 percent of these cells are in cycle. In allophenic chimeras between these two strains, the DBA/2 HSC population predominated early in life, only to be overtaken and eventually eclipsed by the C57BL/6 population. A similar observation was made after bone marrow transplants from chimeras into irradiated F1 recipients. These experiments bear out basic predictions of the generation-age hypothesis and point to intrinsic differences in the HSC as a factor in the longevity of hematopoiesis and of lifespan. Do HSCs also self-renew at a cellular level? This question is critical to the concept of gene therapy as a permanent cure for immunodeficiencies. To answer this question definitively we will need more sophisticated techniques of cell culture and analysis.

CONCLUSIONS

The outcome of human bone marrow transplantation may be improved if enriched populations of early progenitors and HSCs are transplanted rather than whole bone marrow or apheresis products. This could be true in allogeneic transplants, where graft-versus-host disease might be eliminated by T-cell depletion, and also in autotransplants, where residual tumor cells in the graft may contribute to relapse (Gazitt et al., 1995). Application of gene therapy to human immunodeficiency treatments via transplantation will also require HSC enrichment to improve the efficiency of targeting functional genes to the hematopoietic generative compartment. It is critical that we understand the biology of hematopoiesis and know how to maximize the self-renewing potential of transplanted HSCs.

Researchers working in the human system must currently rely on assay systems for long-term repopulation that have not been thoroughly examined for their specific mechanism of detecting the critical (self-renewing) populations of cells. Unraveling of the mysteries of the HSC compartment has been complicated by the difficulty in obtaining native HSCs in any large quantity for classical cell biological studies. This problem is compounded by the observation that HSC biology (phenotype and function) varies among mouse strains, making concrete rules for early hematopoiesis difficult to formulate.

Several recent studies suggest that bone marrow-derived hematopoietic stem cells may have broader developmental potential than originally thought, as examples of differentiation into epithelium, hepatocytes, neurons, and muscle have been reported (Krause et al., 2001; Lagasse et al., 2001). The phenomenon of differentiation across lineage barriers is often referred to as *plasticity* or *transdifferentiation*. Furthermore, evidence suggests that multipotent cells capable of generating blood and other tissues exist in many adult tissues (Anderson et al., 2001). Although these new observations may open new avenues to treatment of genetic diseases, this field is still highly controversial, with many reports describing both the existence and the essential lack of plasticity. In some cases fusions between cells have been found as the underlying mechanism (Alvarez-Dolado et al., 2003; Vassilopoulos et al., 2003). The ability to reprogram fully differentiated mammalian cells to a pluripotent state similar to embryonic stem cells (Yamanaka, 2009) demonstrates that lineage plasticity is in fact a reality that may help open more opportunities for cellular therapy of primary immunodeficiency diseases in the future.

The marked propensity of HSCs to rapidly differentiate in most in vitro culture systems (Rebel et al., 1994) has hampered our ability to investigate under controlled, in vitro conditions the hierarchy of the HSC compartment and to approach the question of how to maintain the essential "stemness" of HSC populations. The possibility that self-renewal in the HSC compartment is limited to a finite number of cell divisions may indicate that even under the best conditions unlimited expansion of true HSCs is an impossible goal to attain. On the other hand, recent studies have begun to reveal transcriptional mechanisms that might be exploited to better regulate HSC self-renewal (Essers et al., 2009; Liu et al., 2009; Luis et al., 2009; Milsom et al., 2009). This possibility has an obvious impact on proposals for gene therapy of immunodeficiencies through transplantation, since self-renewal of transduced stem cells is the only vehicle by which this may be accomplished. Development of better clinical methods for management of the complications of allogeneic transplants will also be an important future direction for effective treatment of congenital immunodeficiencies.

T-CELL DEVELOPMENT

Juan Carlos Zúñiga-Pflücker, Rae Yeung, Pam Ohashi, and Tak W. Mak

INTRODUCTION

The purpose of this chapter is to give a broad overview of the major stages of T-cell development. T-cells are key regulators of acquired immunity, and their functions are determined by events that occur during an intricate developmental process in the thymus (Petrie and Zuniga-Pflucker, 2007). An understanding of T-cell development is fundamental to our understanding of immune responses. The interaction of the T-cell receptor (TCR) expressed by a developing T-cell (thymocyte) with self-antigens presented by stromal cells in the thymus determines the ultimate fate of that thymocyte (Starr et al., 2003). Only a small fraction of thymocytes become the mature T-cells that patrol the body's periphery and respond to foreign antigen. The molecular interactions that lead to the elimination of self-reactive thymocytes ("negative selection") and the survival of those that can potentially mount protective immune responses ("positive selection") are complex (Starr et al., 2003).

Our understanding of T-cell development has been greatly enhanced through the use of genetic tools, particularly mutant mouse models such as transgenic mice and gene-targeted or "knockout" mice (Mak et al., 2001). Additionally, T-cell development has been further dissected with the help of in vitro culture systems such as fetal thymic organ culture (FTOC) (Hare et al., 1999) and the OP9-DL1 cell system (Zuniga-Pflucker, 2004). We start this chapter with overviews of the TCR proteins and the genes encoding them, followed by a brief discussion of the co-receptors CD4 and CD8, which have enormous influence on T-cell development. Finally, we describe the stages of T-cell development in detail at both the cellular and molecular levels. This chapter deals with mouse models of T-cell development; thus, the reader is referred to recent reviews on human T-cell development (Sitnicka, 2009; Spits, 2002; Taghon and Rothenberg, 2008) for further information on this topic.

TCR/CD3 COMPLEX

The TCR is responsible for the recognition of both foreign and self-antigens and is central to both T-cell development and the mounting of specific immune responses. Inability to recognize foreign antigen can lead to overwhelming infection or cancer, while inappropriate recognition of self-antigens can result in autoimmune disease. The binding of antigen, in the form of peptide presented by a major histocompatibility molecule (MHC), by a TCR triggers a complex intracellular signaling cascade that leads to the activation of transcription factors in the T-cell's nucleus (Acuto and Cantrell, 2000). These transcription factors drive gene expression programs that govern the fate and functions of these T-cells, whether they be immature thymocytes developing in the thymus (Rothenberg, 2007) or mature T-cells mediating immune responses in the body's periphery (Smith-Garvin et al., 2009).

TCRs are heterodimeric proteins composed of either TCRα and β chains, or TCRγ and δ chains. In mice, thymocytes and the majority of peripheral T-cells bear $\alpha\beta$ TCRs, but about 5 to 10 percent of all T-cells bear $\gamma\delta$ TCRs. With a few exceptions, TCR$\alpha\beta$ heterodimers recognize peptides complexed with MHC molecules, but some TCR$\gamma\delta$ molecules recognize nonpeptide antigens either directly or bound to the MHC-like molecules (Chien and Konigshofer, 2007). For both $\alpha\beta$ and $\gamma\delta$ TCRs, recognition of the antigen depends on the binding site formed by portions of the $\alpha\beta$ or $\gamma\delta$ chains (Hayday and Tigelaar, 2003). However, surface expression of the TCR and antigen-specific T-cell signaling and activation depend on the association of the TCR with the CD3 complex. The CD3 complex consists of at least five distinct membrane

proteins, CD3γ, δ, ε, ζ, and η, which are noncovalently associated both with each other and the TCR heterodimer (Kuhns et al., 2006). The CD3 γ, δ, and ε chains are found as γε and δε subunits within the TCR/CD3 complex, while the ζ chain is found as a homodimer (in 90 percent of TCRs) or as a ζ heterodimer (~10 percent of TCRs) (Malissen and Malissen, 1996). The CD3ζ and η chains are splice variants derived from the same gene. The minimal stoichiometry of the most common αβ TCRs is TCRαβ: CD3γεCD3δεCD3ζ (Fig. 4.1). All CD3 chains contain at least one of the tyrosine-rich ITAMs (immunoreceptor tyrosine-based activation motifs) essential for initiating intracellular signaling following antigen binding to the TCR (Kuhns et al., 2006; Smith-Garvin et al., 2009).

TCR GENES

An αβ TCR binds to peptide-MHC (pMHC) via its variable (V) region located at the extracellular N-terminus of the heterodimer. The V region is linked to an invariable extracellular region, a transmembrane domain, and a short intracellular domain at the carboxyl terminus of the protein. These latter elements are encoded by the constant (C) region exons of the TCR loci. The V regions of both component TCR chains contribute to the antigen binding site, and each chain's V region is encoded by a V exon. Analogous to the immunoglobulin (Ig) light chain gene, the TCRα and γ V exons contain a V (variable) and a J (joining) gene segment, while, like the Ig heavy chain gene, the TCRβ and δ V exons contain a V, a D (diversity), and a J gene segment. In each developing thymocyte, the V and J or V, D, and J gene segments forming the V exons are randomly chosen from the huge array of multiple V, D, and J gene segments present in germline TCR loci. In a process known as "somatic gene recombination," the RAG1/2 genes are key players that initiate the process of gene recombination (Chen et al., 1994; Schatz et al., 1989). It is the random rearrangement of V(D)J gene segments that generates most of the enormous diversity of TCRs expressed on mature T-cells. Additional diversity is introduced at V-D-J junctions through the introduction of template-independent (or N) nucleotides during V(D)J rearrangement. N-nucleotide addition is mediated by the enzyme terminal deoxynucleotidyl transferase (TdT) (Tonegawa, 1983). The stage-specific timing of when these TCR DNA recombination events take place during T-cell development will be discussed later.

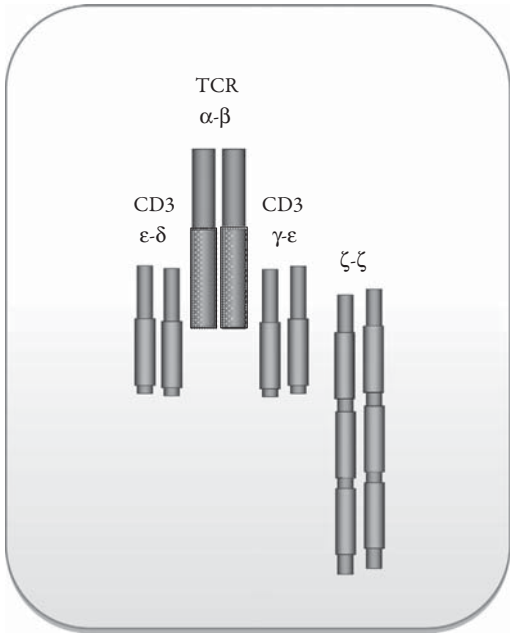

Figure 4.1 αβ TCR/CD3 complex on the surface of T-cells. Schematic drawing of the TCR/CD3 complex in the T-cell membrane. The TCR heterodimer is typically associated with three other CD3 dimers: εδ, γε, and ζζ. The immunoreceptor tyrosine-based activation motif (ITAM) regions are depicted within the CD3 chains. (See Color Plate.)

THE CO-RECEPTORS

Although the TCR antigen binding site is responsible for the recognition of specific peptide in the binding groove of an MHC molecule, the CD8 and CD4 molecules function as germline-encoded cognate receptors that bind to nonpolymorphic regions of MHC class I and MHC class II molecules, respectively (Germain and Stefanova, 1999). The co-receptors facilitate TCR signal transduction because the cytoplasmic domains of both CD4 and CD8 are physically associated (with differing stoichiometry) with Lck tyrosine kinase (Veillette et al., 1988; Weiss and Littman, 1994). Both CD4 and CD8 have important roles in the ontogeny and selection of thymocytes and in the activation of mature T-cells resident in peripheral lymphatic organs (Germain and Stefanova, 1999; Wallace et al., 1993).

CD8 and MHC Class I

CD8 is a cell surface glycoprotein expressed on MHC class I-restricted T-cells. In mice, thymocytes and peripheral T-cells generally express CD8 as heterodimers of CD8α and CD8β. The MHC class I molecule to which CD8 binds is a heterodimer composed of an MHC class I α chain noncovalently associated with the invariant β2-microglobulin (β2M) chain. β2M is crucial for the expression of the MHC class I molecule on the cell surface. The peptides associated with MHC class I molecules are generally derived from endogenous proteins degraded by proteasomes in the cytosol. The peptides are translocated into the endoplasmic reticulum (ER) by a heterodimeric transmembrane transporter complex with structural similarity to ATP binding cassette transporters (Spies and DeMars, 1991). The TAP1 (transporter associated with antigen processing-1) and TAP2 subunits of this transporter complex are encoded by the *Tap1* and *Tap2* genes, which map to the MHC class II region (Deverson et al., 1990; Monaco et al., 1990). Once in the ER lumen, the endogenous peptides are immediately loaded into the binding grooves of newly synthesized MHC class I molecules (Androlewicz and Cresswell, 1996).

Because interaction with MHC class I is required for $CD8^+$ T-cell development, disruptions in either the β2M gene or the *Tap* genes have severe effects on the mature $CD8^+$ T-cell

population. For example, a drastic reduction in the number of $CD8^+$ T-cells is observed in gene-targeted β2M-deficient mice (Koller et al., 1990; Zijlstra et al., 1990), and a similar phenotype is observed in animals in which the *Tap1* gene has been deleted (Van Kaer et al., 1992). Cytotoxic T-cell functions, which are mainly carried out by $CD8^+$ T-cells, are severely impaired in these mutant mouse strains because these cells fail to be generated in the absence of CD8–MHC class I interactions; however, T-helper activities mediated by $CD4^+$ lymphocytes remain normal.

CD4 and MHC Class II

Murine CD4 is a 55 kDa single-chain glycoprotein with four Ig-like extracellular domains, a transmembrane region, and a cytoplasmic domain (Littman, 1987). CD4 molecules interact with MHC class II molecules in both functional studies and binding assays. The two most distal extracellular domains of CD4 bind to the nonpolymorphic β2 domain of MHC class II molecules (Konig et al., 1996). The intracellular domain of CD4 is associated with large quantities of Lck, making it particularly important for the initiation of the complex TCR signaling cascade (Salmond et al., 2009). The majority of T-helper functions, which consist primarily of the secretion of cytokines required for the complete activation of B-cells and cytotoxic T-cells, are carried out by $CD4^+$ T-cells.

The MHC class II molecule to which CD4 binds is a heterodimer composed of an MHC class II α chain noncovalently associated with an MHC class II β chain. MHC class II molecules generally present peptides from exogenous sources. Since both MHC class I and II molecules are assembled in the ER, and both are capable of binding peptides, a mechanism must exist in the ER to protect the peptide-binding groove of class II molecules from occupancy with endogenous peptides (Neefjes and Ploegh, 1992). The invariant chain (Ii) is coordinately expressed with MHC class II in the ER and associates with newly synthesized MHC class II molecules such that the binding of peptide in the MHC class II groove is blocked. As the MHC class II–Ii complexes traverse the increasingly acidic intracellular antigen-processing compartments, Ii undergoes stepwise degradation by cathepsin-like proteases until only a fragment of Ii called CLIP (class II-associated invariant chain peptide) remains in the binding groove (Roche, 1995). CLIP is removed from the binding grove by the action of H2-M or HLA-DM in humans. Both H2-M and HLA-DM are heterodimers with low homology to conventional MHC class II proteins (Roche, 1995). H-2M co-localizes with MHC class II molecules in an endolysosomal compartment called the "MHC class II compartment" (MIIC) (Roche, 1995) and functions as a peptide exchanger, catalyzing the release of CLIP peptides from the MHC class II groove and the subsequent loading of processed exogenous peptides (Denzin and Cresswell, 1995; Sherman et al., 1995). Once the MHC class II molecule is loaded with peptide, H-2M is released and the pMHC complex makes its way to the surface.

The functions of many molecules involved in the exogenous antigen-processing pathway have been clarified through studies of knockout mice. The development and function of $CD4^+$ T-cells is disturbed in mice lacking Ii, confirming the crucial role of this protein in normal MHC class II antigen presentation (Viville et al., 1993). In H2-M-deficient mice, normal amounts of MHC class II molecules are present on the cell surface but the majority of them are associated with CLIP rather than exogenous peptide (Fung-Leung et al., 1996; Martin et al., 1996; Miyazaki et al., 1996). Unexpectedly, positive selection of MHC class II-restricted $CD4^+$ T-cells appeared intact in these animals and they possessed large numbers of $CD4^+$ T-cells that responded vigorously to antigens presented by normal antigen-presenting cells (APCs). However, APCs from H2-M-deficient mice were unable to stimulate T lymphocytes to respond to any antigen (Fung-Leung et al., 1996). In MHC class II-deficient mice (Cosgrove et al., 1991; Grusby et al., 1991; Kontgen et al., 1993), thymocyte development is blocked at an early stage and $CD4^+$ lymphocytes are virtually absent in peripheral lymphoid organs. However, the development and functions of peripheral $CD8^+$ cytotoxic T-cells are normal. Surprisingly, there were significant numbers of $CD4^+$ T-cells in the thymi of MHC class II-deficient mice, although these cells were not of a mature phenotype. A subset of these unusual $CD4^+$ cells was found to be restricted to MHC class I-like CD1 molecules (Cardell et al., 1995). These cells have been further characterized as natural killer (NK)-T-cells, and they belong to a specialized class of T-cells that uses an invariant TCR to select on CD1 molecules expressed by immature thymocytes (Matsuda et al., 2008). These NKT-cells have a unique cytokine expression profile and may play important functions in tumor recognition and inflammation (Bendelac et al., 2007).

Recently, a mouse model in which both class I and class II MHC molecules along with CD4 and CD8 are deleted was generated (Van Laethem et al., 2007). This quadruple-deficient mouse line showed an interesting outcome of T-cell development, in that mature αβ-T-cells were generated in the thymus, which given the MHC deficiency were selected by and restricted to non-MHC ligands. These findings are discussed below, but they highlight the role of CD4 and CD8 in enforcing cognate MHC restriction by the TCR (Singer et al., 2008).

OVERVIEW OF T-CELL DEVELOPMENT

In this section, we present a brief overview of the major stages of T-cell development, in order to better orient the reader for the more detailed discussions of thymocyte migration, selection, and signaling at the different stages of T-cell development.

T-cell development takes place in the thymus from progenitors that immigrate from the bone marrow, and during this process precursor thymocytes proliferate, rearrange their antigen receptor DNA, express functional TCRs and co-receptors, and undergo a series of selection events (Petrie and Zuniga-Pflucker, 2007). Intrathymic T-cell differentiation in the mouse can be divided into three major stages distinguished by the expression of TCR/CD3, CD4, and CD8 (Fig. 4.2). In the first major stage, neither the TCR, CD4, nor CD8 is expressed; most immunologists refer to this stage as the double negative (DN) or $CD4^-$ $CD8^-$ stage. It is during the third phase of this stage (DN3; see below) that rearrangement of the VDJ segments of the TCRβ,

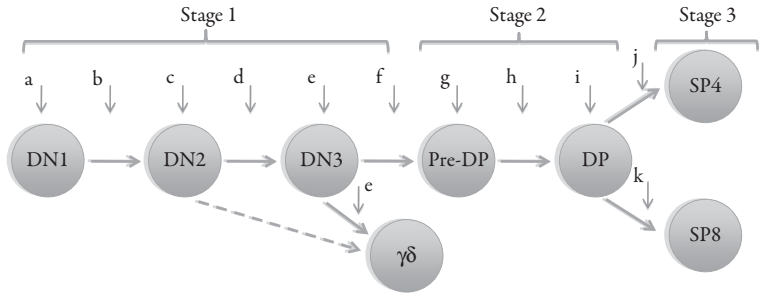

Figure 4.2 Stage-specific events, a brief overview of T-cell development. Stage 1: Double negative: a, DN1 thymocytes are heterogeneous; DN1 cells (CD44+ CD25-) expressing CD117hi CD24-/lo correspond to the ETP subset; b, Notch-1/Delta-like-4 interactions induce commitment to the T-cell lineage; c, TCR rearrangements are initiated by CD44+ CD25+ DN2 cells; d, Irreversible commitment to the T-cell lineage; e, αβ and γδ lineage diverge, due to TCRβ-selection and γδ-TCR signals at the CD44- CD25+ DN3 phase; f, Pre-TCR dependent survival, proliferation, and differentiation are induced. Stage 2: Double positive: g, TCRα rearrangements; CD4 and CD8 expression are initiated; h and i, Positive selection and negative selection take place. Stage 3: Single positive cells: j and k, Final lineage commitment dependent of the kinetic signaling model takes place.

TCRγ, and TCRδ (but not TCRα) loci is completed, and the TCRαβ and TCRγδ lineages diverge (Ciofani et al., 2006). In cells destined to become mature αβ T-cells, the TCRβ chain pairs with an invariant germline-encoded TCRα-surrogate chain known as the pre-Tα chain to form a pre-TCR complex on the cell surface (von Boehmer, 2005). This stage is known as the β-selection checkpoint, as thymocytes expressing nonfunctional TCRβ chains die at this point due to a lack of survival signaling (Michie and Zúñiga-Pflücker, 2002). In the second major stage of αβ T-cell development, thymocytes commence expression of both co-receptors and are known as double positive (DP) or $CD4^+$ $CD8^+$ thymocytes. Rearrangement of the TCRα locus occurs, expression of pre-Tα is extinguished, and true TCRαβ heterodimers are expressed on the surface of DP thymocytes. DP thymocytes then undergo positive selection to preserve cells binding to self-antigen/MHC with low to moderate affinity, followed by commitment to either the CD4 or CD8 lineage. The resulting single positive (SP) thymocytes undergo negative selection to remove autoreactive T-cells and emerge from the thymus as mature $CD4^+$ and $CD8^+$ αβ T-cells. These cells take up residence in the periphery, ready to detect foreign antigens. The development of γδ T-cells parallels the above course but differs from it in significant ways (see below).

The positive and negative selection events that occur during αβ T-cell development ensure that an optimal T-cell repertoire is generated. Negative selection refers to the deletion by induced apoptosis of potentially self-reactive thymocytes; that is, those cells that strongly recognize self-peptide/MHC (pMHC) presented by thymic stromal cells. Positive selection refers to the differentiation of thymocytes that only weakly recognize self-pMHC (those cells that are more likely to recognize a set of foreign peptides presented on self-MHC). Positive selection thus generates a T-cell repertoire that is restricted to self-MHC (Bevan, 1977; Zinkernagel et al., 1978; Zinkernagel and Doherty, 1979), and negative selection ensures that that repertoire is self-tolerant (Kappler et al., 1987a, 1987b, 1988; MacDonald et al., 1988). γδ T-cells also undergo TCR-mediated selection events, but the outcome of this selection process appears to be geared for ligand recognition, which results in the functional maturation of different subsets of γδ T-cells (Hayes and Love, 2007; Jensen and Chien, 2009). Taken together, immunologists call the outcome of these processes "the establishment of *central tolerance and self-MHC-restriction.*" T-cell clones that recognize self-antigens but escape deletion or inactivation in the thymus are functionally inactivated in the periphery by mechanisms of *peripheral tolerance*.

THYMOCYTE DIFFERENTIATION

With this background in T-cell development, we are ready to examine thymocyte differentiation in detail. As we follow hematopoietic precursor cells on their journey from lymphocyte progenitors to developing thymocytes to mature T-cells, we will at times make reference to the gene-targeted mice whose phenotypes have helped to unravel the functions of various genes involved in this process (Mak et al., 2001; Yeung et al., 1994). These mutant animals were of key importance in establishing that T-cells mature through multiple genetic checkpoints (Fig. 4.2). For example, deletion of the TCRβ locus leads to a earlier block in thymocyte development, during Stage 1, than the deletion of the TCRα locus (Mombaerts et al., 1992a), which results in a block at Stage 2. These results helped define the two distinct points during which products of TCR gene rearrangement become necessary for further thymocyte differentiation. The signaling consequences of TCRβ or TCRαβ expression were revealed by the phenotype of Lck-deficient mice (Molina et al., 1992), which were found to have the similar defects as TCRβ-deficient animals. Lck signaling function had not been expected to be important at so early a stage because it was generally assumed that the TCR was not expressed on early thymocytes. The door was thus opened to the discovery of the pre-TCR signaling complex and a key checkpoint in T lymphopoiesis (Michie and Zúñiga-Pflücker, 2002; von Boehmer et al., 1999).

T-CELL DEVELOPMENT

All hematopoietic cells, including T-cells, originate from hematopoietic stem cells present in the fetal liver during embryonic development and in the bone marrow in adulthood.

According to the most widely accepted model of murine hematopoiesis, the process starts with the hematopoietic stem cell (HSC), which is capable of indefinite self-renewal in vivo and can reconstitute the complete spectrum of hematopoietic cells. HSCs, resident in the adult bone marrow, differentiate to give rise to downstream progenitors, which include cells with multipotent progenitor (MPP) function that have short-term reconstitution ability, as well as lineage-restricted progenitors such as lymphoid-primed multipotent progenitors (LMPP) (Adolfsson et al., 2005). These $Flt3^+$ multipotent progenitors retain limited self-renewal capacity and are able to differentiate into the full complement of myeloid cells and lymphoid cells, but not erythroid or megakaryocytic cells lineages. Upon release from the bone marrow into the blood, some LMPPs give rise to lymphoid progenitors that commence expression of the chemokine receptors CCR7, CCR9, and CXCR4 (Benz and Bleul, 2005; Takahama, 2006), as well as other receptors that mediate the receipt of recruitment signals, a combination of chemokine ligands and adhesion molecules, emanating from the cortical side of venules at the corticomedullary junction (CMJ) of the thymus (Fig. 4.3). Upon entering and seeding the thymus, these cells become known as "early thymic progenitors" (ETPs) and belong to the DN1a phase of Stage 1 of T-cell development (Fig. 4.2). These cells are critical for thymic structure and function, as this organ does not contain its own self-renewing stem cell population and depends on continuous colonization by bone marrow-derived ETPs to maintain its ongoing task of producing T-cells (Goldschneider et al., 1986; Petrie and Zuniga-Pflucker, 2007). Several different types of ETPs capable of seeding the thymus and committing to the T lineage have been identified (Porritt et al., 2004), but, due to their scarcity, their further characterization remains under investigation (Bhandoola et al., 2007; Saran et al., 2010).

THYMIC STRUCTURE AND FUNCTION

The mouse thymus makes its first appearance in the embryo between day E10.5 and E11.5, when the third pharyngeal pouch endoderm interacts with surrounding mesenchyme to form the thymic anlagen (Blackburn and Manley, 2004). At this stage, the organ is composed largely of immature or progenitor thymic epithelial cells (TECs), which later generate the cortical and medullary TEC subsets that establish the framework of the mature cortex and medulla regions of the thymus (Rossi et al., 2006). Under the influence of the chemokine CCL25 secreted by TECs, the first ETPs (which express CCL25's receptor CCR9) enter the thymic primordium at about E12 and colonize it. TECs also express P-selectin, an adhesion molecule that can bind to its ligand PSGL-1 expressed on ETPs (Rossi et al., 2005). This binding may be significant for the establishment of progenitors in the thymus, as the thymi of mice lacking PSGL-1 show very few thymocytes. Once in the thymus, the ETPs interact with TECs and receive survival, proliferation, and differentiation signals delivered by cytokines, Flt3, SCF and IL-7, and Notch ligands, Delta-like-4 (Petrie and Zuniga-Pflucker, 2007). Conversely, the ETPs deliver signals to TECs that are needed for the structural organization of the mature thymus (Klug et al., 1998, 2002). Additionally, the formation of a mature medulla relies on signals mediated by

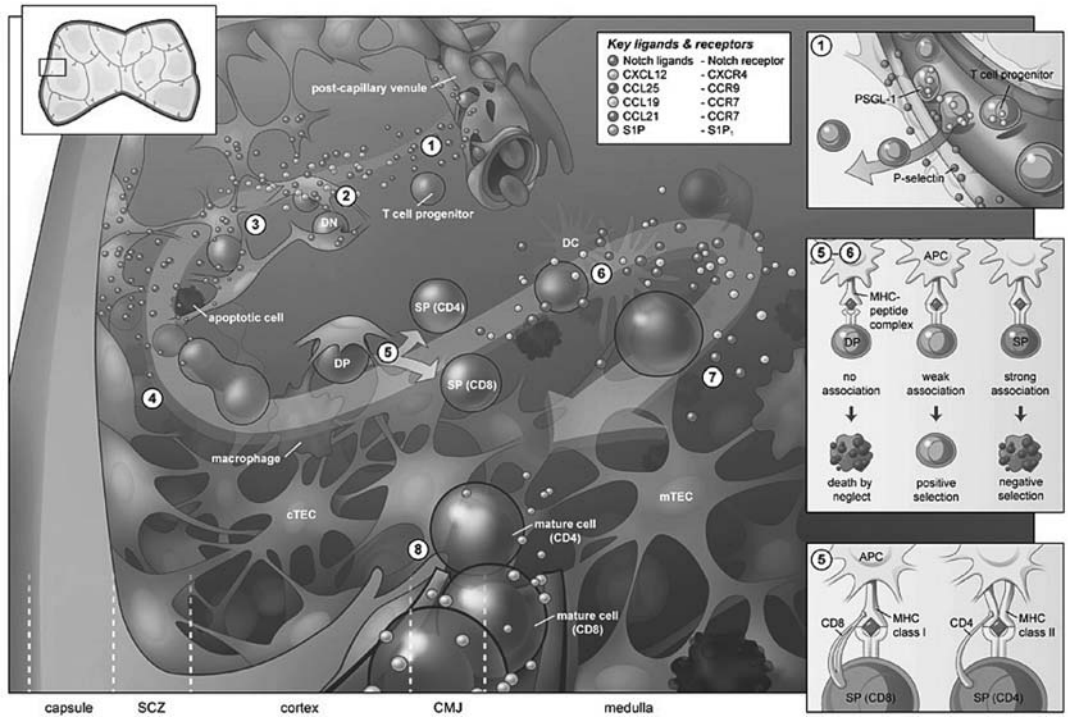

Figure 4.3 Intrathymic T-cell development, step by step. 1: Recruitment of T-cell progenitors; 2: Migration to cortex; 3: TCRβ locus rearrangement; 4: Rapid proliferation of post-β-selected DN cells, followed by TCRα rearrangement and CD4 and CD8 expression; 5: Positive selection, and CD4/CD8 lineage divergence; 6: CCR7-mediated migration to the medulla for negative selection; 7: Final maturation; and 8: Exportation of mature T-cells from the thymus. (See Color Plate.)

the TNF family member, RANKL, expressed by some thymocyte subsets (Hikosaka et al., 2008; Rossi et al., 2007). Several other molecules have been identified as being important for TEC development and/or function, such as FoxN1 (*Whn*), a transcription factor shown to be important for TEC development and the establishment of a normal thymic microenvironment (Blackburn and Manley, 2004; Nehls et al., 1994, 1996); see also Chapter 21.

The thymic microenvironment is absolutely crucial for the development of ETPs through all the stages of T-cell development (Fig. 4.3). *Nude* mice, which lack a thymus and mature TECs due to loss of function of the transcription factor FoxN1 (Blackburn and Manley, 2004; Nehls et al., 1994, 1996), also lack all T-cells. Moreover, specific regions of the thymus foster the progression of different stages of thymocyte development, giving rise to a complex migratory pattern of thymocytes within this organ (Takahama, 2006).

Step by Step, Moving Through the Thymus

In an adult thymus, thymus-seeding cells, which resemble LMPPs, exit the blood and arrive at the thymic CMJ are deemed to be DN1/ETPs thymocytes (refer to Fig. 4.3). With the support of cortical TECs (cTECs), the DN1 cells give rise to DN2 thymocytes and migrate into the center of the cortex, where commitment to the T lineage occurs (a process that can consume up to 2 weeks). The resulting DN3 thymocytes migrate further into the cortex and enter the subcapsular zone (SCZ), where the process of β-selection takes place (Fig. 4.3). The DN4 or pre-DP thymocytes emerging from this culling differentiate further into intermediate single positive (ISP) cells while still in the SCZ and outer cortex, but then migrate back through to the central cortex as they become DP thymocytes. The DP cells in the cortex encounter pMHC complexes presented by cTECs and undergo positive selection to ensure the survival of T-cells that recognize self-MHC. CD4/CD8 lineage commitment to generate early SP cells of both subsets then follows. These SP cells migrate out of the cortex into the medulla, coming into contact with medullary TECs (mTECs) and thymic DCs that enforce negative selection. The SP thymocytes that survive negative selection exit the medulla and enter the blood, becoming new and mature naïve T-cells that will home to the lymphoid organs (Petrie and Zuniga-Pflucker, 2007; Takahama, 2006).

Transcription Factors

The transcription factor PU.1 controls the expression of many cytokine receptors and thus controls the delivery of developmental signaling mediated by the corresponding cytokines (Rothenberg, 2007). In particular, PU.1 is required for the transcription of the IL-7 receptor (IL-7R) subunits needed to receive IL-7 signaling (see below). PU.1$^{-/-}$ mice lack not only T-cells but also B-cells, neutrophils, and macrophages (Singh et al., 1999). The level of PU.1 in a hematopoietic progenitor controls its destiny: low levels of PU.1 induce IL-7R expression and lymphoid development, whereas high levels of PU.1 suppress IL-7R expression and promote the expression of receptors for cytokines favoring myeloid development.

Ikaros is a transcription factor acting slightly later than PU.1 that is also required for lymphoid progenitor development (Rothenberg, 2007). Ikaros is thought to repress the transcription of "lineage-inappropriate" genes by recruiting histone deacetylases that reduce the chromatin accessibility of a locus (Georgopoulos, 2002). For example, CD19 (a B-cell-specific gene) is repressed in progenitors destined to become T-cells, whereas expression of CD4 and CD8 is repressed in precursors destined to become B-cells. A related transcription factor called Aiolos interacts with Ikaros to help establish T-lineage commitment and thymocyte expansion. Mice with reduced levels of Ikaros or Aiolos fail to later activate expression of the CD8α gene, leading to an apparent increase in immature T-cells expressing CD4. Another important transcription factor involved in the divergence of T-cell progenitors from B-cell progenitors is GATA-3 (Pai et al., 2003). GATA3$^{-/-}$ mice can produce B-cells but not even the earliest of thymocyte populations (Hare et al., 1999).

Cell-Fate Molecules

The Notch signaling pathway plays a role in almost all binary cell-fate decisions in a very wide range of organisms (Artavanis-Tsakonas et al., 1999). Interactions between the four mammalian Notch receptors (Notch1–4) and their five ligands (Jagged-1, Jagged-2, Delta-like-1, Delta-like-3, and Delta-like-4) mediate signaling between neighboring cells that leads to the regulation of transcription via direct association with transcription factors (Bray, 2006). Engagement of a Notch receptor by ligand results in proteolytic cleavage of the Notch protein by ADAM proteases and the release of Notch's intracellular domain (Notch-ICD). Of all the Notch receptors and ligands, only Notch-1 interaction with Delta-like ligands is involved in T-lineage specification (Jaleco et al., 2001), and continuous Notch-1 signaling is crucial for murine T-cell development from the earliest DN1 cells through to the DN3 stage (Schmitt et al., 2004). Indeed, a major lymphopoietic function of the thymic microenvironment is to supply ligands, in particular Delta-like-4 being the relevant ligands expressed by TECs (Hozumi et al., 2008; Koch et al., 2008), for Notch signaling (Radtke et al., 2004; Zuniga-Pflucker, 2004). Nevertheless, ectopic expression of Delta-like-1 by bone marrow stromal cell lines induces the differentiation of hematopoietic progenitors into αβ and γδ T-cells but not B-cells (Jaleco et al., 2001; Schmitt and Zuniga-Pflucker, 2002). Conversely, loss of Delta-like-4 expression in fresh ex vivo thymic stromal monolayers prevents them from supporting T-lineage development (Mohtashami and Zuniga-Pflucker, 2006).

In the absence of Notch-1 signaling, V to DJ recombination in the TCRβ locus is impaired and murine thymocyte development is halted at this stage (Wolfer et al., 2002). Moreover, rather than T-lineage cells, progenitors of NK cells or plasmacytoid dendritic cells (pDCs) may appear (Dontje et al., 2006; Schmitt et al., 2004). Notch-1 also interferes with the activity of the E2A transcription factor that facilitates transcription of B-cell-specific genes, blocking development down the B-cell path (Ikawa et al., 2006). Consistent with these findings, loss-of-function mutations of Notch-1 in newborn mice or in bone marrow stem cells result in a severe early block in T-cell

development and the appearance of ectopic B-cells in the thymus (Han et al., 2002; Koch et al., 2008; Radtke et al., 1999; Wilson et al., 2001). In addition, Notch-1 function can be manipulated to favor the development of B-cells in the thymus (Izon et al., 2002; Koch et al., 2001). Conversely, expression of a constitutively active form of Notch-1 in bone marrow stem cells results in the ectopic development of precursor T-cells outside the thymus (Allman et al., 2001; Pui et al., 1999).

Upon Notch-1 cleavage, Notch-ICD translocates to the nucleus and interacts with the RBPJ transcription factor, converting it from a repressor to an activator of genes involved in cell-fate decisions (Hsieh et al., 1996; Struhl and Adachi, 1998). Among the cell-fate genes influenced by Notch-ICD are the HES genes, which encode transcriptional repressors that act as downstream effectors in the Notch-1 signaling pathway. $HES^{-/-}$ mice have a small thymus, which is deficient in mature αβ and γδ T-cells (B and NK cells are normal). The major effect of HES may be on T-lineage progenitor survival and proliferation, as overexpression of Hes-1 in thymocytes enhances their growth (Kaneta et al., 2000) but depresses B-lineage cell numbers (Kawamata et al., 2002). Notch-ICD also recruits transcriptional co-activators of the "mastermind-like" (MamL) family (Bray, 2006). Overexpression of dominant negative (DN) MamL in hematopoietic progenitors results in aberrant lymphopoiesis in the thymus (Maillard et al., 2004). More recently, it has been demonstrated that murine ETPs lacking Mint, an inhibitor of Notch-1-mediated transcription, remain stuck at the DN1 stage (Tsuji et al., 2007), suggesting that the levels of Notch signaling must be appropriately coordinated to ensure proper induction of T-lineage commitment and differentiation.

Cytokines

Stem cell factor (SCF; also known as c-kit ligand) is a key cytokine that binds to c-kit tyrosine kinase receptor (CD117) and triggers signaling supporting the earliest stages of T lymphopoiesis (Rodewald et al., 1995). SCF is produced by TECs but the precise location of these cells in the thymus remains uncertain. SCF, which is required for the expansion of DN1 and DN2 cells but not DN3 cells (Massa et al., 2006), appears to maintain early T-lineage cells in a relatively undifferentiated state. SCF works in concert with low levels of IL-7 to promote the differentiation of HSCs into myriad cell lineages, including T-cells (Rodewald et al., 1997).

Morphogens

Morphogens are secreted molecules that regulate tissue patterning and organogenesis during embryogenesis. Important morphogens are members of the Wnt, Hedgehog, and bone morphogenetic protein (BMP) families. Although these molecules act as cell-fate specifiers in many tissues, they are not involved in this capacity in T-cell development. Rather, morphogens secreted by both thymic stromal cells and thymocytes themselves regulate survival and proliferation. In particular, Wnt is required for regulation of FoxN1 expression in TEC cell lines (Balciunaite et al., 2002) and for proliferative signals during the DN1–DN3 stages (Weerkamp et al., 2006). However, the involvement of the Wnt downstream target β-catenin during T-cell development remains under investigation (Cobas et al., 2004; Xu et al., 2003, 2009). The hedgehog morphogens are also expressed at high levels from the ETP stage until pre-TCR signaling during the DN3 stage (El Andaloussi et al., 2006). Mice deficient for sonic hedgehog have a thymus of reduced cellularity due to defects in DN1 and DN2 thymocyte proliferation (Shah et al., 2004). The BMPs appear to act as brakes on T-cell differentiation. BMP7 is expressed by thymocytes and thymic stromal cells, whereas BMP2 and BMP4 are expressed by stromal cells in the thymic medulla and SCZ (Graf et al., 2002; Hager-Theodorides et al., 2002). Signaling by these molecules is essential for the development of the thymic stroma (Bleul and Boehm, 2005) and modulates the expression of FoxN1 and chemokines by stromal cells (Tsai et al., 2003). With respect to T-cells, BMP2 and BMP4 promote the survival of DN1 cells but inhibit their proliferation and differentiation, and also block the DN4-to-DP transition.

THE DN1 STAGE

The earliest recognizable T-cell precursors belong to the DN1 subset (Figs. 4.2 and 4.3), which lack a TCR complex and co-receptors (and so are characterized as TCR/$CD3^{-}CD4^{-}CD8^{-}$), and have the following phenotype $CD117^{+}CD44^{+}CD25^{-}CD24^{-/lo}$ (Porritt et al., 2004). These cells, which constitute approximately 2 to 3 percent of all thymocytes, have the ability to home directly to the thymus after intravenous transfer into a host animal (Shortman, 1992). Entry of these cells into the thymus is facilitated by their expression of CCR7 and CCR9 chemokine receptors (Zlotoff et al., 2010), along with PSGL-1 (Rossi et al., 2005), which ensure homing and adhesion, respectively. DN1 cells typically reside in the thymic perimedullary cortex (PMC; the narrow band of cortex adjacent to the medulla) for about 10 days, during which time they proliferate vigorously and increase their numbers about 1,000-fold (Shortman et al., 1990). DN1 thymocytes have the differentiation potential to give rise to both αβ and γδ T-lineage cells, as well as other thymus-derived lineages such as certain DCs and NK cells (Bhandoola et al., 2007). DN1 cells subsequently upregulate expression of CD25 to become DN2 cells, and commence migration toward the outer thymic cortex under the influence of CXCL12, CCL19, and CCL21 produced by the cTECs. As pointed out above, Notch signaling plays an instructive role at this stage of differentiation, in which Notch-1 expressed on the DN1 cells engages Delta-like-4 on the cTECs to initiate the induction of T-cell lineage commitment (Rothenberg et al., 2008).

THE DN2 STAGE

DN2 cells show a surface phenotype of $CD117^{+}CD44^{+}CD25^{+}CD24^{hi}$. DN2 cells are also highly proliferative but have a more limited differentiation potential than DN1 cells, so that the T-precursor cell population expands (Petrie and Zuniga-Pflucker, 2007). Although early DN2 cells retain some capacity to develop into NK cells and certain DC

lineages, cTECs continue to deliver strong Notch signals favoring T-lineage commitment and differentiation (Schmitt et al., 2004). DN2 cells reside in the inner cortex and remain there for about 2 days (Porritt et al., 2003), while αβ:γδ lineage divergence commences due to activation of the RAG genes, which will lead to the rearrangement and generation of the TCRs that will ultimately influence the lineage choice. The DN2 cells start to express the pre-Tα chain in preparation for β-selection. The majority of DN2 cells retain potential to give rise to both αβ and γδ lineages, while some DN2 cells with early γδ TCR expression are committed to this lineage (Ciofani et al., 2006).

Cytokines

Although ETP/DN1 cells express only low levels of IL-7Rα (Allman et al., 2003; Porritt et al., 2004), IL-7 (in combination with Flt3-ligand and SCF, all expressed by TECs) is essential for the survival and maturation of the IL-7Rα-expressing DN2 and DN3 cells that follow them. The stromal cells producing this IL-7 are located mainly in the medulla and CMJ of the thymus (Griffith et al., 2009; Zamisch et al., 2005). Mice with disruptions of the genes encoding either IL-7 or the IL-7R subunits have defects in cell-cycle progression and exhibit an abrupt block in thymocyte development at the DN2 stage. If a transgene encoding the anti-apoptotic protein Bcl-2 is introduced into mice deficient in IL-7 or IL-7R, T-cell development can be rescued (Akashi et al., 1997; Maraskovsky et al., 1997; von Freeden-Jeffry et al., 1995). This result implies that a primary function of IL-7 is to maintain thymocyte survival, which is likely mediated by controlling the expression of the Bcl2-related gene, Mcl-1 (Opferman et al., 2003). Interestingly, in addition to its role in preventing apoptosis, signaling delivered through IL-7R is also important for γδ T-cell development. IL-7R$^{-/-}$ mice have decreased numbers of αβ T-cells but a complete absence of γδ T-cells due to a failure in TCRγ locus rearrangement (Laky et al., 2003; Maki et al., 1996). Introduction of an already rearranged TCRγ transgene can rescue γδ T-cell development in these animals (Kang et al., 1999). It was originally thought that signals initiated by IL-7 binding to IL-7R and transduced via the intermediaries Jak and STAT triggered changes to the accessibility of the TCRγ locus that are required for RAG recombinase binding (Schlissel et al., 2000). However, IL-7-deficient mice expressing a γδ TCR transgene still have a defect in T-cell development, implying that IL-7 continues to deliver essential survival signals to γδ T-cells (Laky et al., 2003).

Chemokines

The migration of DN1/ETP cells into the inner cortex to generate DN2 cells is essential for successful T-cell development, and the chemokine CXCL12 may drive this process. Late DN1 thymocytes express CXCR4, which binds to CXCL12 that is expressed by cTECs in the inner cortex (but not by mTECs) (Griffith et al., 2009). Interestingly, CXCL12-expressing cells are scattered throughout the inner cortex, so that recruitment is likely mediated by forces other than a concentration gradient (Pelletier et al., 2000).

THE DN3 STAGE

As DN2 thymocytes give rise to DN3 cells, they downregulate expression of CD117 and CD44 to become CD117$^{-/lo}$CD44$^{-/lo}$CD25^{+} cells (Figs. 4.2 and 4.3). Early DN3 cells reside in the outer cortex and stay in this location for about 2 days before moving to the SCZ and spending another day there (Porritt et al., 2003). It is at the DN3 stage that the final commitment to the αβ or γδ T lineage is made (Ciofani et al., 2006). Although both the αβ and γδ T lineages arise from the same DN progenitors, it is still not absolutely clear how the commitment decision is made due to the difficulty in distinguishing between these cells prior to TCR expression. However, high levels of IL-7R, along with Sox13, expression by DN2 cells may predispose them to adopt the γδ T-cell lineage (Kang et al., 2001; Melichar et al., 2007). Analyses of DN2 cells have indicated that lineage divergence commences at this point and is completed at the DN3 stage, depending on whether a pre-TCR (pTα/TCRβ) or a functional γδ TCR has been expressed on the cell surface (Ciofani et al., 2006). Thus, thymocytes at the DN2 to DN3 stages undergo RAG-mediated somatic recombination at the TCRβ, γ, and δ gene loci (Capone et al., 1998; Livak et al., 1999; Raulet et al., 1985). While only rearrangement of the TCRβ locus is required to initiate αβ T-cell maturation, both TCRγ and TCRδ must be productively rearranged to generate functional γδ T-cells. These is also strong evidence that the strength of the signal delivered via the pre-TCR or γδ TCR solidifies or mediates the commitment decision undertaken by DN2/DN3 thymocytes (Haks et al., 2005; Hayes et al., 2005; Kreslavsky et al., 2008).

Transcription Factors

Sox13 is a transcription factor that has been closely associated with DN2 cell precommitment and αβ:γδ lineage divergence (Melichar et al., 2007). In mice, deficiency for Sox13 impairs γδ T-cell development. Sox13 expression is highest among DN2 cells and drops off dramatically by the DN3 stage. Recently, it was shown that the differential activation of the extracellular signal-related kinase (ERK)-early growth response gene (Egr)-inhibitor of DNA binding 3 (Id3) pathway plays a defining role in mediated strong TCR signals leading to γδ-lineage commitment (Lauritsen et al., 2009). In particular, Id3 expression, a negative regulator of E2A function, served to regulate adoption of the γδ fate.

Cell-Fate Molecules

Expression of Notch-1 and Notch-3 is highest in DN3 cells (Taghon et al., 2006), consistent with an important role for these receptors in the αβ:γδ lineage decision. However, rather than driving a differentiation direction, Notch molecules appear instead to promote the survival and expansion of preselection DN3 thymocytes, and then are required only for the further differentiation of β-selected αβ-lineage cells (Ciofani et al., 2004; Ciofani and Zuniga-Pflucker, 2005, 2007). The key survival kinase Akt remains activated in DN3 cells in response to Notch signaling, and glucose and protein metabolism are bolstered in preparation for the energy-intensive events of αβ:γδ divergence.

Enzymes and Signaling Molecules

Because RAG1 and RAG2 are essential for the rearrangement of all TCR genes (Schatz et al., 1989), it is not surprising that mice deficient for either of these molecules have early defects in lymphocyte development (Mombaerts et al., 1992b; Shinkai et al., 1992, 1993). The thymi of RAG1- or RAG2-deficient mice contain a decreased number of total thymocytes (approximately 1 to 3×10^6 compared to about 1×10^8 thymocytes in normal mice), and T-cell development is arrested at the DN3 stage (Michie and Zúñiga-Pflücker, 2002). Similarly, mice with a natural mutation in the dsDNA-PK (*Prkdc*) gene show normal initiation of gene segment recombination but fail to ligate the segments together, resulting in a lack of mature T and B-cells (Kirchgessner et al., 1995). In contrast, mice with a mutation in the *Tdt* gene responsible for N-nucleotide addition do not show altered T-cell development (Gilfillan et al., 1993; Komori et al., 1993).

DN3 Thymocytes and β-Selection

In DN3 thymocytes destined to become αβ T-cells, the TCRα locus does not initiate rearrangement until considerably later than the other three loci. Instead, newly synthesized TCRβ chains pair with pre-Tα chains to form the pre-TCR. Pre-TCRs undergo testing to determine whether the TCRβ chain can function in a signaling complex (Michie and Zúñiga-Pflücker, 2002). Only DN3 pre-T-cells that have rearranged the TCRβ locus in-frame and have successfully combined it with the pre-Tα chain to form a functional pre-TCR on the thymocyte surface receive a signal permitting further development, a process called "β-selection" (Dudley et al., 1994; Hoffman et al., 1996). Within DN3 cells that are β-selected, further rearrangements of the TCRβ locus on both chromosomes are shut down, a process known as "allelic exclusion."

The survival signal associated with β-selection is mediated by activation of the transcription factor NF-κB, which controls the expression of numerous genes needed for staving off cell death and inducing proliferation (Voll et al., 2000). Cells that have rearranged the TCRβ locus out-of-frame do not receive the survival signal and are induced to undergo apoptosis (Malissen and Malissen, 1996). Thus, disruption of the pre-T gene leads to an arrest in TCRαβ thymocyte development at a phenotypic stage similar to that in TCR-deficient mice (Fehling et al., 1995). TCR-deficient mice have a small thymus due to an early block in T-cell development at the DN3 stage. The pTα/TCRβ complex undergoes self-oligomerization and assembles with the CD3 complex in the plasma membrane microdomains to deliver a cell-autonomous signal that "instructs" T precursors to divert down the αβ differentiation path (O'Shea et al., 1997; Yamasaki et al., 2006). Interestingly, pre-T-deficient mice exhibit normal development of γδ T-cells, indicating that the γδ T lineage diverges from the αβ T lineage at the point of pre-TCR expression (Fehling et al., 1995; Malissen and Malissen, 1996; Michie and Zúñiga-Pflücker, 2002).

In addition to the pre-Tα chain, pre-TCR signaling requires intact function of components of the CD3 complex, signal transduction molecules and adaptor molecules further downstream. For example, $CD3^{-/-}$ thymocytes, although still able to express rearranged TCRβ transcripts, are blocked at the DN3 stage (Malissen et al., 1995). These findings imply that CD3 expression is important for monitoring the productivity of TCR rearrangement by testing for pre-TCR signal transduction. Consistent with the association between pre-TCR signaling and αβ T commitment, rearrangements of TCR (*Tcrg*) and (*Tcrd*) gene segments are normal in $CD3^{-/-}$ mice. Mice deficient for CD3ζ show a profound reduction in the amount of surface TCRs on DP cells as well as a reduced number of thymocytes (Liu et al., 1993; Love et al., 1993; Malissen et al., 1993; Ohno et al., 1993; Shores et al., 1998). In the peripheral lymphoid organs of double mutant $CD3^{-/-}$ mice, abnormal $CD4^+CD8^-TCR\alpha\beta^+$ and $CD4^+CD8^+TCR\alpha\beta^+$ cells were present. Interestingly, the development of thymus-independent intestinal intraepithelial lymphocytes (IELs) occurred normally in these mice, and these IELs expressed TCRs complexed with the $Fc_\varepsilon RI_\gamma$ chain in the absence of CD3ζη (Love et al., 1993; Malissen et al., 1993).

Enzymes and Signaling Molecules

Lck kinase is important for β-selection. Mice either deficient for Lck kinase (Molina et al., 1992) or transgenic for a dominant-negative Lck mutation (Levin et al., 1993) exhibit a small thymus due to an early block in the maturation of both TCRαβ and TCRγδ thymocytes. Indeed, a transgene encoding a constitutively active form of Lck can fully replace defective pre-TCR signaling in RAG1-deficient mice (Mombaerts et al., 1994). Thus, the catalytic activity of Lck is crucial for the maturation of early β- and γδ-selected thymocytes. These results were confirmed using RAG complementation studies in which Lck was shown to be critical for signaling pathways activated by γ-irradiation and CD3ε engagement in $RAG\text{-}1^{-/-}$ immature thymocytes (Wu et al., 1996). However, a loss of Lck function during early thymocyte development and pre-TCR signal transduction can be compensated for by Fyn kinase. Mice deficient for Fyn kinase alone show no overt phenotypic changes in T-cell development (Appleby et al., 1992; Stein et al., 1992), but double Lck/Fyn-deficient mutants have a block at the DN3 stage that is more severe than that observed in Lck-deficient animals (Groves et al., 1996; Van Oers et al., 1996). Several other signaling molecules have been shown to be crucial at the DN3 stage for pre-TCR signaling and DN3 thymocyte maturation along the αβ-lineage, and these have been previously reviewed (Aifantis et al., 2006; Kruisbeek et al., 2000; Michie and Zúñiga-Pflücker, 2002).

Morphogens

Wnt signaling is crucial for the further maturation of αβ DN3 thymocytes (Fukushima et al., 2006; Gounari et al., 2001) but, interestingly, not for γδ DN3 thymocytes (Xu et al., 2003). There is some evidence suggesting that differential Wnt signaling may contribute to the αβ versus γδ lineage decision, since Sox13, which is specific regulator of γδ T-cell

differentiation, may antagonize downstream Wnt effectors (Melichar et al., 2007).

Chemokines

Early DN3 cells in the outer cortex are thought to be influenced by stromal cell-produced CCL25, which binds to CCR9. DN3 cells must express CCR9 to receive signals directing them to the SCZ prior to β-selection (Benz et al., 2004), and overexpression of CCR9 leads to an accumulation of DN3 cells (Uehara et al., 2002). CXCL12, which binds to CXCR4, is also important for DN3 cell migration within the cortex (Plotkin et al., 2003).

γδ DN3 Thymocytes

Murine γδ DN3 thymocytes are $CD25^-CD4^-CD8^-$ but express a complete γδ TCR rather than a molecule analogous to the pre-TCR of αβ DN3 thymocytes. Although this γδ TCR does not associate with either lipid microdomains in the plasma membrane or CD3ε (Saint-Ruf et al., 2000), it mediates the selection γδ DN3 thymocytes. The ligand(s) involved remain unclear (Jensen and Chien, 2009). However, studies employing a green fluorescent protein (GFP) reporter of TCRδ locus transcription in combination with γδ TCR surface expression showed that γδ TCR signaling is necessary for the survival and expansion of γδ DN3 thymocytes that eventually give rise to mature γδ T-cells (Prinz et al., 2006). These β-selection and γδ-selection processes are apparently independent, as mice with a targeted disruption of the TCR Cδ exon have no detectable cell surface expression of any γδ TCR components but display normal αβ T-cell development (Itohara et al., 1993). TCRδ-deficient mice are also able to mount normal antibody responses after immunization with ovalbumin, indicating that αβ T-helper cell function remains intact (Itohara et al., 1993). Conversely, development of γδ cells is unaffected by either *Tcra* or *Tcrb* mutations (Mombaerts et al., 1992a). The independence of the αβ versus γδ lineages is emphasized by the observation that γδ DN3 thymocytes exhibit a gene expression profile that is distinct from that of αβ DN3 thymocytes (Pennington et al., 2003, 2005; Silva-Santos et al., 2005). However, there is clear evidence that the two lineages influence each other's development in subtle ways, as γδ DN3 thymocytes developing in pre-TCR-deficient mice generate atypical γδ T-cells (Pennington et al., 2003; Silva-Santos et al., 2005).

Enzymes and Signaling Molecules

Lck kinase is also involved in the development of γδ DN3 thymocytes. The maturation of transgenic TCRγδ T-cells was followed in $Lck^{-/-}$ mice and found to be blocked at an early stage (Penninger et al., 1993). However, the development of these transgenic γδ T-cells did not require the co-expression of CD4 or CD8, indicating that the Lck/CD4 and Lck/CD8 associations normally observed in wild-type αβ T-cells are not essential for γδ T-cell development (Penninger et al., 1993). Surprisingly, as was true for CD3ζη-deficient mice, intestinal TCRγδ T-cells appeared to be unaffected by the Lck mutation (Penninger et al., 1993).

αβ DN4 OR PRE-DP THYMOCYTES AND THE IMMATURE SINGLE POSITIVE (ISP) STAGE

As β-selected murine DN3 thymocytes further evolve into DN4 cells or per-DP cells, expression of CD25 is lost and the cells become phenotypically $CD44^-CD25^-$. These cells undergo a dramatic expansion that requires the activities of the many transcription factors (e.g., Tcf-1, c-myc, and Notch; Ciofani and Zuniga-Pflucker, 2006; Douglas et al., 2001; Schilham and Clevers, 1998). DN4 cells that expand successfully then pass through the ISP stage, in which CD8 is transiently expressed on the cell surface but a mature TCR is not yet present (Nikolic-Zugic and Bevan, 1988; Nikolic-Zugic et al., 1989; Petrie et al., 1990).

Cell-Fate Molecules and Morphogens

Notch-1 signaling has been shown to be essential for the DN-to-DP transition, but once fully differentiated DP thymocytes express low levels of Notch-1 (Ciofani and Zuniga-Pflucker, 2006). In contrast, the morphogen sonic hedgehog acts on DN thymocytes to hold them at this stage of development (Outram et al., 2000). The transition to DP cells cannot occur until an unknown mechanism blocks sonic hedgehog signaling by thymic stromal cells.

Cytokines

DN3 thymocytes start to downregulate their expression of IL-7R after β-selection so that DN4 cells are refractory to IL-7 signaling, a state maintained into the DP stage that follows (Van De Wiele et al., 2004; Yu et al., 2006).

THE DP STAGE

By definition, DP thymocytes are those that express both CD4 and CD8. In the mouse, these cells reside throughout the thymic cortex for about 2 to 3 days (Egerton et al., 1990). It is thought that gene expression programs differ between the DN thymocytes resident in the cortex and the DP cells resident in the cortex, such that the stromal signals governing DN cells are not received by DP cells and vice versa (Petrie and Zuniga-Pflucker, 2007). In DP cells destined to become mature αβ T-cells, rearrangement of the TCRα locus occurs, and a complete TCRαβ heterodimer is finally expressed on the thymocyte surface. These DP cells then decrease their proliferation in a cell-intrinsic manner (Petrie, 2003) and are subjected to positive selection and CD4/CD8 lineage commitment as described below.

Co-receptor Expression

$CD4^+CD8^+$ DP thymocytes rearrange their TCRα (*Tcra*) locus to generate a functional TCRαβ heterodimer (Petrie et al., 1993). Mice with a disruption in the TCRα locus consequently show a later block in development than do TCRβ-deficient mice. TCRα-deficient animals have a normal-sized thymus and a marked absence only of $CD4^+$ and $CD8^+$ SP cells (Mombaerts et al., 1992a; Philpott et al., 1992). Interestingly, normal numbers of both DN and DP

thymocytes expressing TCRβ chains but not heterodimeric αβ TCRs exist in TCR$\alpha^{-/-}$ animals. In older TCRα-deficient mice, an unusual CD4^{+}TCRβ^{dull} lymphocyte population can be observed in the periphery that is even more apparent after the introduction of a TCRβ transgene (Philpott et al., 1992). These data indicate that, while TCRα is not required for the DN-to-DP transition and the subsequent expansion of the DP thymocyte pool, its expression (along with that of TCRβ) is required for the DP-to-SP transition. The TCRα locus does not undergo allelic exclusion like the TCRβ locus and $V_{\alpha}J_{\alpha}$ rearrangements may continue within a given cell (Petrie et al., 1993), such that two TCRs containing different TCRα chains may be expressed on the surface (Heath et al., 1995). More recently, it has been noted that the progression of $V_{\alpha}J_{\alpha}$ rearrangement is controlled by thymocyte survival in a way that regulates the T-cell repertoire (Guo et al., 2002).

As might be expected, CD4 and CD8 are crucial for DP thymocyte maturation (Zuniga-Pflucker et al., 1991). The CD8α chain is required for the surface expression of both CD8α and CD8β. Thus, in mice with a disrupted *Cd8a* gene, there is a total absence of CD8 expression on the T-cell surface (Fung-Leung et al., 1991, 1994). The vast majority of T-cells in the periphery of these mutants are CD4^{+} T-cells whose maturation appears normal. Cytotoxic responses to alloantigens are partly impaired whereas cytotoxic responses to virus infections are severely inhibited. Studies of CD8$\alpha^{-/-}$ mice transgenic for a CD8α chain bearing point mutations of the Lck binding domain showed that the Lck-associative function of CD8 is not essential for thymic selection (Chan et al., 1994a).

In mice with a disrupted *Cd8b* gene, the CD8α^{+} T-cell population in the thymus and in most peripheral lymphoid organs is reduced to 20 to 30 percent of normal, and CD8α expression on thymocytes is decreased to approximately 50 percent of normal (Fung-Leung et al., 1994). This defect does not extend to CD8αα-expressing IELs, which develop extrathymically (Guy-Grand et al., 1991). Thus, CD8 is important only for thymically derived CD8^{+} T-cells. The absence of CD8β reduces but does not completely abolish thymic maturation of CD8^{+} T-cells. Moreover, peripheral T-cells in CD8$^{-/-}$ mice display effective cytotoxic activity against virus infections, suggesting that CD8β is not essential for cytotoxic effector functions of CD8^{+} T-cells (Fung-Leung et al., 1994).

Mice with a disruption in the *Cd4* gene have markedly decreased T-helper cell activity but normal development and function of CD8^{+} T-cells. Thus, the expression of CD4 on progenitor cells and on DP thymocytes is not obligatory for the differentiation of CD8^{+} cytotoxic effectors (Killeen et al., 1993; Rahemtulla et al., 1991). Curiously, CD4$^{-/-}$ mice are still able to mount detectable T-helper cell responses. This residual T-helper activity has been attributed to a population of TCRαβ^{+}CD4–8^{-} T-cells present in peripheral lymphatic organs (Locksley et al., 1993; Rahemtulla et al., 1994).

Overview of Thymic Selection

Positive selection of murine DP thymocytes typically leads to the generation of mature CD4^{+} TCR^{high} helper or CD8^{+} TCR^{high} cytotoxic SP T-cells that are able to react to non-self while self-tolerant and self-MHC restricted (Starr et al., 2003). Negative selection of these SP populations then eliminates potentially harmful self-reactive T-cells (von Boehmer et al., 1989). The mechanisms governing thymic selection are dependent on physical interactions between the TCRs expressed on developing thymocytes and the pMHC complexes expressed on surrounding thymic stromal cells (such as TECs and thymic DCs). Studies of most animal models of thymic selection support an affinity/avidity mechanism for this process, in which the type of selection a thymocyte undergoes depends on the strength of the TCR–pMHC interaction (Starr et al., 2003). According to this model, thymocytes with TCRs of low affinity/avidity for self-MHC (regardless of the peptide that MHC has bound) do not receive any type of signal and undergo apoptosis by default. More than 80 percent of developing T-cells fall into this category. However, thymocytes expressing TCRs with intermediate affinity/avidity for self-MHC receive a survival signal and are positively selected (Starr et al., 2003). These TCRs are those most likely to recognize foreign peptides presented in the context of self-MHC and thus may be useful in host defense against pathogen infections. In contrast, thymocytes expressing TCRs with high affinity/avidity for self-peptide/self-MHC receive a signal that induces them to undergo either clonal deletion or clonal inactivation. This negative selection of thymocyte clones removes potentially self-reactive cells. The affinity/avidity model has been tested using fetal thymic organ culture in which the density of specific pMHC complexes has been titrated against specific outcome. A low concentration of the peptide antigen recognized by a transgenic TCR resulted in positive selection, whereas a high concentration of the peptide antigen resulted in negative selection and immunological tolerance (Ashton-Rickardt et al., 1994; Hogquist et al., 1994; Sebzda et al., 1994; Starr et al., 2003).

Positive Thymic Selection

Murine DP thymocytes entering the inner cortex encounter cTECs that present self-MHC molecules loaded with peptides from a broad range of self-determinants (Starr et al., 2003). DP cells whose TCRs bind to these pMHCs with moderate affinity receive a survival signal, whereas cells whose TCRs fail to recognize self-MHC do not receive such a signal and are said to "die of neglect."

Anti-apoptotic and Transcription Factors

Studies of transgenic and knockout mice have shown that the genes encoding the anti-apoptotic protein Bcl-X_L, RhoA GTPase, the transcription factors NFAT and c-Myb, the retinoid-related orphan receptor (RORγ), and members of the E family of regulatory proteins are important for DP thymocyte survival (Ciofani and Zuniga-Pflucker, 2006). Similarly, studies of mice transgenic for mutant NF-κB regulatory proteins that act as inhibitors have shown that this transcription factor is crucial for positive selection.

Enzymes and Signaling Molecules

Dominant-negative transgenes have been used to inhibit various molecules within the mitogen-activated protein kinase

(MAPK) pathways important for signaling downstream of the TCR, particularly extracellular signal-regulated kinase (ERK) (Alberola-Ila et al., 1995b, 1996; O'Shea et al., 1996; Swan et al., 1995). Positive selection is blocked in mutants lacking ERK function, leading to a significant reduction in mature SP thymocytes. These results have been confirmed in mice genetically deficient for ERK1 (Pages et al., 1999) or its upstream mediator RasGRP (Dower et al., 2000). Other evidence suggests that the level of ERK signaling as induced by TCR affinity/avidity for the pMHC complex in question determines positive versus negative selection (Bommhardt et al., 2000; Hogquist, 2001; Mariathasan et al., 2000, 2001). In situations of negative thymocyte selection, ERK activation is vigorous but short-lived, whereas positive selection generates weak ERK signaling that is sustained (Mariathasan et al., 2001; Werlen et al., 2000). In contrast to the MAPK pathways, the phospholipid- signaling pathway that is activated in mature T-cells following TCR engagement does not appear to be important for thymic selection of DP cells. Initial analysis of mice deficient for protein kinase C theta (PKCθ) suggested that this kinase does not play an essential role in either positive or negative selection (Sun et al., 2000); however, it plays an important role in TCR signaling (Marsland and Kopf, 2008). It also remains controversial whether calcineurin is important for positive or negative selection (Chan et al., 2002; Hayden-Martinez et al., 2000; Kane and Hedrick, 1996).

Receptor proximal signaling elements such as components of the CD3 complex, CD45, Lck, ZAP70, and Vav influence thymic selection. Although other CD3 chains are important for the DN stages of murine thymocyte differentiation (Sommers et al., 2000), CD3δ appears to act at the DP stage (Delgado et al., 2000). γδ T-cells are normal in Cd3δ-deficient mice (Dave et al., 1997), implying that CD3δ is specifically required for αβ DP positive selection. Similarly, a loss of CD45 blocks the transition of DP thymocytes to mature $CD4^+$ and $CD8^+$ SP cells (Byth et al., 1996; Kishihara et al., 1993). Vav1 regulates peptide-specific apoptosis in thymocytes and is required for both positive and negative selection (Kong et al., 1998; Turner et al., 1997). Mice deficient for ZAP70 have DP thymocytes but these cells do not progress to mature $CD4^+$ or $CD8^+$ SP cells and exhibit blocks in both positive and negative selection (Negishi et al., 1995).

The Tec family kinases are also involved in thymic selection. Several members of the Tec family, including Itk and Rlk, are important for setting the signaling thresholds of positive and negative selection (Blomberg et al., 2009; Liao and Littman, 1995; Schaeffer et al., 2000). Id3, a nuclear helix-loop-helix protein regulated by Itk, may play a role in positive selection. (Bain et al., 2001; Rivera et al., 2000).

Morphogens

Wnt signaling results in the activation of many factors required for the growth and survival of DP cells. C-fos, c-jun, Bcl-xL, and various integrins are among the many cell-cycle, survival, and cell adhesion molecules induced by Wnt (Ioannidis et al., 2001; Staal et al., 2004). In addition, Wnt signaling to its downstream target TCF controls CD4 expression in DP cells (Huang et al., 2006).

CD4/CD8 Lineage Commitment

The engagement of MHC class I or II during the positive selection of a DP thymocyte spurs it to extend its survival and differentiate into mature $CD8^+$ or $CD4^+$ SP cells, respectively. This process is called *CD4/CD8 lineage commitment*, and the most current model that provides an excellent framework for the mechanism underpinning CD4/CD8 lineage commitment is called the "kinetic signaling model" (Singer et al., 2008).

Precisely how a DP cell determines that it should become a $CD4^+$ SP or a $CD8^+$ SP cell is beginning to be elucidated (Singer et al., 2008), along with the key transcriptional controllers that are required to induce either lineage choice (Allen, 2009; Bosselut, 2004; Collins et al., 2009). Previous models proposed to account for CD4/CD8 lineage commitment fell into two camps: those based on an instructive mechanism versus those based on a stochastic (random choice) mechanism. The original instructive model proposed that differentiation into a CD4 or a CD8 cell was determined by engagement of the TCR plus CD4 or CD8 by either MHC class II or class I, respectively (von Boehmer, 1986). In other words, thymocytes recognizing MHC class I were instructed to differentiate into $CD8^+$ T-cells, while thymocytes expressing TCRs with affinity for MHC class II were instructed to become $CD4^+$ T-cells. Although initial results using TCR transgenic mice were consistent with this model, later analyses of various mutant mouse strains as well as additional TCR transgenic mice favored a stochastic mechanism (Chan et al., 1993; Davis et al., 1993; Itano et al., 1994; Kaye et al., 1989; Robey et al., 1994; van Meerwijk et al., 1995; von Boehmer, 1996). Subsets of $CD4^+8^{lo}$ and $CD4^{lo}8^+$ T-cells expressing intermediate levels of CD4 and CD8 were identified in different MHC-deficient mutant mouse strains, consistent with the idea that DP thymocytes randomly downregulate the expression of one or the other co-receptor as they move toward becoming mature $CD4^+8^-$ and $CD4^-8^+$ SP cells. This hypothesis was supported by findings that transgenic expression of CD4 in thymocytes could mediate development of $CD4^-8^+$ TCR transgenic cells in class I-deficient mice, and that transgenic expression of CD8 molecules could mediate development of $CD4^+8^-$ TCR Tg cells in class II-deficient mice (Baron et al., 1994; Chan et al., 1994b; Robey et al., 1994; van Meerwijk et al., 1995; von Boehmer, 1996). The stochastic mechanism of CD4/CD8 commitment was also supported by a study examining the deletion of a regulatory motif functioning as a silencer of CD4 expression (Leung et al., 2001). β2M-deficient mice, which usually have only very low numbers of $CD8^+$ T-cells, were transfected with a transgene conferring constant expression of CD4 due to the absence of the silencer. These mice contained mature T-cells, which expressed both CD4 and CD8 and exhibited MHC class II restriction. These cells developed into cytotoxic effectors after antigen stimulation.

The "co-receptor reversal" model, which later gave rise to the "kinetic signaling model," incorporates both stochastic and instructive elements (Brugnera et al., 2000; Sarafova et al., 2005). This model posits that CD8 expression is first downregulated in all DP thymocytes regardless of their MHC

restriction, so that all thymocytes initially become $CD4^+$ cells. These cells then upregulate IL-7R expression. Those thymocytes that subsequently receive both an IL-7 signal and a weak signal delivered by binding to MHC class I resume CD8 expression and downregulate CD4 expression, effectively "reversing" their prior $CD4^+$ phenotype to a $CD8^+$ phenotype (Park et al., 2010). However, those thymocytes that receive a signal through MHC class II maintain their CD4 expression and do not resume CD8 expression. In this case, stromal cells play a prominent role, both as secretors of IL-7 and as suppliers of the pMHC ligand.

Cell-Fate Molecules

Some studies had suggested that Notch-1 may contribute to CD4/CD8 lineage commitment, although its involvement is still the subject of much debate (Deftos and Bevan, 2000; Osborne and Miele, 1999; Robey, 1999; Tanigaki et al., 2004; von Boehmer, 2001). Robey et al. demonstrated that expression of an active form of Notch-1 in developing T-cells resulted in an increase in $CD8^+$ lineage cells and a decrease in $CD4^+$ lineage cells, even if MHC class I was absent (Robey, 1999; Robey et al., 1996). In addition, when Notch-1 signaling was blocked with antibodies, $CD8^+$ SP development was favored (Yasutomo et al., 2000a). Complementary studies revealed that the CD4 silencer that prevents CD4 expression in DN and CD8 SP thymocytes has an HES-1 binding site (Kim and Siu, 1998), and HES genes are known to be regulated by Notch-1 (Bray, 2006). However, other data have suggested that, rather than promoting only the development of $CD8^+$ SP cells, Notch-1 signaling is involved in the maturation of both CD4 and CD8 SP thymocytes (Deftos et al., 1998, 2000). Still others showed that Notch-1 may exert its effect indirectly, by reducing the strength of signal delivered through the TCR (Anderson et al., 2001; Izon et al., 2001). In this hypothesis, cells receiving high Notch-1 signals have reduced signaling through the TCR and consequently adopt the CD8 cell fate, whereas cells receiving lower Notch-1 signals have stronger TCR signals and become CD4 cells. In support of this notion, mice with a loss in Presenilin-1 and -2 function, which are critical for Notch signaling (Bray, 2006), showed a defect in CD4 lineage differentiation from DP cells (Laky and Fowlkes, 2007). However, mice with a conditional deficiency of Notch-1 signaling in thymocytes showed a normal ratio of intrathymic CD4:CD8 T-cells and no differentiation defects (Tanigaki et al., 2004; Wolfer et al., 2002). Thus, further experiments are still required to clarify the issue of how and/or whether Notch regulates CD4/CD8 lineage commitment.

Enzymes and Signaling Molecules

Lck signaling has been proposed as a mechanism of CD4/CD8 commitment because Lck associates with the cytoplasmic tails of both co-receptors (Turner et al., 1990). The model holds that strong Lck signaling helps to favor the differentiation of DP cells into $CD4^+$ SP cells, while little or no signaling results in $CD8^+$ SP cells (Hernandez-Hoyos et al., 2000). The amount of Lck signaling is determined by the MHC restriction of the TCR: MHC class I-restricted TCRs bind to CD8, which is associated with low levels of Lck activity, whereas MHC class II-restricted TCRs bind to CD4, which is associated with about 20-fold higher levels of Lck activity (Salmond et al., 2009). Experiments in which mutated CD8 molecules capable of binding different amounts of Lck were compared showed that the greater the amount of Lck bound to CD8, the more $CD4^+$ T-cells emerged from the DP population (Salmon et al., 1999). Yasutomo et al. devised an in vitro culture system that allowed them to monitor SP development following the binding of a TCR to either wild-type MHC class II (fully capable of binding Lck) or mutated MHC class II lacking the CD4 binding site (decreased Lck binding). In the absence of significant Lck binding, thymocyte differentiation was skewed to $CD8^+$ (Yasutomo et al., 2000b). The authors interpreted their data to mean that the duration of antigen signaling as transduced by Lck determines CD4/CD8 commitment. Additional evidence supporting a commitment model based on quantitative differences in Lck signaling has come out of transgenic studies in which constitutively active or dominant-negative mutants of Lck were used (Hernandez-Hoyos et al., 2000). Overexpression of Lck induced MHC class I-restricted thymocytes to develop into $CD4^+$ T-cells, whereas reduced levels of Lck drove MHC class II-restricted thymocytes down the $CD8^+$ path. Confirmation of these results has been obtained by the introduction of a transgene specifying tetracycline-inducible Lck expression into $Lck^{-/-}$ cells (Zamoyska et al., 2003). Induced expression of Lck resulted in high levels of Lck activity and the exclusive differentiation of $CD4^+$ T-cells. In an interesting twist to the role of Lck in CD4/CD8 lineage commitment, Singer et al. generated a mouse in which CD4, CD8, and class I and class II MHC were deleted (Van Laethem et al., 2007), with the intent to allow the TCR free access to Lck (Haughn et al., 1992)—that is, without Lck being restricted to CD4:MHC-II or CD8:MHC-I requirements for the TCR to have access to its function. In this quadruple knockout mouse, mature T-cells developed, but these were no longer MHC-restricted and appeared to have a CD4-like lineage outcome. This suggests that unrestricted access by TCR to Lck favors a CD4-lineage outcome, and that the normal role of the co-receptors is to ensure that self-MHC restriction is obeyed by tethering Lck availability to MHC recognition by the TCR (Van Laethem et al., 2007).

There is some evidence supporting a role for ERK signaling in CD4/CD8 lineage commitment. In one study, high levels of ERK signaling appeared to favor $CD4^+$ over $CD8^+$ SP development. Transfection of mice with a transgene encoding a constitutively active form of ERK resulted in increased numbers of $CD4^+$ thymocytes but decreased numbers of $CD8^+$ cells (Sharp et al., 1997). Consistent with this result, CD4 maturation was blocked by inhibition of ERK signaling, whereas CD8 development was enhanced (Bommhardt et al., 1999; Sharp and Hedrick, 1999). However, other studies have shown that CD8 differentiation can be blocked by deletion, inhibition, or interference with ERK activity (Alberola-Ila et al., 1995a; Mariathasan et al., 2000; Pages et al., 1999).

Interestingly, mice with a targeted disruption of the interferon regulatory factor 1 (IRF-1) gene have a block specifically

in the development of DP cells into CD8 SP thymocytes as well as a profound reduction in mature $CD8^+$ T-cells (Matsuyama et al., 1993). The development of $CD4^+$ T-cells is normal. IRF1 controls the expression of the *Tap* and other genes required for MHC class I loading, explaining part of the reduction in $CD8^+$ T-cells (White et al., 1996). However, there also appears to be a defect in selection that is intrinsic to $CD8^+$ thymocytes (Penninger et al., 1997).

Chemokines

DP cells that survive positive selection within the cortex and undergo CD4/CD8 lineage commitment become CD4 or CD8 SP cells in the medulla. These thymocytes upregulate their expression of CCR7 so that they can follow chemokine signals (including CCL19 and CCL21) that emanate from mTECs and lead them into the outer medulla (Uehara et al., 2002; Ueno et al., 2002, 2004). It is in this location that negative selection takes place (Fig. 4.3), removing SP thymocytes with autoreactive TCRs from the repertoire and establishing central tolerance (Starr et al., 2003; Takahama, 2006). Accordingly, CCR7-deficient mice exhibit SP cells that cannot migrate properly into the medulla (Ueno et al., 2004). These thymocytes escape negative selection, which is mediated within the medulla, such that autoreactive cells survive and cause the animals to develop autoimmune symptoms (Kurobe et al., 2006).

THE SP STAGE

Negative Thymic Selection

Thymocytes that have been positively selected and undergone CD4/CD8 lineage commitment to become either CD4 or CD8 SP cells migrate into the outer medulla, where they linger for 5 to 7 days (Egerton et al., 1990). Although it was clear by the early 1990s that negative selection of autoreactive thymocytes occurred in the thymus, it took considerably longer to identify the thymic stromal cell types responsible for presenting the selecting ligands and establishing central tolerance (Starr et al., 2003). In 2002, Kyewski et al. demonstrated that mTECs can transiently express a wide range of "housekeeping" and non-thymic tissue-specific proteins, allowing the deletion of reactive T-cell clones before their release to the periphery (Kyewski et al., 2002). mTECs express RNAs encoding tissue-restricted antigens, such as hormones, secreted proteins, membrane proteins, and transcription factors. Experiments in transgenic and nontransgenic mice have confirmed that ectopic expression of a protein by mTECs leads to tolerance of that protein (Anderson et al., 2002; Derbinski et al., 2001; Klein and Kyewski, 2000). Subsequently, it was shown that mTECs synthesize these tissue-restricted self-proteins in such a way that they are taken up by thymic DCs, which then present peptides derived from these antigens on self-MHC to SP thymocytes to induce negative selection (Kyewski and Derbinski, 2004). A TCR that binds tightly to such a pMHC triggers the apoptosis of the SP thymocyte, removing the self-reactive cell from the repertoire (Starr et al., 2003). Other evidence suggests that mTECs may also be involved in the differentiation of regulatory T-cells that can suppress autoimmune responses (Sakaguchi, 2000; Seddon and Mason, 2000).

It is not yet clear whether the expression of tissue-specific genes by mTECs is the result of random derepression of transcription or a more directed activation process. The influence of external factors on mTEC gene expression also remains a mystery. However, a transcription factor called AIRE (autoimmune regulator) appears to play a key controlling role in mTEC-induced central tolerance (Anderson et al., 2002). Both humans and mice deficient for AIRE suffer from autoimmune symptoms that affect multiple organs (Anderson et al., 2002; Bjorses et al., 1998; Ramsey et al., 2002); see also Chapter 31. Analysis of transcription by cells of AIRE-deficient mice showed that mTEC expression of several tissue-specific proteins associated with various autoimmune symptoms was reduced in the absence of AIRE. Furthermore, although the highest levels of AIRE expression occurred in mTECs, AIRE was not required for the differentiation or antigen-presenting function of mTECs. Studies of chimeric animals in which AIRE expression was missing either from hematopoietic cells or from stromal cells showed that peripheral autoimmunity was present only in the latter situation. AIRE is known to interact with the transcriptional co-activator CREB-binding protein (Pitkanen et al., 2000), and it has been suggested that AIRE may participate in a multi-subunit complex in mTECs that activates the transcription of multiple genes encoding tissue-specific proteins. The importance of AIRE for negative selection and tolerance induction in humans is evidenced by the autoimmune symptoms exhibited by patients with autoi mmune-polyendocrinopathy-candidiasis ectodermal dystrophy (APECED, Chapter 21) who have AIRE dysfunction (Aaltonen et al., 1997; Nagamine et al., 1997).

Enzymes and Signaling Molecules

Genes specifically associated with negative selection have been difficult to identify, although many have been implicated (Starr et al., 2003). The engagement of co-stimulatory molecules such as CD28 by binding partners on thymic stromal APCs has been shown to promote negative selection (Amsen and Kruisbeek, 1996; Punt et al., 1997). Interestingly, mice heterozygous for a null Grb2 mutation express subnormal levels of this adaptor and show impaired negative thymocyte selection (Gong et al., 2001). Positive selection is normal in these mutants. Based on the above findings, it has been proposed that negative selection may proceed to ERK activation via Grb2, but that positive selection takes a different route to ERK through RasGRP (Hogquist, 2001). Lck is necessary for the TCR-mediated clonal deletion underlying negative selection (Penninger et al., 1996).

Maturation of SP Cells in the Medulla

The SP thymocytes that emerge from successful positive and negative selection remain in the medulla for another 3 to 5 days, receiving IL-7–mediated survival signals and other stromal cell-derived maturation factors (Zamisch et al., 2005). These thymocytes are not yet functionally mature (Ramsdell et al., 1991), and while some go on to become SP T-cells suitable for

export to peripheral lymphoid tissues, others undergo alternative differentiation and become regulatory T-cells (Hsieh et al., 2006). Both the TCR and CD69 are thought to mediate signaling required for SP maturation, and thymic export may also play a role (Feng et al., 2002; Nakayama et al., 2002). Just prior to export, SP thymocytes in the deep medulla encounter mTECs presenting additional tissue-specific peripheral antigens so that tolerance induction is extended (Kurobe et al., 2006). These mTECs must have experienced signaling mediated by the lymphotoxin-β receptor to achieve the proper degree of differentiation needed to support normal thymic structure and tolerance induction (Boehm et al., 2003). It is after this point that the mature, naïve SP thymocytes leave the thymus at a precise location and via mechanisms that remain to be precisely determined.

CONCLUDING REMARKS

T-cell development is coordinated by the concerted actions of a variety of surface receptors, signal transduction molecules, and transcription factors. Both proper intrathymic localization and specific interactions between thymocytes and thymic epithelial cells and DCs are essential for proper T-cell development. Future challenges include elucidating the precise signals that draw T-cell progenitors into the thymus, orchestrate the coordinated maturation and migration within this organ, and direct the maturation of SP T-cells prior their exit to the periphery. Another task is to continue the refinement of in vitro culture systems for human hematopoietic cells so that human T-cell progenitors can more easily be derived from human HSCs in the future (Awong et al., 2007, 2009). These technologies, plus a greater understanding of T-cell development, will assist in the design of rational therapeutics for the treatment of cancer, autoimmunity, and chronic inflammatory diseases.

ACKNOWLEDGMENTS

We are grateful to Ms. Joyce Hui for allowing the use of her drawing depicting T-cell development, shown as Figure 4.3, and to N/N for expert editorial assistance in the preparation of this chapter.

5.

MOLECULAR MECHANISMS GUIDING B-CELL DEVELOPMENT

Antonius G. Rolink and Roxane Tussiwand

INTRODUCTION

B lymphocytes develop from hematopoietic stem cells. In the mouse, B-cell development takes place at different sites in the body during ontogeny, starting at day 8 to 8.5 of gestation in yolk sac and fetal aorta (Cumano et al., 1993; Godin et al., 1993; Palacios et al., 1984). When blood circulation begins at day 9 of gestation, B-cell precursors can still be found in the yolk sac and fetal aorta and, later, around days 10 to 11, in the liver, spleen, and omentum (Ogawa et al., 1988; Owen et al., 1975; Rolink and Melchers, 1991; Solvason and Kearney, 1992). From day 15 to 16 of gestation, B-cell precursors are also found in the bone marrow. After birth, the bone marrow becomes the major site for B lymphopoiesis (Hardy et al., 1991, Osmond, 1991; Rolink et al., 1993, 1994a).

The commitment to various cell lineages, including B-cells, occurs as multipotent hematopoietic stem cells progress through a cascade of several differentiation steps. The classical model of linage determination foresees a hierarchical differentiation, where lineage specification on the one hand progressively defines the commitment and on the other hand restricts other differentiation options.

A complex interplay between specific cytokines and environmental stimuli delivered by stromal cells, together with the gene-expression profile, will determine the developmental cues guiding multipotent progenitors towards a specific fate. B-cell development in mouse and human bone marrow from progenitor (pro) and precursor (pre) B-cells to immature and mature surface immunoglobulin (Ig)-positive B-cells is characterized by changes in:

- Rearrangement of the Ig heavy (IgH) and light (IgL) chain genes
- Expression of intracellular and surface-bound markers
- Cell-cycle status
- In vitro growth properties
- Life expectancy in vivo

Figure 5.1 summarizes the different stages of B-cell development and the markers expressed at the various stages.

TRANSCRIPTION FACTORS CONTROLLING B-CELL COMMITMENT

Various transcription factors have been shown, by loss- and gain-of-function experiments, to be required for early B-cell development (Matthias and Rolink, 2005). Phenotypic analysis of mice carrying deletions or overexpressing these transcription factors helped to order their requirement during B-cell development. In this section we will focus on the description of transcription factors involved in B-cell commitment.

E2A

The mouse E2A gene encodes for two different proteins of the E-box basic helix-loop-helix (bHLH) family, E12 and E47, which are generated by alternative splicing (Bain et al., 1994;, Zhuang et al., 1994). In B lymphocytes target sequences were found in the IgH and IgL chain enhancer regions (Bain et al., 1994; Zhuang et al., 1994). Despite the broad expression pattern among multipotent progenitors, targeted deletion of E2A leads exclusively to a B-cell deficiency. Almost no $B220^+$ cells are detectable in these mice, with a complete absence of DJ heavy chain rearrangement. Moreover, essential components involved in B-cell development like Rag-1, mb-1, Pax5, and λ5 are absent. In addition, overexpression of E2A in pre-T-cell

Figure 5.1 B-cell Development in the bone marrow. Expression of surface and intracellular markers at the different stages of B-cell development.

lines can induce transcription and rearrangement of the IgH chain locus (Schlissel et al., 1991). Collectively, E2A plays a fundamental role in B-cell commitment during early stages of B-cell development when other lineage options are still open.

EBF

A similar phenotype is observed in EBF-deficient mice. The transcriptional activator EBF, also called early B-cell factor, has an early B-cell-restricted tissue expression (Feldhaus et al., 1992; Hagman et al., 1991). Despite the similar phenotype observed in E2A- and EBF-deficient animals, EBF seems to act downstream of E2A, since reintroduction of EBF in E47 null progenitors restores B-cell differentiation (Seet et al., 2004). The suggested model of action for these transcription factors foresees the induction of EBF transcription by E2A, both of which promote Pax5 transcription, and by a feedback loop mechanism, Pax5 is able to reinforce and sustain EBF expression (Northrup and Allman, 2008; Roessler et al., 2007).

PAX5

The transcription factor Pax5, a homeodomain protein, is considered to be the master regulator of B-cell development that controls the commitment to the B-cell lineage by actively repressing the transcription of lineage-inappropriate genes while activating the expression of B-cell lineage-specific genes (Busslinger and Urbanek, 1995; Delogu et al., 2006; Nutt et al., 1999; Schebesta et al., 2007) As for E2A and EBF, also Pax5 deficiency leads to a specific B-cell defect. The block in B-cell development is downstream of the one seen in the absence of E2A and EBF, at the transition from pre-B-I (pro-B) to pre-B-II in the bone marrow. Pre-B-I cells are relatively normal in terms of cell numbers and display DJ heavy chain rearrangement on both alleles, and only proximal V-to-DJ rearrangement can be detected (Fuxa et al., 2004). Surprisingly, the levels of recombination-inducing gene products, such as Rag-1, Rag-2, and TdT, as well as those necessary for the expression of the pre-BCR, like VpreB and λ5, are normal in $Pax5^{-/-}$ pre-B-I cells (Busslinger and Urbanek, 1995). One of the known targets of Pax5 is CD19 (Urbanek et al., 1994), which is undetectable in $Pax5^{-/-}$ pre-B-I cells. However, the absence of CD19 expression cannot explain the $Pax5^{-/-}$ phenotype, since CD19 deficiency has a marginal influence on B-cell development in mice (Engel et al., 1995; Rickert et al., 1995). The defect related to Pax5 deficiency can also not be ascribed to other B-cell lineage-specific genes, since EBF and E2A transcription factors as well as Igα and Igβ B-cell co-receptors are detectable at similar amounts in wild-type and Pax5-deficient pre-B-I cells (Nutt et al., 1997; Schebesta et al., 2002). In contrast to wild-type cells, $Pax5^{-/-}$ pre-B-I cells can, under appropriate in vitro conditions, be driven toward other lineages, namely macrophages, T-cells, natural killer (NK) cells, granulocytes, osteoclasts, and dendritic cells (Busslinger, 2004; Nutt et al., 1999; Rolink et al., 1999b; Schebesta et al., 2002). Pax5-deficient, like wild-type, pre-B-I cells can be maintained indefinitely in vitro on stromal cells in the presence of IL-7 and upon transplantation into lethally irradiated host, can differentiate in vivo into all the above-mentioned lineages (Rolink et al., 1999b; Schaniel et al., 2002a). Moreover, $Pax5^{-/-}$ pre-B-I cells retain extensive self-renewal potential as well as multilineage differentiation capacity, characteristic of hematopoietic stem cells, as shown by serial transplantation experiments (Schaniel et al., 2002b).

The importance of Pax5 in the B-cell lineage is also evident by its maintained expression throughout the B-cell lineage until its downmodulation at the terminal differentiation into plasma cells (Fuxa et al., 2004). There is now broad consensus that Pax5 exerts its action in directing B-cell development by promoting V-to-DJ rearrangement at the heavy chain locus, by inducing expression of B-cell lineage-affiliated genes, and last but not least by repressing a large number of lineage-inappropriate genes (Delogu et al., 2006; Fuxa et al., 2004; Nutt et al., 1997; Pridans et al., 2008; Schebesta et al., 2007).

Recent work of Busslinger et al. introduced the idea that besides commitment, also maintenance of the lineage identity through a specific transcriptional profile is required on immature as well as on fully differentiated cells. They could show that the maintenance of the B-cell lineage is an active process that relies on the transcription factor Pax5. Induced inactivation of Pax5 in committed progenitors is able to induce their differentiation toward other lineages (Schebesta et al., 2007). Moreover, inactivation on mature B-cells induced their dedifferentiation into immature cells; which acquire on one hand self-renewal capacity and on the other hand the potential to differentiate into other lineages (Cobaleda et al., 2007). Gain- and loss-of-function experiments allowed researchers to unravel major mechanisms involved in the development of hematopoietic stem cells into the various lineages. A complex interplay between transcription factors, chemokines, cytokines, and environmental stimuli is needed to progress through development. Moreover, these recent experiments highlighted the possibility that besides a controlled development, also maintenance of a specific lineage identity relies on an active process. While the possibility of lineage conversion remains questionable under physiologic conditions, occurrence of transdifferentiation and dedifferentiation might be critical under diseased conditions.

DEVELOPMENTAL STAGES OF B-CELL DEVELOPMENT

B-cell development can be subdivided into distinct stages from a pro-B and a pre-B-cell to an immature and mature B-cell stage. The rearrangement of the IgH and IgL chain, the expression of intracellular and surface markers, the cell-cycle status, in vitro growth properties, and life expectancy in vivo are all characteristics used to define each stage of B-cell commitment. Figure 5.1 summarizes the early stages of B-cell development with the markers commonly used to identify each step. Upon successful rearrangement of a surface B-cell receptor (BCR), immature B-cells leave the bone marrow and enter the spleen to accomplish the final stages of differentiation into a mature naïve B-cell.

EARLY PROGENITOR OF LYMPHOID-MYELOID CELLS (EPLM) (ALSO CALLED PRE-PRO-B-CELLS)

The search for the physiological counterpart of Pax5-deficient pro-B-cells led to the identification of EPLMs (Balciunaite et al., 2005). EPLMs represent about 0.2 percent of all nucleated bone marrow cells. They are characterized by the expression of B220, CD43, CD135 (FLT3-R), CD127 (IL7R), and CD117 (c-Kit). These cells are contained within the "Fraction A" of Hardy's scheme of mouse B-cell development (Hardy et al., 1991). They are still negative for the B-cell lineage-specific marker CD19 and the IgH and IgL chain loci are still in germline configuration (Rolink et al., 1996). These cells retain various differentiation options as pointed out by the name EPLM, meaning they can give rise in vitro to B, T, and myeloid cells. Upon in vivo transfer, EPLMs were shown to be able to reconstitute the B- and T-cell compartment of immune-deficient mice. Moreover, they were shown to be highly responsive to the cytokine FLT3 ligand. In fact, the number of EPLMs seems to be controlled by the level of this cytokine, where high levels impair B-cell development (Ceredig et al., 2006).

PRE-B-I CELLS (ALSO CALLED PRO-B-CELLS)

EPLMs cells are the direct precursors of pre-B-I cells along the B-cell development pathway. Expression of E2A and EBF induces upregulation of the B-cell master transcription factor Pax5, making the generation of other lineages under physiological conditions rather unlikely. The transcription factor Pax5 induces the surface expression of CD19, the B-cell lineage-specific marker. Therefore, the phenotypic characterization by means of surface markers of pre-B-I cells is identified by the expression of CD117, CD43, and CD19. Besides the surface markers, other elements required for the B-cell lineage commitment start to be expressed at this stage of development: the surrogate light chain (SLC) encoded by the VpreB (gene name: *Vpreb1*, pre-B lymphocyte gene 1) and λ5 genes (gene name: *Igll1*, immunoglobulin lambda-like polypeptide 1) and specific elements of the recombination machinery: Rag-1, Rag-2, and terminal deoxynucleotidyl transferase (TdT) (Grawunder et al., 1995a, 1995b). Moreover, expression of CD135 is at this stage of differentiation lost.

It is at this stage of development that the IgH chain loci undergo their first rearrangement: DH-to-JH rearrangement (ten Boekel et al., 1995). Therefore, mutations affecting the recombination machinery were shown to drastically affect B-cell differentiation at this stage of commitment—that is, severe combined immunodeficiency (SCID) (Bosma et al., 1983), Rag-1 (Mombaerts et al., 1992), and Rag-2 (Shinkai et al., 1992). The same phenotype is also observed in mice that cannot undergo IgH chain rearrangements (J-heavy chain-deficient mice) (Chen et al., 1993).

Pre-B-I cells share with EPLMs the ability to proliferate on stromal cells in the presence of IL-7 (Rolink et al., 1991, 1993; Winkler et al., 1995). Upon in vivo transfer in Rag-2-deficient mice, pre-B-I cells are able to partially reconstitute only the B-cell compartment (Reininger et al., 1992; Rolink et al., 1991, 1994b), indicating that at this stage of development the commitment toward the B-cell lineage has occurred.

In addition to cell intrinsic signals, differentiation, survival, as well as proliferation of B-cell progenitors are regulated by the surrounding environment. The growth factor IL-7 and

its receptor were shown to play a crucial role at this stage of mouse B-cell development. This is best exemplified by a major defect at this early stage of development in mice deficient for the receptor or the cytokine (Peschon et al., 1994; von Freeden-Jeffry et al., 1995). The mechanism by which IL-7 influences B-cell lineage differentiation is probably through increased proliferation and survival.

PRE-B-II

The next developmental stage along the B-cell lineage is characterized by cytoplasmic μ heavy chain expression, which defines the pre-B-II cells (see Fig. 5.1)—that is, they have undergone a productive VDJ rearrangement. Moreover, this cell subset has lost the surface expression of CD117, while most of them gained CD25 expression (Rolink et al., 1994a). Pre-B-II cells can be further subdivided into two different subsets, large and small pre-B-II.

Large pre-B-cells are actively cycling and express on their surface the pre-B-cell receptor (pre-BCR), consisting of the rearranged μ heavy chain in association with the surrogate light chain products (Karasuyama et al., 1996; Rolink et al., 1994a; Winkler et al., 1995). At this stage of development, the recombination machinery is switched off and these cells do not express Rag-1 and Rag-2. Their Ig light chain loci are still in germline configuration and are not yet transcriptionally active (Grawunder et al., 1995a; ten Boekel et al., 1995). It is exactly at this stage of development that allelic exclusion of the second heavy chain allele is likely to be established (Grawunder et al., 1995a).

The importance of this developmental stage, especially the surface expression of the pre-BCR, is best exemplified by mutants where components of the surrogate light chain or the signaling pathway are defective. In mice with a deletion in the transmembrane portion of their μ heavy chain, or deficient for the surrogate light chain components (λ5 or VpreB), large cycling pre-B-II cells are not detectable, resulting in a drastic reduction of small pre-B-cells (Kitamura et al., 1991, 1992; Kitamura and Rajewsky, 1992; Mundt et al., 2001). A similar phenotype is found in mice carrying a deletion in the gene encoding for Igβ (Gong and Nussenzweig, 1996), suggesting that the association between the pre-BCR with Igα and Igβ and thus signaling via the pre-BCR is required for the transition from pre-B-I to pre-B-II cells. In line with this, mice defective for the tyrosine kinase Syk as well as for the adaptor protein BLNK display a block at this early stage of B-cell development, indicating that these are crucial components of the pre-BCR signaling complex (Cheng et al., 1995; Hayashi et al., 2000; Jumaa et al., 1999; Pappu et al., 1999; Turner et al., 1995). The importance of pre-BCR is also evident in experiments in which Rag-1- or Rag-2-deficient mice are supplemented with a transgenic μ heavy chain (Rolink et al., 1994a; Spanopoulou et al., 1994; Young et al., 1994). Rag-1- or Rag-2-deficient mice display a block at the pre-B-I cell stage. However, supplementation with a transgenic rearranged μ heavy chain allows B-cell development to progress up to the small pre-B-II cell stage. Thus, surface expression and signaling via the pre-BCR ensures a proliferative expansion that constitutes a positive selection for pre-B-cells with a productive VDJ rearrangement.

We have shown that this pre-BCR-mediated selection and expansion can be mimicked in vitro. Sorted pre-B-I cells of wild-type mouse cultured in vitro without the addition of cytokines were selected for productive VDJ rearrangement (Rolink et al., 2000). By day 5 of culture, 70 to 80 percent of the recovered cells expressed surface IgM, whereas no expansion and/or selection was observed in pre-B-I cells of λ5-deficient mice. Moreover, single-cell experiments indicated that in wild-type mice approximately 15 percent of pre-B-I cells were able to be selected and expanded. The fact that single ex vivo isolated pre-B-I cells proliferated to different clone sizes in vitro may indicate that the fitness of the different pre-BCRs, by means of pairing ability to the surrogate light chain and the tonic signal delivered, might determine their extent of proliferation and expansion. Moreover, these experiments suggest that the pre-BCR exerts its function in a ligand-independent fashion. Recently it was also shown that pre-BCR signaling downmodulates transcription of the surrogate light chain genes encoding VpreB and λ5 (Parker et al., 2005) and thereby extinguishes its own expression.

The next developmental stage identifies large, cycling pre-B-II cells in which the expression of the surrogate light chain is lost (Karasuyama et al., 1996; Rolink et al., 1994a; Winkler et al., 1995). At this stage of developmenT-cells reactivate the expression of Rag-1 and Rag-2 at the mRNA level but not yet at the protein level (Grawunder et al., 1995a). Moreover, sterile transcripts of the light chain locus become detectable, although it is still in germline configuration (ten Boekel et al., 1995; Yamagami et al., 1999a, 1999b).

When the large cycling pre-B-II cells become resting and small, the recombination machinery is active, the light chain locus is rearranged, and a large proportion of the cells carry rearranged light chain genes (ten Boekel et al., 1995; Yamagami et al., 1999a, 1999b). Experiments by Engel et al. (1995) and Goldmit et al. (2005) suggest that chromatin structural changes rendering the Ig light chain locus accessible for VJ recombination occur earlier within the κ-light chain locus than within the λ-light chain locus. In wild-type mice about half of the Ig-positive B-cells have rearranged only one allele at the κ-light chain locus. Most of these cells show only a single rearrangement, preferentially Jκ1, the most V proximal of the functional J segments. In marked contrast, small pre-B-II cells show a dramatically increased frequency of multiple κ-light chain rearrangements (Yamagami et al., 1999a, 1999b). Moreover, about 20 percent of small pre-B-II cells express a cytoplasmic κ-light chain that is not transferred to the cell surface, although half of the cells have productively rearranged VκJκ segments. This lack of surface BCR expression can be explained by an inefficient pairing of the produced light chain with the already present heavy chain, or the produced BCR might be autoreactive and therefore downregulated. Upon productive light chain rearrangement and efficient pairing with the heavy chain, small pre-B-II cells become surface IgM-positive immature bone marrow B-cells.

IMMATURE B-CELLS

Osmond et al. have determined that an adult mouse produces about 2×10^7 immature B-cells per day (Osmond, 1991, 1993). Immature B-cells are characterized, besides sIgM, by the expression of CD93, recognized by the monoclonal antibodies 493 and AA4.1 (Petrenko et al., 1999; Rolink et al., 1998, 1999a, 2001). At this stage of development B-cells are screened for the expression of an autoreactive BCR. The selection process that occurs will be discussed in detail later. Those immature B-cells that survive this selection process (positive selected ones) will then migrate to the spleen. However, in an adult mouse only about 2×10^6 immature B-cells enter the spleen per day, indicating that 90 percent of them get lost during this transition (Osmond, 1991, 1993; Rolink et al., 1998; Tussiwand et al., 2009). A large part of this loss is likely due to deletion of autoreactive B-cells. Moreover, the quality of the produced BCR and thus its ability to signal also seems to play a crucial role in this transition. This is best exemplified by the fact that Syk-deficient mice and mice expressing a cytoplasmic deleted form of the Igα show a great loss at this stage of B-cell development (Torres et al., 1996; Turner et al., 1995). Moreover, the finding that in CD45-deficient mice more immature B-cells enter the spleen might indicate that the phosphatase CD45 is critically involved in signaling thresholds (Rolink et al., 1999a, 2001).

Also, other mutations were shown to affect the transition of immature B-cells from bone marrow to the spleen. Mice deficient for the transcriptional co-activator OBF show a severe reduction of immature B-cells in the spleen (Schubart et al., 1996). This reduction is even more pronounced in OBF/Oct-2 and OBF/Btk double deficient mice (Schubart et al., 1996, 2001), although molecular mechanisms underlying these defects are still unclear. Overexpression of the anti-apoptotic gene *Bc12* can overcome these defects, which is an indication that survival plays a crucial role in the transition from the bone marrow to the spleen.

TRANSITIONAL B-CELLS

Within the spleen immature B-cells, referred to as transitional B-cells, can be distinguished from their mature counterpart by the expression of CD93 (Rolink et al., 1998). Transitional B-cells can be subdivided into transitional type 1, 2, and 3 (T1, T2, and T3, respectively) according to the expression of CD21, CD23, IgM, and IgD. Figure 5.2 summarizes the different surface markers commonly used to identify the different B-cell subsets present in the spleen. Transitional B-cells are thought to be the direct precursors of the mature naïve B-cells. However, a recent report suggested that T3 cells might represent an anergic B-cell pool (Merrell et al., 2006).

Transitional B-cells are further characterized by their high turnover and their sensitivity to undergo apoptosis upon BCR cross-linking. The latter suggests that also at this stage of development negative selection can still take place (Allman et al., 1992, 1993; Rolink et al., 1998). Some in vivo studies indicated that a significant deletion can occur within the transitional B-cell pool (Allman et al., 1993). On the other hand, turnover studies showed a limited loss of cells along the progression from transitional to naïve mature B-cells. Therefore, the real amount of B-cells that are deleted at this point of differentiation still remains to be determined.

Several mutations affecting this stage of development or the progression to mature B-cells have been identified. Btk-deficient mice have normal numbers of immature splenic B-cells but show a five-fold reduction within the mature compartment. However, the transcriptome of the T1 population is significantly altered in Btk-defective mice (Lindvall et al., 2006). Since the lifespan of mature B-cells in these mice is comparable to wild-type mice, the defect might reflect a reduced transition to the mature compartment (Rolink et al., 1999a). Also in this case increased survival provided by a *Bc12* transgene is able to rescue the phenotype, suggesting that the signaling threshold determines the survival of these transitional B-cell subsets, which is crucial for allowing their differentiation into the pool of long-lived mature B-cells.

The major histocompatibility complex (MHC) class II was also shown to be involved in the transition from immature to mature B-cells in the spleen, but the underlying mechanism is still unclear (Rolink et al., 1999a; Shachar and Flavell, 1996).

The transition from immature to mature B-cells in the spleen is regulated by B-cell activating factor (BAFF) and its receptor. Thus, BAFF- and BAFF-R-deficient mice show a block in the T1-to-T2 B-cell differentiation (Sasaki et al., 2004; Schiemann et al., 2001; Shulga-Morskaya et al., 2004; Yan et al., 2001). BAFF (also termed TALL-1, THANK, BlyS, and zTNF4) is a member of the TNF family (Mackay et al., 2003). It can bind to three different receptors: to BAFF-R, to TACI (transmembrane activator and CAML interactor), and, with lower affinity, to BCMA (B-cell maturation antigen). BAFF-R was shown to be expressed from transitional B-cells up to all mature B-cell subsets, and it is during the transition from T1 to T2 that B-cells become dependent on BAFF–BAFF-R signaling. The binding of BAFF to BAFF-R leads to NF-κB activation mainly through the alternative pathway and ultimately to the upregulation of anti-apoptotic proteins (Sasaki et al., 2006; Tardivel et al., 2004). It is reasonable to assume that interplay between the signaling mediated by the BCR, through the canonical NF-κB pathway, and by BAFF-R through the alternative NF-κB pathway determines the survival and the differentiation of immature B-cell into the mature pool. In vitro studies have shown that immature splenic B-cells treated with BAFF acquire a mature phenotype and become resistant to BCR-cross-linking-induced apoptosis (Batten et al., 2000; Rolink and Melchers, 2002; Rolink et al., 2002). Nevertheless, whether BAFF is necessary for promoting the survival of T2 cells or whether it plays an instructive role during the transition to mature B-cells remains an open question. The defect of BAFF-R deficiency could be rescued by Bcl-2 overexpression, suggesting a survival role for transitional and follicular B-cells (Sasaki et al., 2006; Tardivel et al., 2004). However, since marginal-zone B-cells could not be detected in these mice, an instructive role during marginal-zone B-cell development is likely mediated by BAFF–BAFF-R signaling (Tardivel et al., 2004).

	T1	T2	T3	MZ	B2
IgM	high	high	low	high	low
IgD	low	low	high	low	high
493	+	+	+	–	–
CD21	–	+	+	+	+
CD23	–	+	+	–	+

Figure 5.2 B-cell development in the Spleen. Surface marker expression of different B-cell subsets in the spleen.

MATURE B-CELLS

The mature B-cell compartment can be subdivided into three different subsets: B-1, B-2, and marginal-zone B-cells. Mature B-cells as compared to transitional B-cells in the spleen have lost the expression of CD93, are long-lived, and upon antigenic and mitogenic stimulation respond by proliferation and maturation into Ig-secreting cells (Rolink et al., 1998).

The different mature B-cell compartments are localized within specific microenvironments in the body. Thus, B-1 cells are primarily found in the peritoneal cavity (Hardy and Hayakawa, 2001); B-2 cells are found in the circulation and in the primary follicles of secondary lymphoid organs; while marginal-zone B-cells, as specified by the name, localize in the marginal zone of the spleen, which surrounds the primary follicles (Dammers et al., 1999; Martin et al., 2001).

B-1 cells have a self-renewing potential and are mainly derived from fetal liver stem cells (Hayakawa et al., 2003). The B-1 B-cell subset is the only one that does not require BAFF–BAFF-R signaling for development (Sasaki et al., 2004; Schiemann et al., 2001; Yan et al., 2001). It is responsible for the production of so-called natural antibodies and largely contributes to the T-cell-independent antibody response (Coutinho et al., 1995). The BCR repertoire of B-1 cells was shown to display low affinity for self-antigens, and several studies showed that a low-affinity BCR for self-antigens might drive developing B-cells toward this subset (Hardy and Hayakawa, 2001; Hayakawa et al., 1999).

Marginal-zone B-cells show an activated phenotype as compared to B-2 B-cells; they respond faster and better upon Toll-like receptors triggering (Martin et al., 2001). Moreover, it was shown that marginal-zone B-cells are responsible for the production of the first wave of low-affinity IgM antibodies against bloodborne pathogens (Lopes-Carvalho and Kearney, 2004). Both B-1 and marginal-zone B-cells preferentially respond to T-cell-independent antigens; nevertheless, marginal-zone B-cells can participate in T-cell-dependent antigen responses. As for B-1 cells, the specificity of the BCR might direct developing B-cells into the marginal-zone B-cell lineage (Casola et al., 2004). Moreover, the differentiation of marginal-zone B-cells strictly requires BAFF–BAFF-R signaling, as shown by their complete absence in BAFF- as well as BAFF-R-deficient mice (Sasaki et al., 2004; Tardivel et al., 2004). Besides BAFF, Notch signaling was also shown to be essential for their development; targeted deletion of Notch2 as well as Delta-like-1 results in impaired marginal-zone B-cell compartment without affecting other mature B-cell subsets (Hozumi et al., 2004; Saito et al., 2003). Moreover, Tanigaki et al. (2002) showed that RBP-J, a signaling adaptor protein for all four mammalian Notch receptors, is essential for marginal-zone B-cell development. Conversely, in irradiated Rag-2-deficient mice reconstituted with bone marrow from mice deficient for the negative regulator of Notch signaling MINT, marginal-zone B-cells develop preferentially (Kuroda et al., 2003).

The vast majority of mature B-cells belong to the B-2 B-cell subset. B-2 cells or follicular B-cells are small and resting. They are primarily responsible for T-cell-dependent antibody response and differentiate upon antigenic stimulation into antibody-secreting plasma and memory B-cells. Like B-1 and marginal-zone B-cells, also follicular B-cell development might be influenced by the BCR expressed by the differentiating clone. Several studies showed that mutations causing a weakening of BCR signaling affected the formation of B-1 B-cells but not of B-2 and marginal-zone B-cells (Cariappa and Pillai, 2002; Hardy and Hayakawa, 2001). Moreover, evidence that the expressed BCR might influence the developmental direction toward one or the other B-cell lineage arises from experiments by Rajewsky et al. (Casola et al., 2004), yet direct experimental proof for this is not available.

While on one hand BCR specificity might influence the developmental fate of B-cells, the expression of a signaling competent BCR is required for the maintenance of all three subsets upon maturation (Kraus et al., 2004; Lam et al., 1997). Conditional deletion of the BCR is inducing apoptosis in mature B-cells, suggesting that signaling fitness through tonic BCR signaling is maintaining the pool of mature B-cells. Recent evidence showed that besides playing a crucial role during B-cell development, BAFF–BAFF-R signaling is also required for the maintenance of mature B-cells (Rauch et al., 2009). However, BAFF–BAFF-R signaling plays a crucial role not only in B-cell development and homeostasis but also in B-cell tolerance. It has been shown that mice overexpressing BAFF develop a lupus-like disease (Batten, 2000; Gross, 2000; Khare, 2000; Mackay, 1999). Moreover, elevated BAFF serum levels have been found in patients with autoimmune diseases in which B-cells play an important role (Cheema, 2001; Zhang, 2001). Studies aimed at elucidating the mechanisms by which overexpression of BAFF can result in loss of B-cell tolerance showed that BAFF overexpression does not interfere with the central tolerance program in the bone marrow but rather prevents autoreactive B-cells from being anergized in the periphery (Thien, 2004). Currently, the potential of neutralizing BAFF as a therapy for autoimmunity is being tested both in mouse and clinical settings.

TOLERANCE CHECKPOINTS DURING B-CELL DEVELOPMENT

LARGE PRE-B-II CELLS

At the large-pre-B-II stage of B-cell development, the pre-BCR consisting of the surrogate light chain components, λ5 and VpreB, and the μH chain is expressed. Cells that have undergone a successful V-to-DJ recombination are selected, and the expression of the pre-BCR mediates their proliferative expansion (Bradl and Jack, 2001; Bradl et al., 2003; Ehlich et al., 1994; Gauthier et al., 2002; Melchers et al., 2000; Rolink et al., 2000; ten Boekel et al., 1995; Vettermann et al., 2008). In mice lacking the surrogate light chain components and thus unable to express the pre-BCR, this selection and expansion process fails to operate, resulting in the generation of fewer immature and mature B-cells (Ehlich et al., 1994; Harfst et al., 2005; Melchers et al., 2000; Rolink et al., 2000; Shimizu et al., 2002). Nevertheless, serum antibodies are at normal levels and moreover these mice are able to mount T-cell-dependent and -independent humoral immune responses (Harfst et al., 2005).

Recently it was shown that despite the absence of obvious pathology, surrogate light chain-deficient mice have elevated levels of IgG antinuclear autoantibodies in their serum (Keenan et al., 2008). Thus, autoreactive B-cells can escape negative selection in the absence of the pre-BCR checkpoint. Whether this leakiness in tolerance induction is mediated directly by the pre-BCR, in that pre-B-cells expressing an autoreactive μH chain are deleted at the pre-BCR positive stage of development, or indirectly, by autoreactive B-cells escaping negative selection more readily in situations of reduced B-cell generation, as is the case in pre-BCR-deficient mice, is still open for clarification.

The peripheral mature B-cell compartment in surrogate light chain-deficient mice is about 20 percent the size of that in wild-type mice (Harfst et al., 2005; Shimizu et al., 2002). Moreover, the turnover of mature B-cells in pre-BCR-deficient mice in comparison to wild-type mice is largely reduced (Harfst et al., 2005). Thus, competition for newly formed B-cells to enter the peripheral B-cell pool is far less in surrogate light chain-deficient mice than in wild-type mice. Therefore, it could be envisaged that negative selection of immature autoreactive B-cells in the bone marrow of these mice is less stringent, resulting in higher titers of autoantibodies.

At this point it is worthwhile noting that in humans, as well as in mice, B-cell production in the bone marrow decreases with age and correlates with an increased incidence of autoantibodies in the serum (Dorshkind et al., 2009; Ghia et al., 1996, 2000; Rolink et al., 1993; Yung and Julius, 2008). To test the hypothesis that decreased B-cell production in the bone marrow increases the chance of developing autoimmunity, other mutant mice in which bone marrow B-cell development is reduced should be analyzed.

IMMATURE BONE MARROW B-CELLS

More than 50 years ago Sir Frank Macfarlane Burnet put forward the clonal-selection hypothesis (Burnet, 1959). According to this hypothesis, recognition of foreign antigen by mature B-cells induces clonal expansion and antibody secretion and thus yields an antigen-specific immune response and the induction of memory, whereas newly formed immature B-cells with an autoreactive receptor will die upon encounter with their autoantigen. That death was inevitable for an immature B-cell that had its BCR triggered was challenged about 15 years ago by findings reported by Nemazee et al. (Tiegs et al., 1993) and Weigert et al. (Gay et al., 1993; Radic et al., 1993) and reviewed by Nemazee (2006) and Nemazee and Weigert (2000). The groups of Nemazee and Weigert independently showed that autoreactive immature B-cells, upon encounter of their autoantigen, do not automatically have to die, but can rather eliminate their autoreactive specificity and express a novel non-autoreactive receptor by secondary V(D)J recombination events (Gay et al., 1993; Hertz & Nemazee, 1997; Nemazee, 2006; Nemazee and Weigert, 2000; Radic et al., 1993; Retter & Nemazee, 1998; Tiegs et al., 1993). This process of receptor revision was then called receptor editing (Casellas et al., 2001;Gay et al., 1993; Nemazee and Weigert, 2000; Nemazee, 2006; Radic et al., 1993; Tiegs et al., 1993).

At least three types of immature B-cells can be distinguished: (1) those that express a non-autoreactive receptor with which the IgH and IgL chains pair well and therefore express high levels of the BCR; (2) those that express a non-autoreactive BCR with which the IgH and IgL chains poorly interact and therefore express low levels of the BCR; and (3) those that express an autoreactive receptor. Several studies have now indicated that it is the strength of the BCR signal that determines whether the BCR-triggered cells are allowed to progress in development (positive selection) or will have to undergo receptor editing in order to be rescued (Buhl et al., 2000; Diamant et al., 2005; Fuentes-Panana et al., 2004; Hayashi et al., 2004; Keren et al., 2004; Kouskoff et al., 2000; Pelanda and Torres, 2006; Tze et al., 2005; Verkoczy et al., 2007; Xu and Lam, 2002). Thus, immature B-cells that express a non-autoreactive receptor consisting of an efficiently interacting combination of IgH and IgL chains seem to receive the right amount of BCR signaling (also called tonic or basal BCR signaling), which allows them to progress in development and be positively selected (Buhl et al., 2000; Diamant et al., 2005; Fuentes-Panana et al., 2004; Hayashi et al., 2004; Keren et al., 2004; Kouskoff et al., 2000; Pelanda and Torres, 2006; Tze et al., 2005; Verkoczy et al., 2007; Xu and Lam, 2002). These cells then switch off RAG expression and are allowed to migrate to the spleen. In mutant mice in which this tonic BCR signaling is abrogated and/or impaired, as in CD19-deficient mice, positive selection of immature B-cells is dramatically reduced (Keren et al., 2004).

For the population of immature B-cells that express a non-autoreactive BCR but at low levels, signaling via the receptor is below the threshold required for positive selection, RAG expression is not turned off, and these cells undergo secondary IgL chain rearrangements. If they manage to generate a new IgL chain that interacts well with their IgH chain, resulting in the formation of a non-autoreactive BCR, they will now receive the basal level of BCR signaling required for positive selection.

For the immature B-cells expressing an autoreactive BCR, encounter with their self-antigen generates a strong BCR signal. These cells will therefore not progress in development and will not switch off RAG expression. The latter allows them to undergo secondary IgL chain rearrangements, which can lead to the generation of a new IgL chain. If the resulting new BCR is non-autoreactive and the new IgL chain pairs well with the IgH chain, these cells will be positively selected. Thus, receptor editing can rescue immature B-cells that express a "poor" or autoreactive BCR from apoptosis (clonal deletion); however, the efficiency of this rescue program is still not completely clear. Several studies with transgenic mice have suggested that receptor editing is very efficient in rescuing autoreactive immature B-cells (Ait-Azzouzene et al., 2005; Halverson et al., 2004; Pelanda and Torres, 2006), but whether this conclusion is also warranted for a nontransgenic wild-type situation is unknown. Whether immature B-cells expressing an autoreactive BCR are more easily rescued by receptor editing then those that express a poorly interacting IgH and IgL chain combination is, in our opinion, still unclear.

Yet another important point to be noted is that receptor editing does not automatically result in the deletion of the first expressed IgL chain. A productive secondary rearrangement, taking place either at the unrearranged or nonproductively rearranged allele, will result in the formation of immature B-cells expressing two IgL chains. In fact, it has recently been shown that about half the peripheral mature B-cells derived from immature B-cells that had undergone receptor editing express two IgL chains (Casellas et al., 2007). Moreover, several studies have indicated that dual IgL chain-expressing autoreactive immature B-cells can escape deletion by being positively selected by the non-autoreactive IgL and IgH chain combination (Gerdes and Wabl, 2004; Li et al., 2002, 2005).

TRANSITIONAL SPLENIC B-CELLS

Immature B-cells that are positively selected in the bone marrow will migrate to the spleen and are then called transitional B-cells (Allman et al., 2001; Carsetti et al., 1995; Loder et al., 1999; Rolink et al., 1998, 1999a). Transitional B-cells are still immature and can be distinguished from their mature counterparts by surface marker expression, their short half-life, and their sensitivity to anti-IgM-induced apoptosis—that is, they can still undergo negative selection.

Several in vitro studies have shown that upon anti-IgM triggering, transitional B-cells undergo apoptosis (Allman et al., 2001; Carsetti et al., 1995; Loder et al., 1999; Rolink et al., 1998, 1999a). Moreover, in vivo studies have also indicated that a counterselection against autoreactivity might take place at this stage of development (Meffre and Wardemann, 2008; Wardemann et al., 2003). In fact, some investigators have suggested that only 10 percent of transitional B-cells enter the pool of long-lived mature B-cells (Allman et al., 1992, 1993). However, turnover studies of transitional and mature B-cell subpopulations performed by us suggested very little loss of cells as they progress from transitional to mature B-cells (Rolink et al., 1998). Thus, the transitional stage of B-cell development is yet another checkpoint for BCR autoreactivity. However, how many B-cells are deleted at this developmental stage is still unclear. Furthermore, whether autoreactive transitional B-cells can still be rescued by receptor editing is also unclear.

SIGNAL TRANSDUCTION BY T- AND B-LYMPHOCYTE ANTIGEN RECEPTORS

Anthony DeFranco and Arthur Weiss

Considerable progress has been made toward our understanding of the processes by which T and B lymphocytes become activated. Antigen-specific activation of these quiescent cells involves the triggering of antigen receptors to induce signal transduction events that can lead to both the cell-cycle progression and differentiation of T and B cells. A remarkable synergy has resulted from a convergence of studies of the most fundamental processes involved in T- and B-cell activation and those involving clinical and experimental immunodeficiency syndromes. Clinical and experimental immunodeficiency states often result when the functions of T- and B-cell antigen receptors (TCRs and BCRs) or critical components in the pathways regulated by these receptors are interrupted or altered.

An increasing number of cell surface receptors on T and B cells contribute to the activation of these cells. However, the specificity of the response to antigen dictates that the antigen receptors on these cells play the central role in the initiation of responses. Although the forms of antigens recognized and the effector functions mediated by these two cell lineages are quite distinct, the mechanisms by which the antigen receptors transduce signals and the ensuing molecular events are remarkably similar. Stimulation of the TCR and BCR induces the protein tyrosine phosphorylation of a large number of proteins implicated in signal transduction processes that contribute to cellular activation. Here, we will focus on the means by which the TCR and BCR induce protein tyrosine phosphorylation and the consequences of these phosphorylation events.

ANTIGEN RECEPTORS ON T AND B LYMPHOCYTES

The TCR and BCR are both oligomeric complexes that contain subunits responsible for antigen recognition and other subunits involved in signal transduction (Fig. 6.1A). The repertoires of the clonally distributed ligand-binding subunits of these receptors are entrusted with the responsibility of recognizing the vast array of antigens or peptides bound to major histocompatibility complex (MHC) molecules that may be encountered during interactions with pathogens. In the case of the TCR, the antigen- or ligand-binding subunit consists of productively rearranged $\alpha\beta$ or $\gamma\delta$ heterodimers. The antigen-binding subunit of the BCR consists of the heavy and light chains of membrane immunoglobulin (Ig). Whereas these subunits have all of the information necessary for specific antigen recognition, their short cytoplasmic domains do not contain sufficient information to interact with cytoplasmic molecules involved in signal transduction.

In the case of the TCR, the $\alpha\beta$ or $\gamma\delta$ heterodimers assemble in the endoplasmic reticulum with the invariant CD3 $\varepsilon\gamma$ and $\varepsilon\delta$ chains and a homodimer of the ζ chain (Manolios et al., 1991). The assembly of all of the components is necessary for efficient expression on the plasma membrane. Human or murine T-cell immune deficiency syndromes characterized by lower TCR expression have been associated with CD3γ or ε mutations (Perez-Aciego et al., 1991; Tanaka et al., 1995). Studies in T-cell lines and heterologous cells show that most incomplete complexes are retained in the endoplasmic reticulum or Golgi and shunted toward a degradative pathway (Bonifacino et al., 1989). Unusually placed transmembrane acidic and basic residues appear to play an important role in the interaction of the CD3 and ζ chains with the ligand-binding $\alpha\beta$ or $\gamma\delta$ heterodimers (Call et al., 2002). In addition to being required for proper cell-surface expression, the CD3 and ζ chain dimers are responsible for the signal transduction function of the receptor.

Membrane Ig also assembles with invariant chains involved in signal transduction, called Igα and Igβ. Like the CD3 chains, Igα and Igβ form heterodimers and each chain

Figure 6.1 *ITAMs and antigen receptors.* (A) Schematic representation of the T-cell antigen receptor (TCR) and B-cell antigen receptor (BCR) structure. (B) Immunoreceptor tyrosine-based activation motifs present in hematopoietic receptors involved in antigen recognition and in viruses that infect T or B cells. h, human; r, rat; m, mouse; BLV, bovine leukemia virus; EBV, Epstein-Barr virus; SIV, simian immunodeficiency virus; KSHV, Kaposi's sarcoma–associated herpes virus.

has a single extracellular Ig-like domain and intracellular domains with signaling function. Recent data suggest that a single Igα/Igβ dimer is associated with a dimer of membrane Ig (Schamel and Reth, 2000; Sohn et al., 2006). As is the case with the TCR, efficient cell-surface expression of membrane Ig requires association with Igα and Igβ. Although charged amino acid residues are not present in the transmembrane domains of BCR subunits, these domains do interact with each other, and this interaction is necessary for assembly (Venkitaraman et al., 1991). Thus, the BCR and TCR are both obligate multi-subunit complexes in which antigen-binding functions and signal transduction functions are provided by distinct chains.

In addition to the antigen receptors found on mature lymphocytes, related receptors are found on pre-B cells in the bone marrow and on immature double negative ($CD4^-/CD8^-$) thymocytes (Roth and DeFranco, 1995; von Boehmer, 2005). These receptors contain only one of the two antigen-binding chains, the one that is generated by recombination first during development of the cell. The place of the other antigen-binding chain is taken by a surrogate for the second chain. In B cells, this "pre-BCR" contains the Ig μ heavy chain together with the λ_5 and V_{preB} proteins, each of which mimics one half of the Ig light chain of the BCR (Bankovich et al., 2007). This pre-BCR also contains Igα/Igβ heterodimers. Similarly, the pre-TCR contains a complex of the TCRβ chain with an α chain surrogate called pre-Tα, and this complex is associated with CD3 and ζ chains. There is some evidence, in the case of both of these immature receptors, that they dimerize or oligomerize to induce signaling in a ligand-independent manner (Bankovich et al., 2007; Irving et al., 1998; Melchers, 2005; Yamasaki et al., 2006). In any case, these receptors play critical roles in allowing developing lymphocytes to sense the successful rearrangement of the first antigen receptor gene and thereby promote passage through a developmental checkpoint and initiate a limited proliferative expansion, after which rearrangement at that locus ceases and rearrangement of the Ig light chain gene or the TCRα gene increases. For this reason, genetic defects in TCR or BCR signaling reactions result in an early block in lymphocyte development, a prime example being the strong block in B-cell development in X-linked agammaglobulinemia caused by mutations in the gene encoding Btk (Conley et al., 2000; Lindvall et al., 2005).

The CD3 and ζ chains of the TCR and the Igα and Igβ chains of the BCR have substantial cytoplasmic domains, which contain sequences responsible for the signal transduction function of these receptors. These signal transduction functions were initially definitively established through the use of chimeric receptors in which the cytoplasmic domains of several of these proteins were linked to the extracellular and transmembrane domains of heterologous proteins (Irving and Weiss, 1991; Law et al., 1993; Romeo and Seed, 1991). Although these cytoplasmic domains do not encode enzymatic functions, they can confer TCR and BCR signal transduction functions to heterologous receptors if expressed in hematopoietic cells having the appropriate downstream signaling molecules. This signal transduction function is encoded in a sequence motif termed ITAM (for immunoreceptor tyrosine-based activation motif), which is present as a single copy in all of the CD3 chains and the Igα and Igβ chains, and as three copies in the ζ chain (Fig. 6.1A and B) (Flaswinkel et al., 1995). ITAMs are also present and functionally active in the cytoplasmic domains of the non-ligand-binding subunits of the high-affinity IgE Fc receptor (β and Fcγ chains), the phagocytic Fcγ receptors on macrophages, and the DAP-12 chain that associates with natural killer (NK) cell-activating receptors. Interestingly, the ITAM sequence motif, D/ExxYxxL(x)6–8YxxL (one letter amino acid code; x = any amino acid), in many of these chains is encoded by two exons with similar organization, suggesting a common evolutionary origin (Wegener et al., 1992). Indeed, all of these receptors involved in antigen recognition use similar mechanisms to transduce signals. Mutagenesis studies have shown that both tyrosines and both leucines are critical for the ability of ITAMs to confer signal transduction function to heterologous

receptors (Sefton and Taddie, 1994). The amino acid residues surrounding the conserved tyrosines and leucines can be quite variable. A major question that arises and remains unsettled is whether ITAMs, which contain such variable sequences, have equivalent functions or whether part of their functions are distinctive. Some investigations have suggested that multiple ITAMs are present in TCRs and BCRs to recruit distinct signaling molecules (Clark et al., 1992; Frank et al., 1990; Siemasko and Clark, 2001). Others have suggested that the presence of multiple ITAMs may play a role in signal amplification (Irving et al., 1993; Law et al., 1993; Love and Shores, 2000). In mouse experiments involving genetic deletion of all or part of the CD3ζ ITAMs, it was shown that the CD3γ, δ, ε subunits are sufficient for TCR signaling events and effector functions and that the CD3ζ ITAMs do not play any exclusive role (Ardouin et al., 1999). However, experiments with receptors containing multimers of ITAMs suggest signal amplification may be a role for the 10 ITAMs of the TCR (Irving et al., 1993; Love and Shores, 2000). Moreover, sufficient numbers of ITAMs and their signaling function may prevent the development of autoimmunity (Holst et al., 2008).

B-cell development requires at least one functional ITAM in the Igα/Igβ heterodimer, but defects are seen in mice with mutations in either ITAM. Mice containing mutations of the ITAM tyrosines in Igα did not exhibit any major defects in the development of follicular B cells, whereas there was a reduction in B-1 and marginal-zone B cells. Combining the Igα mutation with a truncation in Igβ resulted in a marked arrest in B-cell development at the pro-B cell stage (Kraus et al., 2001; Reichlin et al., 2001), demonstrating the requirement for functional ITAMs on at least one of the signal transducing chains of the BCR for progression through early development. Mice carrying a truncation in the cytoplasmic tail of Igβ alone progress to the immature stage and respond normally to BCR ligation; however, they are arrested at this stage in the bone marrow and die by apoptosis. These observations indicate that Igα and Igβ might have distinct biological activities in vivo in addition to some redundancy.

As in other situations where pathogens have usurped or targeted normal cellular machinery to their benefit, at least four viruses that infect T or B cells encode ITAMs that appear to play an important role in their pathogenesis. The bovine leukemia virus, which can transform B cells, contains an ITAM in the cytoplasmic domain of the gp30 envelope glycoprotein that is critically important for viral infection and/or replication (Willems et al., 1995). An ITAM is also present in the latent membrane protein 2 (LMP2) of the Epstein-Barr virus (EBV) and has been implicated in maintaining a state of viral latency in transformed B-cell lines (Fruehling and Longnecker, 1997). LMP2 serves to recruit E3 protein ubiquitin ligases that target BCR-activated protein kinases, thereby downregulating BCR signaling, but also induces a low level of constitutive ITAM signaling (Pang et al., 2009). A rare mutation of the Nef protein of the simian immunodeficiency virus results in the creation of an ITAM sequence (Du et al., 1995). This mutation is associated with the unusual ability of this viral isolate to infect and replicate in primary resting T cells and cause a fulminant viral infection. Finally, human herpesvirus 8 (HHV8; also known as Kaposi's sarcoma [KS]-associated herpesvirus, or KSHV), which causes Kaposi's sarcoma, primary effusion lymphoma, and multicentric Castleman's disease, encodes the K1 gene product that contains an ITAM-like sequence in its C-terminal cytoplasmic tail. Expression of this protein leads to ligand-independent signaling in B cells that is abrogated upon mutation of the ITAMs (Lagunoff et al., 1999). Thus, the ITAM plays a critical role in normal T- and B-cell antigen receptor function, and some pathogens have capitalized on this function.

ITAMS OF T- AND B-CELL ANTIGEN RECEPTORS INTERACT WITH DISTINCT FAMILIES OF PROTEIN TYROSINE KINASES

Stimulation of the TCR and BCR leads to the activation of protein tyrosine kinases (PTKs) that are critical for lymphocyte responses to antigen. Two families of cytoplasmic PTKs, members of the Src and Syk/ZAP-70 families, have been implicated in the most proximal signaling events induced by these receptors. Indeed, considerable evidence has accumulated to suggest a model in which the TCR and BCR ITAMs interact with these two families of PTKs in a sequential and coordinated manner (Fig. 6.2) (Weiss, 1993). Whereas the members of the families of the PTKs that are expressed in T and B cells differ, they appear to subserve similar functions.

In B cells and in T cells, the earliest event associated with antigen receptor stimulation is the tyrosine phosphorylation of ITAMs (Iwashima et al., 1994; Law et al., 1993). In some cases, in ex vivo T cells, phosphorylation of the ITAM tyrosines is present in the basal state (van Oers, Tao et al., 1993). Both the inducible and basal phosphorylation of ITAM tyrosines depends on members of the Src family (Iwashima et al., 1994; Richards et al., 1996; Saijo et al., 2003; van Oers, Killeen et al., 1996). Src family kinases expressed in T cells are Lck and Fyn and those expressed in B cells are primarily Lyn, Fyn, and Blk. These kinases are peripheral membrane proteins characterized by the following: (1) a unique N-terminal domain that is myristylated in all family members and also may be palmitoylated; (2) an SH3 domain involved in mediating protein–protein interactions by binding to proline-rich sequences; (3) an SH2 domain involved in mediating protein–protein interactions by binding phosphorylated tyrosine residues in the context of particular neighboring amino acid residues; (4) a catalytic domain; and (5) a carboxy-terminal domain that contains a negative regulatory site of tyrosine phosphorylation.

In T cells, the function of Lck is especially critical for TCR signal transduction (Straus and Weiss, 1992; van Oers, Killeen et al., 1996), although Fyn is thought to play roles in some circumstances (Filby et al., 2007; Mamchak et al., 2008). Lck and Fyn both co-immunoprecipitate with the TCR complex and can interact with ITAMs (Beyers et al., 1992; Samelson et al., 1990), but genetic studies with cell lines and mice have indicated a more important role for Lck in the phosphorylation of the ITAMs (Straus and Weiss, 1992; van Oers, Killeen et al., 1996). However, in the absence of Lck, or when Lck function

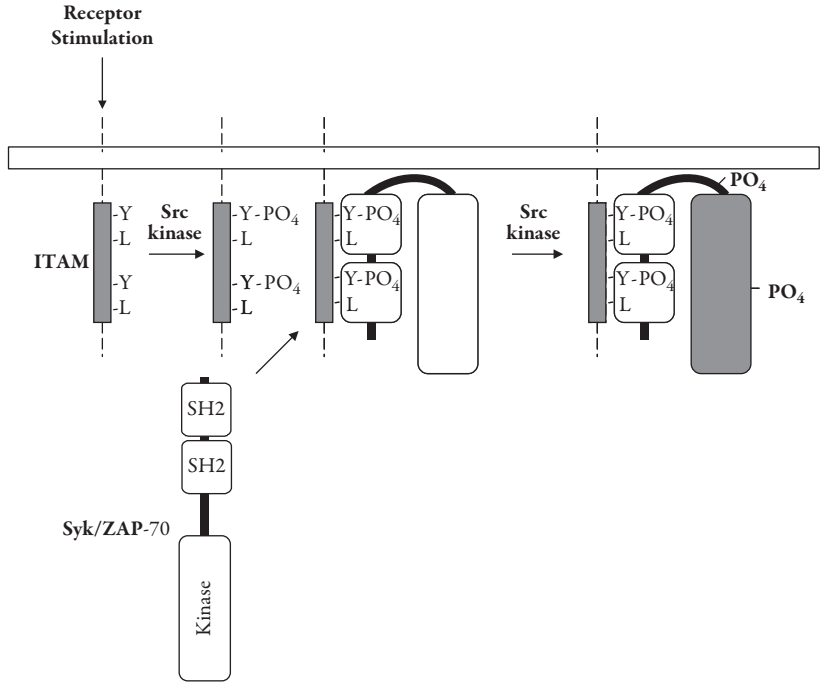

Figure 6.2 *Model for sequential interaction of Src and Syk/ZAP-70 protein tyrosine kinases with an ITAM*. See text for details. The subsequent interaction of the Src family kinase, involving its SH2 domain, with the phosphorylated Syk or ZAP-70 kinase is not depicted.

might be limiting, Fyn may be able to play a compensatory role. This view is consistent with the developmental phenotypes seen in mice deficient in one or both of these kinases: mice deficient in Fyn have no developmental abnormality of conventional αβ T cells but they lack NK1. 1+ T (NKT) cells (Appleby et al., 1992; Eberl et al., 1999; Stein et al., 1992), whereas the loss of Lck is associated with a severe but incomplete arrest in T-cell development (Molina et al., 1992). The residual development in the latter case is completely absent in thymocytes from mice deficient in both kinases (van Oers, Lowin-Kropf et al., 1996). These thymocytes exhibit a complete developmental block at a stage where the function of the pre-TCR is important (Fehling et al., 1995). Presumably, this reflects the inability of the pre-TCR to transduce signals in the absence of Lck or Fyn.

A unique feature of Lck is the ability of its N-terminal region to associate with the cytoplasmic tails of the CD4 and CD8 co-receptors, which are involved in recognition of MHC class II or I molecules, respectively (Chow and Veillette, 1995). A primary role for Lck function in the initiation of TCR signaling is also consistent with its association with CD4 and CD8. The co-localization of CD4 or CD8 with the TCR during peptide antigen-MHC molecule recognition may serve to localize Lck in close proximity with the TCR, facilitating its participation in early signaling events.

In B cells the Src family kinases are also believed to be responsible for ITAM phosphorylation, although Syk may contribute as well. For example, in a chicken B-cell line, DT-40, Lyn is apparently the only Src family kinase expressed. Disruption of the Lyn gene in these cells decreased anti-IgM-induced tyrosine phosphorylation of Igα and Igβ but did not eliminate it (Takata et al., 1994). Moreover, subsequent signaling events were decreased but not eliminated. Conversely, when the BCR was expressed in the AtT-20 rat pituitary cell line following the introduction of cDNA expression vectors, BCR stimulation led to strong tyrosine phosphorylation of Igα and Igβ but minimal downstream signaling. These cells express Fyn but not Syk, Lyn, or Blk. Introduction of Syk restored some downstream signaling events and also boosted the stimulation-dependent phosphorylation of Igα and Igβ (Richards et al., 1996). In murine splenic B cells, Lyn is the most abundant Src family member present, although substantial amounts of Blk and Fyn are also detectable. B cells from mice rendered deficient in Lyn by targeted gene disruption exhibit significantly delayed tyrosine phosphorylation of Igα after BCR stimulation (Chan et al., 1997; Nishizumi et al., 1995), indicating that Lyn is important but not essential for Igα phosphorylation. Mice genetically defective in Lyn, Blk, and Fyn, the three major Src family kinases in B cells, exhibit a strong block at the pre-BCR signaling checkpoint, whereas the single and double mutant mice have a less severe defect, strongly suggesting that these three kinases all contribute significantly to pre-BCR signaling (Saijo et al., 2003). Thus, the situation is a bit more complex than in T cells, but again, Src family kinases are primarily responsible for phosphorylation of Igα and Igβ ITAM tyrosines.

In the absence of co-receptor involvement, the low stoichiometry of the documented interactions of the Src family members with the TCR and BCR, as well as the apparent redundancy in some functions among these PTKs, raises questions about how TCR and BCR stimulation induces these kinases to phosphorylate the ITAMs. Receptor ligation does appear to increase the catalytic activity of these PTKs (Saouaf et al., 1994). Some recent studies suggest that

a conformational change occurs following TCR stimulation. This can be detected in at least some studies as increased accessibility of a proline-rich motif in the cytoplasmic domain of CD3ε to binding by the N-terminal SH3-domain of the adaptor protein, Nck, or to a monoclonal antibody directed against the proline-rich motif (Gil et al., 2002; Martinez-Martin et al., 2009). The inability of some to document the importance of the proline-rich motif in initiating signaling raises questions regarding the significance of the conformational change (Mingueneau et al., 2008). However, it has been suggested that the motif may help couple the TCR to Lck, directly or indirectly. Recent total internal reflection fluorescence microscopy (TIRF) studies examining BCR signaling in response to a monomeric antigen presented in a planar lipid bilayer have provided evidence that conformational changes may play a role in BCR signaling in such situations. These studies indicated that antigen binding induces conformation changes in the constant domain of mIg closest to the membrane, which then promotes BCR oligomerization and signaling (Tolar et al., 2009). Alternatively, or additionally, engagement of antigen receptors may promote interactions with Src family kinases by altering their location within the plasma membrane from the non-membrane raft region to the membrane raft region, which is highly enriched in Src family kinases (see below).

The stoichiometry of ITAM phosphorylation is low, even in systems where receptor stimulation is maximal. Some studies suggest that some of the tyrosines of TCRζ or CD3 chains may be sequestered in the unphosphorylated state by the hydrophobic environment of the plasma membrane (Aivazian and Stern, 2000; Xu et al., 2008). In any case, the association of the antigen receptor and Src family kinase could be based on an interaction between the SH2 domain of the Src family PTK and a small percentage of ITAMs that may be tyrosine phosphorylated in the basal state. The recruitment of Src family PTKs to phosphorylated ITAMs is attractive in view of studies suggesting that the tyrosine phosphorylated YEEI sequence, similar to the YxxL sequences in ITAMs, is a preferred binding site for the SH2 domains of Src kinases (Songyang et al., 1993). Most ITAMs have at least one negatively charged amino acid residue between the tyrosines and leucines (Fig. 6.1B). Indeed, cross-linking of chimeric transmembrane proteins with Igα or Igβ ITAMs leads to induced association of Lyn (Law et al., 1993). Moreover, the inducible phosphorylation of ζ chain ITAMs requires the function of the Lck SH2 domain (Straus et al., 1996). This could reflect a positive feedback loop whereby once a few ITAM tyrosines are phosphorylated, Lck binds and then phosphorylates other ITAMs of neighboring receptors aggregated by the triggering stimulus.

Both tyrosines of an ITAM are necessary for its signal transduction function (Sefton and Taddie, 1994). This dependency on both tyrosines likely reflects the requirement for tyrosine phosphorylation of both sites for high-affinity binding of a second type of PTK, ZAP-70 and/or Syk. ZAP-70 and Syk have a similar overall structure, containing N-terminal tandem SH2 domains and a C-terminal catalytic domain. ZAP-70 is expressed predominantly in T cells and NK cells, whereas Syk is more broadly expressed within the hematopoietic lineages. ZAP-70 and Syk bind to doubly phosphorylated ITAMs with relatively high affinity via an interaction that depends on both of their SH2 domains (Bu et al., 1995; Iwashima et al., 1994; Wange et al., 1993). The crystal structure of the ZAP-70 tandem SH2 domains bound to a doubly phosphorylated TCRζ ITAM peptide confirms that both SH2 domains interact with a single, doubly phosphorylated ITAM and helps explain their cooperative binding (Hatada et al., 1995). Recent mutagenesis and structural data suggest that ZAP-70 and probably Syk are in an inactive autoinhibited conformation in the unbound state in which the SH2 domains are not optimally aligned for binding to a doubly phosphorylated ITAM (Brdicka et al., 2005; Deindl et al., 2007). ITAM binding stabilizes alignment of the SH2 domains and transmits a conformational change that can contribute to kinase domain activation.

If ITAMs are phosphorylated in the basal state, as has been observed in ex vivo thymocytes and peripheral T cells, ZAP-70 and/or Syk are then bound and poised to respond to receptor stimulation (van Oers, Killeen et al., 1994). Thus, the induction of PTK activity following Syk/ZAP-70 recruitment to the receptor complexes likely involves additional interactions between the Src and Syk/ZAP-70 PTKs. In vitro studies suggest that the binding of Syk, but not ZAP-70, to ITAMs can lead to its activation (Shiue et al., 1995). However, simple binding of Syk and ZAP-70 to ITAMs in vivo is probably not sufficient for stimulation of their kinase activity and subsequent signal transduction, since Syk and ZAP-70 bound to the ITAMs in ex vivo thymocytes are not activated (van Oers, Killeen et al., 1994). Rather, both Syk and ZAP-70 kinase activities are regulated by phosphorylation of tyrosine residues within a region between the SH2 domains and kinase domain (interdomain B) as well as tyrosine residues within the activation loop of their catalytic domains (Brdicka et al., 2005; Chan et al., 1995; Wange et al., 1995). In the case of ZAP-70, phosphorylation of tyrosines in interdomain B stabilizes the active conformation of ZAP-70 (Brdicka et al., 2005; Deindl et al., 2007). The phosphorylation of the tyrosines in interdomain B can be mediated by Lck or Fyn but not by ZAP-70 itself (Brdicka et al., 2005). In contrast, Syk can activate itself, and this is seen in overexpression studies in Cos cells or upon cross-linking of a chimeric protein in which Syk has been fused to the cytoplasmic domain of a transmembrane protein (Couture et al., 1994; Kolanus et al., 1993). However, Syk is probably more efficiently activated by Src family PTKs such as Lyn than by itself. Thus, the Src kinases can play a critical role in Syk and ZAP-70 catalytic activation by phosphorylating regulatory tyrosines. This is then likely followed by trans-autophosphorylation of tyrosines in their activation loop, which stabilizes the active conformation of the catalytic domain.

In addition to the phosphorylations that lead to activation of ZAP-70 and Syk kinase activity, there are a number of tyrosines in these proteins that become tyrosine phosphorylated, which leads to the recruitment of signaling components. Tyrosine phosphorylation of Y292 in ZAP-70 leads to negative regulation (Kong et al., 1996; Magnan et al., 2001; Zhao and Weiss, 1996). Tyrosines in interdomain B, Y315 and Y319, that are involved in autoinhibition in the basal

unphosphorylated state also have positive regulatory functions following their phosphorylation (Gong et al., 2001; Magnan et al., 2001). These latter phosphorylation sites are involved in recruitment of substrates that contain SH2 domains with specificity for the phosphorylated sequence motifs, in a manner analogous to that observed with PTK growth factor receptors. Proteins that have been reported to bind to either Syk or ZAP-70 include Lck (Straus et al., 1996; Thome et al., 1995), Lyn (Sidorenko et al., 1995), Shc (Katzav et al., 1994; Nagai et al., 1995), PLCγ1 (Law et al., 1996), SHIP (a phosphoinositide 5 phosphatase) (Crowley et al., 1996), and Cbl (Fournel et al., 1996). The functions of some of these signaling components will be discussed in a later section. The interaction of one of these sites with Src kinases is of particular interest. A stable complex of Lck and ZAP-70 or Syk has been observed following TCR stimulation (Straus et al., 1996; Thome et al., 1995). The interaction appears to depend on the binding of the Lck SH2 domain to tyrosine phosphorylated residues in the interdomain B region of ZAP-70 (Y319) or Syk (Y346). This may serve not only to stabilize the active conformation of ZAP-70 or Syk, but also to stabilize and potentiate the activity of the bound Src kinase.

The relative contribution of the two families of PTKs toward phosphorylation of downstream signaling substrates has not been entirely clarified. However, activation of Lck alone by cross-linking CD4 or CD8 fails to mimic TCR stimulation. This suggests a critical function provided by Syk and ZAP-70 in later signal transduction events. Successful reconstitution of Syk-deficient B cells or ZAP-70-deficient T cells with ZAP-70 or Syk depends on the catalytic functions of these PTKs and the presence of the activating tyrosine of the kinase domain (Y518, Y519 for Syk, and Y493 for ZAP-70) (Kong et al., 1996; Takata and Kurosaki, 1995; Williams et al., 1998). Thus, a contribution of both Src and Syk/ZAP-70 catalytic function is important for effective downstream signaling events.

Both ZAP-70 and Syk play critical roles in lymphocyte development, presumably because signal transduction through immature and mature antigen receptors is critical for transition through certain developmental checkpoints. Mice and humans deficient in ZAP-70 exhibit distinct developmental arrests and marked impairment in TCR signal transduction function (Arpaia et al., 1994; Chan et al., 1994; Elder et al., 1994; Negishi et al., 1995); see Chapter 14. In Syk-deficient mice, profound B-cell developmental arrest and abnormal development of the vascular and lymphatic vessels leading to shunts in blood flow that contribute to high-output cardiac failure are observed (Cheng et al., 1995; Turner et al., 1995). The B-cell developmental arrest in these mice occurs at the same stage as seen with mutations that prevent expression of the membrane-bound form of the Igμ heavy chain. Thus, it is thought that the developmental block results from impaired pre-BCR function. This interpretation is consistent with the impaired BCR signal transduction function observed in an avian B-cell line deficient in Syk (Takata et al., 1994). Thus, analysis of loss-of-function mutations of Syk or ZAP-70 supports the conclusion that these PTKs play critically important roles in TCR and BCR signal transduction function.

In some systems it has been suggested that Syk and ZAP-70 may be interchangable (Gelfand et al., 1995; Kong et al., 1995). One clear difference is that Syk appears to be less dependent on interactions with Src kinases than is ZAP-70 (Chu et al., 1996; Kolanus et al., 1993). Syk and ZAP-70 are probably not entirely redundant during early thymocyte development. In competitive repopulation studies, Syk appears to play a more important function earlier, one that is critical for initial pre-TCR signaling (Palacios and Weiss, 2007). A pre-TCR Syk-dependent signal induces expression of ZAP-70, which then plays a preferred role in clonal expansion past the pre-TCR checkpoint and in subsequent T lineage stages of development and in mature T-cell function. There is other evidence for distinct functions. For instance, the αβ T-cell lineage is primarily affected in mice made deficient in ZAP-70 (Negishi et al., 1995), whereas the γδ lineage of T cells in epithelial tissues seems to be defective in Syk-deficient mice (Mallick-Wood et al., 1996). Thus, many of the functions of these PTKs overlap, but they appear to have unique functions as well.

REGULATION OF ANTIGEN RECEPTOR SIGNAL TRANSDUCTION

CO-RECEPTORS ON T CELLS

The immune system has evolved great sensitivity to antigen to allow immune responses to be initiated early upon infection with pathogens. While receptors with high affinity exist within the derived repertoire of antigen receptors on T and B cells, the immune sytem has also developed mechanisms to increase the sensitivity of responsiveness until the clonal expansion of cells with high-affinity receptors can take place. T and B cells both have distinct co-receptor molecules that function in concert with antigen receptors to recognize antigen and induce signaling events. Here we will restrict our use of the term *co-receptors* to refer to molecules that along with the antigen receptor recognize intact antigen or the antigenic peptide antigen–MHC complex.

The positive selection of most αβ thymocytes and the primary response of αβ T cells to antigen usually depend on the functional contributions of the co-receptors CD4 and CD8. The CD4 and CD8 molecules are integral membrane glycoproteins whose extracellular domains bind to the β2 domain of class II MHC molecules or the α3 domain of class I MHC molecules, respectively, on antigen-presenting cells (Rudolph et al., 2006). These interactions are of relatively low affinity and may depend on the simultaneous binding of the TCR as well. In fact, some evidence suggests that a TCR-initiated signaling event may be required for the recruitment and effective participation of the CD4 coreceptor (Xu and Littman, 1993). An alternative but not mutually exclusive view is that the CD4 or CD8 participation stabilizes the low-affinity TCR-MHC/peptide interaction and also potentiates TCR signal transduction by delivering Lck to the TCR complex (Fig. 6.3).

The cytoplasmic domains of CD4 and CD8 bind to the unique N-terminal region of Lck through a cysteine-containing

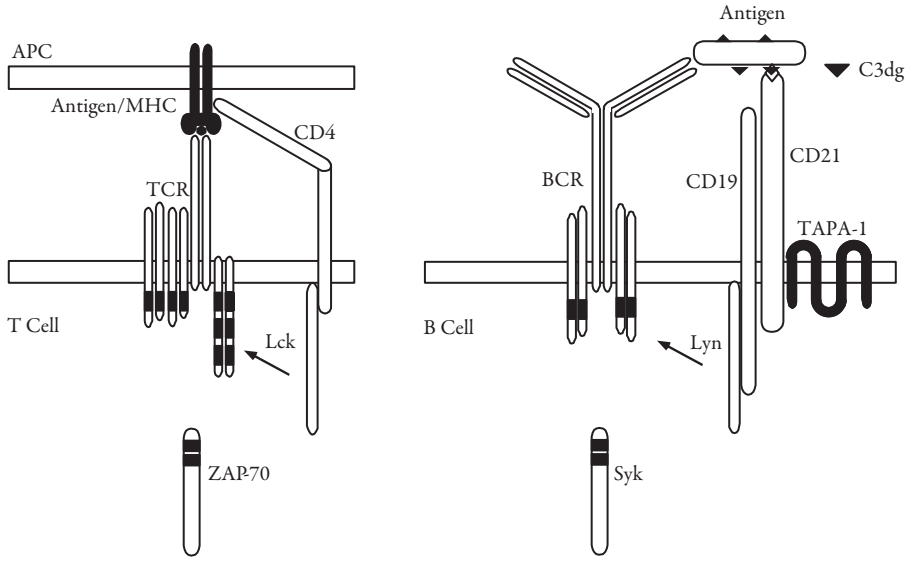

Figure 6.3 ***Models of co-receptor/antigen receptor engagement on T and B cells.*** CD19 also recruits downstream signaling components to its cytoplasmic domain, as discussed later in this review. APC, antigen-presenting cell; MHC, major histocompatibility complex.

motif shared by CD4 and CD8 (Chow and Veillette, 1995). This interaction is important but not essential for TCR signal transduction during development or at low antigen concentrations (Singer and Bosselut, 2004). Several functional consequences may result from the interaction of Lck with the CD4 and CD8 co-receptors. If CD4 or CD8 delivers Lck to the TCR complex through co-localization driven by the interaction of the co-receptors with the MHC/peptide complex, the phosphorylation of ITAMs by Lck would be facilitated and subsequent interactions involving the phosphorylation and activation of ZAP-70 or Syk could be potentiated (Weiss, 1993). In addition to this initiating function of Lck in TCR signal transduction, Lck appears to contribute to T-cell activation in a second way in which a CD4-bound Lck molecule binds to phosphorylated ZAP-70 or Syk via its SH2 domain, thereby stabilizing the interaction of the co-receptor with the TCR-MHC/peptide complex (Straus et al., 1996; Thome et al., 1995; Xu and Littman, 1993). However, there are some data suggesting that the CD4 complex that delivers Lck to the ITAMs may not be able to bind to the same MHC molecule as the TCR (Davis and van der Merwe, 2006). However, this does not exclude the notion that CD4 does help to concentrate Lck in the region of the TCR.

Mature CD4 or CD8 T cells are derived from thymocyte precursors that express both of these coreceptors. Evidence suggests that these two co-receptors play an active role in the decision process regarding lineage commitment (Singer et al., 2008). Moreover, T cells that express CD4 or CD8, in addition to recognizing peptide antigens on distinct classes of MHC molecules, generally have distinct effector functions, helper or cytolytic functions, respectively. To explain this linkage of co-receptor expression to differentiated phenotype, it was initially proposed that the engagement of the TCR with each of these co-receptors leads to distinct signaling events. The identity of such specialized events remains unknown, and subsequent work has provided evidence instead for two distinct types of models that base lineage choice on quantitative levels of co-receptor-dependent TCR signaling. The first model, based on the fact that the interaction of CD4 with Lck appears to be more avid than that of CD8 with Lck, postulates that a higher level of TCR signaling during positive selection favors CD4 lineage development, whereas a lower level of TCR signaling favors CD8 lineage development (Hogquist, 2001). The second model postulates that the lineage decision is informed by the nature of temporal changes in the level of TCR signaling, as $CD4^+$ $CD8^+$ thymocytes undergoing positive selection downregulate CD8 in the transition to becoming a single positive thymocyte (Singer et al., 2008). According to the latter model, if TCR signaling continues, the cell becomes a CD4 T cell, but if positive selection signaling ceases, the cell then re-expresses CD8 and turns CD4 expression off, and if TCR signaling resumes then the cell becomes a CD8 T cell.

CO-RECEPTORS ON B CELLS

Unlike most αβ TCR-expressing T cells, B cells do not recognize complexes of antigen-derived peptides with MHC molecules and hence do not need the CD4 or CD8 co-receptors. Nonetheless, B cells do express their own dedicated co-receptors and use these co-receptors to gain important information about the nature of an antigen. B-cell co-receptors substantially alter the magnitude and possibly alter the nature of the signaling by the BCR and hence can greatly affect activation of the B cell. B-cell co-receptors can promote activation of B cells, by indicating that the antigen is likely to be foreign, for example if it has been decorated with complement components, or they can inhibit activation to antigens that are linked to sialic acid-containing oligosaccharides or are coated with IgG antibodies. The former is likely an indication that the antigen may be a self-antigen, whereas the latter may indicate

that sufficient antigen-specific IgG has already been made and additional activation of naïve B cells is unnecessary.

Strong evidence for the ability of complement to tag an antigen and thereby promote antibody responses in vivo was obtained through the use of fusion proteins between lysozyme and one or more copies of the C3d fragment of complement, which is a ligand for complement receptor 2 (CR2) on B cells. Addition of a single C3d to lysozyme decreased the amount of protein needed to induce an antibody response by ten-fold, and addition of three tandem C3d fragments decreased the amount needed by more than 1,000-fold (Dempsey et al., 1996), demonstrating a strong enhancing function of CR2 for B-cell activation. This appears to require co-localization of the CR2 complex with the BCR, as shown by co-cross-linking studies. Interestingly, preligation of CD19, the signaling component of the CR2 complex, inhibits IgM-mediated B-cell proliferation in a manner that is remarkably similar to the effects on T-cell activation of preligating the T-cell coreceptors, CD4 and CD8.

CR2, also known as CD21, forms a molecular complex with CD19 and the tetraspanin CD81, also known as TAPA-1 (Fig. 6.3). CD19 and CD81 are thought not to have ligands of their own, although CD81 serves as an entry receptor for infection of cells by hepatitis C virus (Pileri et al., 1998). CD81 may serve to promote the association of the CR2 complex with membrane rafts (see below), whereas the cytoplasmic tail of CD19 provides the major signaling function to the complex. The enhancement of BCR signaling by CD19 appears to extend beyond CR2 engagement, since the B-cell phenotype of $CD19^{-/-}$ mice is more severe than the phenotype of $CD21^{-/-}$ mice. CD19 appears to promote BCR signaling in the absence of complement deposition on the antigen, particularly when the B cell contacts a membrane-bound antigen (Depoil et al., 2008), for example when antigen is held on the surface of a follicular dendritic cell in a germinal center reaction, or when it is held on the surface of a macrophage or dendritic cell in the secondary lymphoid organs. The positive role of CD19 in B-cell activation is additionally illustrated by the striking effects of increasing CD19 expression via a transgene in mice, which results in an abundance of highly activated B cells (Engel et al., 1995).

CD19 is thought to promote BCR signaling by several mechanisms, including binding of the signaling components phosphoinositide 3-kinase (PI 3-kinase) and Vav, and binding of the Src-family PTK Lyn. Phosphorylation of CD19 on its two YxxM motifs (Y482 and Y531) results in recruitment of PI 3-kinase via the SH2 domain of the p85 regulatory subunit (Tuveson et al., 1993). This occurs when CD19 is co-localized with a signaling BCR and its activated protein tyrosine kinases. Mutation of the PI 3-kinase binding sites in the YxxM motifs of CD19 results in a strong defect in the ability of B cells to undergo a successful germinal center reaction, leading to production of high-affinity class-switched antibodies (Wang et al., 2002; Wang and Carter, 2005). The role of CD19 in humans is likely to be similar to what has been reported in mice since defects in CD19 result in common variable immunodeficiency, the main hallmark of which is a defective germinal center response (Schaffer et al., 2007).

The important role of the YxxM motifs in the cytoplasmic tail of CD19 likely reflects the central role of PI 3-kinase in BCR signaling, as is discussed in more detail below. However, it should be noted that Lyn also binds to one of these sites (Y531), complicating the interpretation of mutations of this site. Recruitment and activation of Vav is also likely to be important for the ability of CD19 to promote recognition of membrane-bound antigens (Arana et al., 2008; Weber et al., 2008). The importance of Lyn association with CD19 is less well understood, but by analogy with the role of CD4 and CD8 in TCR signaling, described above, it is attractive to think that this contributes to the great sensitivity of the B cell to lysozyme-C3d fusion proteins observed in vivo.

CORECEPTORS WITH INHIBITORY FUNCTIONS

Inhibitory receptors are now recognized to play critical roles in restraining activation of immune cells by ITAM-containing receptors (Ravetch and Lanier, 2000). Many of these receptors contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs), which become phosphorylated when the inhibitory receptor is brought adjacent to an activating receptor with ITAMs and then recruits one or more SH2-containing phosphatases that attenuate the signaling. In the case of B cells, two inhibitory receptors, FcγRIIB and CD22, appear to function to inhibit BCR signaling when the antigen is decorated with their ligands and hence can mediate their juxtaposition with the antigen-engaged BCR. Thus, they function analogously to the positively acting coreceptors described above, except that they function oppositely to inhibit antigen receptor signaling.

The best understood of these inhibitory receptors is FcγRIIB. Co-ligation of this receptor with the BCR inhibits B-cell proliferative responses and promotes B-cell apoptosis (Nimmerjahn and Ravetch, 2008). Physiologically, co-ligation is likely to occur during the binding of antigen–antibody complexes to antigen-specific B cells. The presence of IgG bound to the antigen reflects the presence of specific high-affinity antibody, so inhibition of further B-cell activation is a mechanism for downregulating antibody production late in an immune response. Indeed, mice made deficient in FcγRIIB have heightened B-cell responses to BCR stimulation, especially at later times after immunization (Takai et al., 1996). Co-ligation of the BCR with FcγRIIB leads to FcγRIIB tyrosine phosphorylation (Muta et al., 1994). The major inhibitory function of this receptor maps to a single tyrosine residue in its cytoplasmic domain that is in the context of the ITIM consensus sequence (I/L/VxYxxL). Phosphorylation of the tyrosine residue in the ITIM leads to the recruitment of the SHIP-1 inositol 5-phosphatase via its SH2 domains (Nimmerjahn and Ravetch, 2008). SHIP-1 modulates BCR signaling by removing the 5-phosphate from phosphatidylinositol 3, 4, 5 trisphosphate (PIP_3), a key molecule involved in BCR signaling, as described in detail below. In addition, SHIP forms a complex with another adaptor protein, $p62^{dok}$, which becomes strongly tyrosine phosphorylated upon BCR-FcγRIIB co-cross-linking and recruits RasGAP, a suppressor of Ras activity (Tamir et al., 2000; Yamanashi et al., 2000).

CD22 is a second cell-surface protein that attenuates signaling via the BCR in a proximity-dependent manner (Nitschke, 2005). CD22 is a transmembrane glycoprotein that belongs to the family of Siglecs (sialic acid binding Ig-like lectins) and is expressed exclusively on B cells. It has been proposed that CD22 acts as a co-receptor that inhibits activation of B cells recognizing cell-surface self-antigens, since such antigens would be expected to include sialic acid-containing oligosaccharides that could bind CD22 and recruit it to the BCR (Lanoue et al., 2002), where it can inhibit BCR signaling by ITIM recruitment of SHP-1 (SH2-containing protein tyrosine phosphatase 1) and SHIP-1. Accordingly, CD22-deficient B cells show augmented BCR-induced calcium and Erk MAP kinase responses (Nitschke, 2005). Moreover, sequestering CD22 away from the BCR by preincubation with anti-CD22-coated beads leads to robust mitogen-activated protein kinase (MAPK) activation upon BCR stimulation, whereas co-ligating BCR with CD22 suppresses MAPK activation.

Alternatively or additionally, CD22 associates with ligands on the surface of the B cell, and this association promotes its inhibitory function. In this way, CD22 may act as a rheostat that attenuates BCR signaling in a manner that is dependent on developmental maturity and/or activation state. In agreement with this view, recent studies have shown that the inhibitory effect of CD22 on BCR signaling is much stronger in mature resting B cells than it is on immature B cells of the bone marrow or their counterparts in the spleen, the transitional 1 (T1) and transitional 2 (T2) B cells (Gross et al., 2009). This developmental regulation of the inhibitory function of CD22 is due in part to a two- to three-fold upregulation of CD22 cell-surface expression on mature follicular B cells compared to T1 B cells, and may also be due to a change in the acetylation of B-cell-surface sialic acids that regulates their ability to bind to CD22 (Cariappa et al., 2009).

Upon BCR engagement in splenic B cells, most of which are mature, the cytoplasmic tail of CD22 is phosphorylated by the Src family kinase Lyn on six tyrosine residues. Three of these are in the context of ITIMs, in agreement with a negative regulatory role for CD22. Lyn-deficient mice lack BCR-induced tyrosine phosphorylation of CD22 and have reduced phosphorylation of FcγRIIB (Xu et al., 2005), arguing that Lyn is the primary tyrosine kinase involved in phosphorylation of the ITIMs of these inhibitory co-receptors. Interestingly, both Lyn-deficient and CD22-deficient mice spontaneously develop substantial titers of IgG anti-nuclear antibodies and anti-native DNA antibodies, autoantibodies characteristic of the autoimmune disease systemic lupus erythematosus. These results suggest that the Lyn/CD22/SHP-1 inhibitory pathway plays an important role in maintaining tolerance to nuclear autoantigens. Unknown is whether this reflects the proposed co-receptor role of CD22 or simply its ability to act as a rheostat that attenuates BCR signaling in mature follicular B cells, setting a higher threshold for B-cell activation.

BCR signaling can also be inhibited by the ITIM-containing cell-surface molecules CD72 and the paired immunoglobulin-like receptor B (PIR-B), although whether or not they are properly thought of as inhibitory coreceptors for the BCR is not known. B cells from CD72-deficient mice are hyperresponsive to suboptimal doses of antigenic and mitogenic stimulation and exhibit enhanced BCR signaling, which is consistent with an inhibitory coreceptor function (Li et al., 2006).

T cells also express a number of ITIM-containing inhibitory receptors, most of which are primarily expressed after antigen stimulation of naïve T cells. These include the inhibitory costimulatory receptors CTLA-4 and PD-1 and a variety of inhibitory receptors also expressed on NK cells. CTLA-4 (CD152) is closely related to the costimulatory receptor, CD28. Both bind to the counter-receptors, CD80 (B7-1) and CD86 (B7-2), which are upregulated on antigen-presenting cells. Antigen stimulation induces B7-2 on B cells, and innate immune stimuli induce expression of B7-1 and B7-2 on dendritic cells and macrophages. Whereas CD28 provides a second requisite signal, which together with that of the TCR can activate T cells, CTLA-4 has a negative regulatory function that serves to maintain a higher threshold for T-cell activation and can prevent T cells from making cytokines or proliferating to antigen. Its importance is highlighted by the lethal T-cell lymphoproliferative syndrome in mice when the *ctla-4* gene is inactivated (Fife and Bluestone, 2008).

CTLA-4 expression is upregulated in activated T cells and is relatively high in T regulatory cells. Exactly how CTLA-4 provides a negative regulatory function is not clear. The following mechanisms have been implicated: (1) competitive binding to CD80 and CD86 (CTLA-4 has a higher affinity for B7s than does CD28), thereby inhibiting the positive function of CD28; (2) downregulation of CD80 and CD86 on the surface of antigen-presenting cells; (3) binding of its cytoplasmic tail to PP2A, a protein serine-threonine phosphatase; and (4) binding of its cytoplasmic tail to SHP-2, a protein tyrosine phosphatase. These mechanisms all could mediate a direct inhibitory effect within effector T cells, but there is some evidence that CTLA-4 can provide inhibitory function in a cell non-autonomous fashion (Fife and Bluestone, 2008), which would fit with a function on regulatory T cells contributing to their inhibitory function. One striking feature of CTLA-4 that might provide a clue regarding its negative regulatory mechanism is that it rapidly recycles from the cell surface via endocytic pathways, maintaining a relatively low number of molecules on the cell surface.

PD-1 (CD279) is a cell-surface molecule expressed on some thymocyte subsets and on activated T cells. It has two ligands, PDL-1 and PDL-2; the expression of the former is fairly broad, while the expression of the latter seems limited to dendritic cells and monocytes. In peripheral T cells, PD-1 negatively regulates T-cell activation, and in chronically activated T cells, it can prevent further T-cell activation (Barber et al., 2006). It is inducibly tyrosine phosphorylated on two tyrosines, one of which is a classical ITIM motif (discussed above). It is known to interact with two cytoplasmic tyrosine phosphatases, SHP-1 and SHP-2 (Chemnitz et al., 2004; Okazaki et al., 2001). These phosphatases can then negatively regulate tyrosine phosphorylation-dependent events downstream of the TCR and thereby dampen or inhibit T-cell activation.

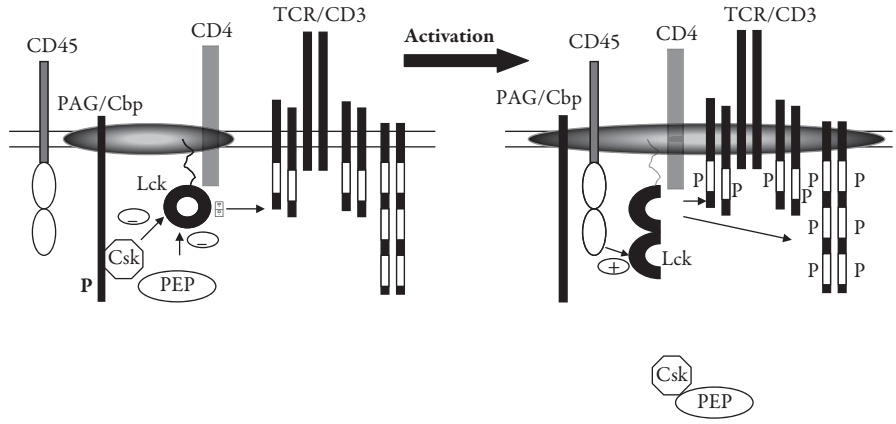

Figure 6.4 ***Dynamic regulation of Src family kinases by Csk and tyrosine phosphatases, CD45 and PEP, in plasma membrane microdomains (membrane rafts).*** According to one model that has received recent support, an early event in TCR signaling is dephosphorylation of PAG to release Csk and PEP from the plasma membrane, which promotes conversion of Src family kinases to a more highly activated form. This would positively amplify TCR signaling.

REGULATION BY CD45 AND CSK

The function of Src PTKs is tightly regulated by tyrosine phosphorylation (Cooper and Howell, 1993), which in turn is the result of a dynamic equilibrium involving the opposing actions of kinases and phosphatases. Phosphorylation of a tyrosine near the catalytic site of the kinase domain is associated with the activated state of these kinases. In addition, the C-terminal regulatory region of the Src kinases contains a tyrosine residue whose phosphorylation negatively regulates their activity. In T and B cells, the phosphorylation of this negative regulatory site in Src PTKs appears to be regulated by the opposing actions of the transmembrane PTP CD45 (as well as the transmembrane PTP CD148, in B cells; Hermiston et al., 2009) and the cytoplasmic PTK Csk (Fig. 6.4) (Chow and Veillette, 1995). The regulation of Lck in T cells by CD45 and Csk has been most thoroughly studied.

Various isoforms of CD45, derived by alternative splicing of exons 4 to 6, which encode portions of the extracellular domain, are expressed in a cell type- and activation-specific manner on all nucleated cells of the hematopoietic lineage (Hermiston et al., 2009; Lynch, 2004). Although the regulated expression of specific isoforms of CD45 suggests that CD45 may bind or be influenced by extracellular ligands, definitive identification of such ligands has not yet been achieved. As described above for CD22, it is also possible that the extracellular domain of CD45 interacts laterally with other molecules present in the same plasma membrane, thereby delivering the phosphatase domains to their targets. Some evidence of this has been obtained for interaction of the low-molecular-weight isoforms of CD45 with CD4 and the TCR (Dornan et al., 2002). Like most transmembrane PTPases, CD45 contains two tandem PTP homology domains in its cytoplasmic domain. Only the membrane proximal PTP domain clearly has catalytic phosphatase function, although the membrane distal domain may play an important regulatory function since it appears to be necessary for PTP activity of CD45 (Desai et al., 1994).

CD45 expression is required for normal T-cell development in mice (Kishihara et al., 1993). Interestingly, B-cell development is not as dependent on CD45, although the B cells that do develop in CD45-negative mice show functional defects. Another receptor-like PTP, CD148, which is not expressed on most thymocytes or naïve T cells, is expressed constitutively throughout B-cell and myeloid-cell development and appears to provide at least partially redundant phosphatase function with CD45 in the B-cell lineage (Zhu et al., 2008). In peripheral mature T and B cells as well as cell lines and clones, CD45, together with CD148 in the case of B cells, is required for TCR- and BCR-induced signal transduction (Hermiston et al., 2009). The PTP catalytic function of CD45 is required for this molecule to support TCR signal transduction. In its absence, the earliest phosphorylation of ITAMs or recruitment of ZAP-70 does not occur. In CD45-deficient T-cell lines, although there is not a substantial increase in basal tyrosine phosphorylation of most proteins, the negative regulatory tyrosine phosphorylation sites of Lck and Fyn are hyperphosphorylated (Hermiston et al., 2009; Ostergaard, Shackelford et al., 1989). Likewise, the Lyn negative regulatory site is hyperphosphorylated in B cells from CD45 and CD148 doubly deficient mice (Zhu et al., 2008). Phosphorylation of this site results in an inactive state of these PTKs because of a conformational constraint imposed by an intramolecular interaction between the C-terminal phospho-tyrosine and the SH2 domain of the kinase (Sicheri et al., 1997). Accordingly, Src family kinases are largely inactive in CD45-deficient lymphocytes. The observations made in CD45-deficient cells are consistent with the notion that the phosphotyrosines in the C-terminal regions of Src family kinases are physiological substrates of CD45 and CD148. Moreover, the greatly decreased activity of Lck and Fyn can account for the defect in TCR signal transduction function. Thus, in normal resting cells where these kinases are mostly dephosphorylated at the C-terminal-negative regulatory sites, CD45 and CD148 maintain the Src kinases in an antigen receptor-responsive but not fully active state. Activation of Src family kinases involves the phosphorylation of a critical tyrosine within the regulatory loop of the kinase domain in addition to the lack of phosphorylation of the negative regulatory site.

Observations of isoform-specific effects of CD45 in reconstituted T-cell hybridoma systems are suggestive of specific functional properties for the different isoforms (Novak et al., 1994). Studies with an epidermal growth factor receptor-CD45 chimera suggest that ligand-induced dimerization may negatively regulate the phosphatase function of CD45 (Desai et al., 1993). Inactivation by dimerization of CD45 appears to be mediated by a putative wedge-like structure in the juxtamembrane region that blocks the catalytic site of the partner molecule during dimerzation (Majeti et al., 1998). Supporting the significance of this regulatory mechanism, disruption of the wedge function in mice leads to lymphoproliferation and autoimmunity (Majeti et al., 2000). Interestingly, the different splice variants of CD45 have differences in their affinities for homodimerization, likely affecting the overall activity of CD45 in the cell (Xu and Weiss, 2002). Thus, the dimerization of CD45 is a regulated event that affects its activity and thereby restrains lymphocyte activation.

The PTK responsible for the phosphorylation of the negative regulatory sites of Src PTKs is Csk, a widely expressed PTK that contains SH2 and SH3 domains (Chow and Veillette, 1995). In the basal state, Csk and CD45 are presumably in equilibrium, maintaining the C-terminal tyrosines of Src family protein kinases primarily in the unphosphosphorylated form. Overexpression of Csk can inhibit TCR-induced protein tyrosine phosphorylation and interleukin-2 (IL-2) production. Regulation of Csk occurs by its differential distribution between the cytosol and lipid raft fraction of the plasma membrane during lymphocyte activation (Fig. 6.4). The lipid raft resident transmembrane adaptor protein PAG1 was identified as a binding partner for Csk in resting T cells (Brdicka et al., 2000). PAG1 is constitutively tyrosine phosphorylated in resting T cells and binds to Csk via the SH2 domain of the latter. Following TCR cross-linking, PAG1 is dephosphorylated by an unknown tyrosine phosphatase, thereby releasing Csk, which relocalizes to the cytosol, allowing the balance to be shifted in the favor of Src family kinase activation (Davidson et al., 2003). This could be part of a positive feedback loop, whereby release of the negative regulator Csk from the membrane results in diminished phosphorylation of Src kinases on their negative regulatory sites. Later, PAG1 gets rephosphorylated and recruits Csk back to the lipid microdomains, where it can exert its negative regulatory effect on Lck and Fyn once again. Surprisingly, mice deficient in PAG1 have little phenotypic abnormality (Dobenecker et al., 2005). However, this may simply reflect the presence of proteins with functions redundant with that of PAG1. For instance, the LIME protein has been shown to interact with Csk and Lck (Brdickova et al., 2003; Hur et al., 2003).

In addition to its role in phosphorylating the negative regulatory C-terminal tyrosine of Src family kinases, Csk also negatively regulates TCR signaling by associating with an intracellular protein tyrosine phosphatase, proline-enriched phosphatase (PEP) (Hermiston et al., 2009), which is expressed in hematopoeitic cells. PEP has been found to associate with Csk via the SH3 domain of Csk (Veillette et al., 2009). Substrate-trapping experiments using mutant PEP identified Zap-70 and FynT as two proximal targets of PEP-mediated inhibition and the site of dephosphorylation on FynT was mapped to the positive regulatory tyrosine 417. Thus, a complex of Csk–PEP acts synergistically to interfere with TCR signaling by phosphorylating the C-terminal negative regulatory tyrosine and dephosphorylating the activating tyrosine of Src family kinases (Cloutier and Veillette, 1999). Mice made deficient in PEP have a rather mild phenotype, with increased T-cell proliferative responses during secondary responses (Hasegawa et al., 2004). In addition to PEP, two other members of the PEP family, PTP-PEST and PTP-HSCF, have been reported to cooperate with Csk in the regulation of antigen-receptor signaling in T cells (Veillette et al., 2009). Whether PEP, PTP-PEST, and PTP-HSCF all act redundantly or uniquely is currently unknown. Nonetheless, the importance of PEP in the immune system is indicated by the association of a moderately common allele of PTPN22 (the gene for the human homolog of PEP) with increased susceptibility for several autoimmune diseases, including type 1 diabetes, rheumatoid arthritis, and systemic lupus erythematosus (Vang et al., 2007). The amino acid change seen in this allele disrupts PTPN22's association with Csk, indicating that this association is important for maintaining tolerance to self. This is consistent with the reduced inhibition of TCR signal transduction by Csk and the allele of PTPN22 that does not associate with Csk (Zikherman et al., 2009).

Genetic analysis in model organisms also supports the view that Csk plays an important role in regulating lymphocyte function. In Csk-deficient chicken B cells, Lyn was found to be highly phosphorylated at the autophosphorylation site and constitutively active. In addition, Syk was also constitutively activated, to an extent similar to that observed upon BCR stimulation. However, BCR cross-linking was still required for other cellular proteins to be tyrosine phosphorylated and for inositol 1, 4, 5-trisphosphate (IP_3) generation and calcium mobilization (Hata et al., 1994). Homozygous mutant mice with a disruption in the Csk gene were found to have neural tube defects, were embryonic lethal, and died during gestation at days 9 to 10. The Csk-deficient embryonic cells exhibited an increase in the activity of Src, Fyn, and Lyn kinases, which suggests that Csk regulates the activity of these kinases; this may be essential during embryogenesis (Imamoto and Soriano, 1993). The role of Csk in lymphocyte development was studied by conditionally inactivating Csk in immature thymocytes. Lack of Csk was found to override the requirement for pre-TCR, αβ TCR, and MHC class II for the development of $CD4^+CD8^+$ double-positive and $CD4^+$ single-positive thymocytes as well as peripheral CD4 αβ T-lineage cells (Schmedt et al., 1998; Schmedt and Tarakhovsky, 2001). Thus, in the absence of negative regulation of the Src family kinases, these kinases can drive the development of αβ T cells independently of the pre-TCR and the αβ TCR. In support of this conclusion, triple knockout mice lacking Csk, Lck, and Fyn show a block in the development of αβ T cells, indicating that Lck and Fyn are responsible for driving T-cell development in the absence of Csk. Furthermore, Csk was shown to play a differential role in positive and negative selection during development (Schmedt and Tarakhovsky, 2001).

SIGNALING PATHWAYS ACTIVATED BY ANTIGEN RECEPTOR-INDUCED TYROSINE PHOSPHORYLATION

Stimulation of the TCR and BCR induces the tyrosine phosphorylation of many intracellular proteins and sets into motion a number of signaling pathways. In the following sections, we will focus on some of the better-understood TCR- and BCR-regulated signaling pathways and discuss the involvement of some of these proteins in lymphocyte activation.

ROLE OF ADAPTOR PROTEINS

Signal transduction via the TCR and BCR flows from the membrane proximal tyrosine kinases to downstream signaling events such as activation of signaling enzymes, opening of endoplasmic reticulum (ER) and cell surface calcium channels, activation of small GTPases of the Ras superfamily, conversion of cell-surface integrins to their high-affinity state, rearrangement of the actin cytoskeleton, and changes in the activity of a variety of transcriptional regulators. The transmission of these signals requires the formation of multimolecular complexes consisting of signaling components with adaptor molecules that contribute to the specificity and localization of signaling events. Adaptor proteins are those signaling components that lack enzymatic or transcriptional activity, but instead act to bring together other signaling components or bring them to the plasma membrane to promote their functions. Adaptors often comprise modular domains such as the SH2, SH3, PTB, PDZ, or PH domains or simply multiple tyrosines or proline-rich motifs that can act as docking sites for some of the above domains (Pawson, 1995; Pawson and Nash, 2000).

Some adaptors are membrane proteins whereas others are located in the cytosol in unstimulated cells and are recruited to the plasma membrane by initial receptor signaling events. In the former category are the transmembrane adaptors LAT, which is required for TCR signaling, and CD19, which is part of the complement receptor 2 co-receptor complex in B cells and also participates in BCR signaling in the absence of complement tagging of the antigen. Both proteins contain multiple tyrosine residues that are phosphorylated upon receptor ligation and form docking sites for other downstream adaptors and signaling enzymes and therefore serve to nucleate the formation of multimeric signaling complexes, or "signalosomes."

TCR-associated and activated ZAP-70 phosphorylates LAT, which then recruits the signaling enzyme phospholipase Cγ1, the Ras-activator mSOS via its association with the SH2 domain-containing adaptor Grb2, and the cytosolic adaptor SLP-76 via its association with a related SH2 domain-containing adaptor Gads (Samelson, 2002). SLP-76 in turn nucleates a complex with other signaling molecules, including the cytoplasmic protein tyrosine kinase Itk and the Rho family GEF Vav (Yablonski and Weiss, 2001). Several molecules related to LAT have been identified, including LAB (also called NTAL), LAX, and LIME (Horejsi et al., 2004). Although these molecules are also localized in the plasma membrane and have multiple sites of phosphorylation, none seems to play as central a role in immunoreceptor signaling as LAT.

The connections between antigen receptor-activated tyrosine kinases and signaling reactions in B cells is only analogous to T cells in some ways but different in others. No single transmembrane adaptor analogous to LAT that is essential for BCR signaling has been found, and it is likely that there is no such adaptor. B cells do express a relative of SLP-76 called B-cell linker protein (BLNK) (also called SLP-65 or BASH) (Wollscheid et al., 1999). SLP-76 and BLNK have similar domain structures and recruit several of the same signaling molecules in T and B cells. Both SLP-76 and BLNK have a single C-terminal SH2 domain, which recruits them from the cytosol to the plasma membrane when signaling is initiated. As mentioned above, SLP-76 is recruited to LAT. In contrast, BLNK is recruited directly to the BCR, binding to a phosphorylated non-ITAM tyrosine (Y204) in the Igα cytoplasmic domain (Engels et al., 2001; Kabak et al., 2002; Patterson et al., 2006). There is likely an alternative mechanism of recruitment of BLNK to the plasma membrane, possibly involving direct interaction with the lipid bilayer (Kohler et al., 2005), since mice with specific mutation in Y204 of Igα have a less severe B-cell phenotype than mice lacking BLNK altogether (Patterson et al., 2006).

SLP-76 and BLNK have multiple tyrosines that are phosphorylated upon stimulation and thereby contribute to signaling-dependent formation of multicomponent signaling complexes at the plasma membrane adjacent to signaling antigen receptors. Other protein–protein interaction domains and motifs that are present in these proteins also contribute to the formation of these signaling complexes.

In cells lacking SLP76 or BLNK, proximal receptor engagement is uncoupled from distal events such as calcium flux and IL-2 production (Clements et al., 1998; Pappu et al., 1999; Yablonski et al., 1998). Deficiency of SLP-76 or BLNK in mice leads to strong defects in T- and B-cell development, respectively (Clements et al., 1998; Hayashi et al., 2000; Pappu et al., 1999). BLNK also plays an essential role in BCR signaling in humans, and genetic deficiency in this component leads to a severe agammaglobulinemia (Minegishi et al., 1999), similar in phenotype to a Btk deficiency but much less common because BLNK is encoded on an autosomal chromosome rather than the X chromosome (Chapter 25).

As mentioned above, CD19 also contributes to BCR signaling some of the functions provided by LAT and SLP-76. Mice genetically defective in CD19 have impaired B-cell development (Engel et al., 1995), indicating the importance of the contribution of CD19 to BCR signaling.

THE PHOSPHATIDYLINOSITOL-BASED SIGNALING PATHWAYS

Two of the central signaling reactions triggered by antigen receptors utilize enzymes acting on the plasma membrane phospholipid phosphatidylinositiol 4,5-bisphosphate (PIP_2) to generate second messengers, which in turn activate a variety of signaling reactions. PIP_2 is acted upon either by PI 3-kinase, which adds a third phosphate to the inositol head group,

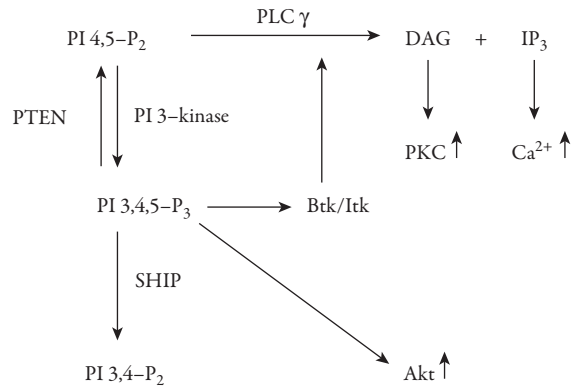

Figure 6.5 ***Critical signaling events involving phosphatidylinositol-containing lipids.*** Both the PI 3-kinase signaling pathway and the phosphoinositide hydrolysis signaling pathway emanate from PIP2, as shown. PI, phosphatidylinositol; PLC, phospholipase C; DAG, diacylglycerol; PKC, protein kinase C; IP3, inositol trisphosphate; SHIP, SH2 domain-containing inositol phosphatase.

generating phosphatidylinositol 3,4,5-trisphosphate (PIP_3), or by phospholipase Cγ1 (PLC-γ1) in T cells or PLCγ2 in B cells, both of which hydrolyze PIP_2 to yield the second messengers inositol 1,4,5-trisphosphate (IP_3) and diacylglyercol (DAG) (Fig. 6.5). While it was initially thought that these were two independent signaling reactions emanating from the same precursor, subsequent studies have shown a more hierarchical signaling architecture in which PIP_3, in addition to promoting unique signaling events, contributes importantly to the activation of PLC-γ. The latter role appears to be more pronounced in B cells than in T cells (Fruman and Bismuth, 2009).

The product of PI 3-kinase, PIP_3 serves two major signaling functions. It serves as a binding site for several signaling molecules that contain pleckstrin homology (PH) domains, including the Tec family tyrosine protein kinases Itk (T cells) and Btk (B cells), and PLC-γ, thereby directing their localization within the cell. In addition, PIP_3 promotes activation of the protein kinases PDK1 and Akt. Akt has a PH domain that binds PIP_3, which allows Akt to be recruited to the membrane in response to PIP_3 elevation. Once at the membrane, Akt is activated by a second kinase, PDK-1 (3-phosphoinositide-dependent protein kinase 1). Activated Akt in turn promotes survival, inhibits the quiescence-promoting transcription factors of the FOXO subfamily (Fruman and Bismuth, 2009), and promotes glucose uptake and metabolism (Jones and Thompson, 2007), all of which contribute to antigen-induced activation of mature lymphocytes (Fig. 6.5). The biological importance of this pathway is illustrated by the promotion of autoimmunity and lymphoproliferation in the mouse by loss-of-function mutations of PTEN, which enhance PI 3-kinase signaling by decreasing hydrolysis of PIP_3 by PTEN, and conversely by the immunodeficiency that results from targeted disruption of PI 3-kinase subunits in B cells or T cells (Fruman and Bismuth, 2009).

The PI 3-kinase isoforms activated by antigen receptors are class IA PI 3-kinases containing a 110 kDa catalytic subunit (mostly the p110δ isoform, although T cells also express the p110α and p110β isoforms), with an SH2 domain-containing regulatory subunit of either 85 kDa (p85α or p85β) or of 50 or 55 kDa (p50α, p55α, or p55γ). The larger isoforms of the PI 3-kinase regulatory subunit contain additional protein–protein interaction domains (a SH3 domain and a RhoGAP-like domain) lacking in the small forms, but the contributions of these domains to lymphocyte signaling are not understood. Mice with genetic ablation of p85α or p110δ, the main subunits of PI 3-kinase in B cells, exhibit impaired maturation of developing B cells and poor B-cell activation via the BCR, defects that are very similar to those seen in mice deficient in Btk (Fruman and Bismuth, 2009). Moreover, in both the Btk mutant B cells and the B cells with defective PI 3-kinase, there is defective BCR-induced calcium elevation, due to substantially impaired PIP_2 hydrolysis by PLC-γ. It is currently thought that this reflects the BCR-induced formation of a multimolecular complex including BLNK, Btk, and PLC-γ2, which fails to localize properly to the plasma membrane in the absence of binding of the PH domains of Btk and/or PLC-γ2 to PIP_3 in the membrane. In comparison, PIP_2 hydrolysis downstream of the TCR is less dependent on PIP_3 in the membrane. The reasons for this difference between B cells and T cells are not well established, but possible explanations include the fact that there is a transmembrane adaptor (LAT) that recruits PLC-γ1 to the plasma membrane, and that Tec family tyrosine kinases in T cells include, in addition to an isoform that must be recruited to the plasma membrane (Itk), an isoform that is constitutively tethered to the membrane (Rlk). In any case, PIP_3 plays an important role in promoting T-cell activation through its critical role in activating PDK1 and Akt.

Whereas both the BCR and the TCR directly activate the PI 3-kinase signaling pathway, co-receptors or co-stimulatory receptors amplify or inhibit this pathway to influence lymphocyte activation. In B cells, the positively acting CD19 and the negatively acting FcγRIIB act primarily to increase or decrease, respectively, the amount of PIP_3 formed in the membrane in response to BCR engagement. The cytoplasmic domain of CD19, which is the signaling component of the CR2 coreceptor complex and also contributes to BCR signaling in the absence of complement involvement, contains two copies of the YxxM motif, which matches the consensus for binding by the two SH2 domains of the PI 3-kinase regulatory subunits, and these motifs are required for recruitment of PI 3-kinase to CD19 and its participation in BCR signaling. PI 3-kinase activation in B cells is additionally supported by a cytosolic adaptor protein called B-cell adaptor for PI 3-kinase (BCAP) (Kurosaki and Hikida, 2009). Signaling downstream of PI 3-kinase is greatly attenuated by the negative coreceptor FcγRIIB, the ITIM of which recruits selectively SHIP-1 (SH2-containing polyphosphate inositol 5-phosphatase), which removes the 5-phosphate from PIP_3, generating phosphatidylinositol 3,4-bisphosphate, an isomer of the form of PIP_2 that is the starting point for both PI 3-kinase and PLC-γ signaling pathways. The form of PIP_2 generated by SHIP-1 is a ligand for the PH domains of some signaling components, but its function is not well understood. The major effect of SHIP-1 is thought to be reduction of PIP_3 in the plasma membrane and attenuation of PIP_3-dependent signaling events. Correspondingly, a major effect of co-ligation of FcγRIIB with

the BCR is to greatly attenuate PIP_2 hydrolysis and calcium elevation. Thus, both the positively acting CR2 coreceptor and the negatively acting FcγRIIB coreceptor primarily work through modulation of the PI 3-kinase signaling pathway.

In T cells, it is co-stimulatory receptors rather than co-receptors that modulate PI 3-kinase signaling. Co-stimulatory receptors recognize ligands on antigen-presenting cells and either promote T-cell activation or inhibit it, depending on the receptor. On naïve, resting T cells, CD28 plays a critical co-stimulatory function in T-cell activation by binding CD80 and CD86 (B7-1 and B7-2), the expression of which is greatly upregulated on antigen-presenting cells by Toll-like receptors and receptors for inflammatory cytokines. CD28 costimulation can lead to increased cytokine production, enhanced proliferation, and diminished apoptosis in TCR-mediated responses (Salomon and Bluestone, 2001). The cytoplasmic domains of CD28 contains a YxxM motif for recruiting PI 3-kinase and boosting this signaling reaction. Depending on the model system used, the PI 3-kinase binding motif in the cytoplasmic tail of CD28 is required to mediate the co-stimulatory effect being measured or is unimportant, with several proline-rich putative SH3-binding motifs implicated in promoting alternative signaling pathways (Parry et al., 2007). One downstream effector of the PI 3-kinase pathway, the Akt serine/threonine kinase, can partially substitute for CD28 signals in T-cell lines and in CD28-deficient T cells (Kane et al., 2001), supporting the importance of this pathway in primary T cells. ICOS, a second co-stimulatory receptor that plays a critical role in promoting T-cell help for antibody responses, also recruits PI 3-kinase as part of its stimulatory function (Dong et al., 2003). In addition, two inhibitory members of the co-stimulatory receptor family, CTLA-4 and PD-1, have been reported to attenuate Akt activation, but the biochemical mechanisms of these effects are not well established, nor is the importance of this regulation for their inhibitory function. Thus, it appears that a significant mechanism by which co-stimulatory receptors affect T-cell activation is via modulation of the PI 3-kinase signaling pathway, but further studies are needed to establish this point.

A second key signaling reaction starting from PIP_2 is the hydrolysis of this molecule by PLCγ1 or PLCγ2. PLCγ2 is preferentially expressed in B cells, whereas PLCγ1 is preferentially expressed in T cells. Hydrolysis of PIP_2 by these enzymes generates IP_3, which is responsible for elevation of calcium levels in the cytoplasm, and diacylglycerol (DAG), which promotes activation of protein kinase C (PKC) isozymes and activation of the Ras activator, RasGRP. Following TCR or BCR stimulation, PLCγ isozymes translocate to the membrane, where they become tyrosine phosphorylated on critical tyrosine residues, increasing their catalytic activity. This translocation involves the recruitment of PLCγ isozymes via their SH2 domains to phosphorylated tyrosine residues on LAT in T cells and BLNK in B cells. Moreover, the SH3 domain of PLCγ1 interacts with a proline-rich motif in SLP-76, which may explain the requirement of this adaptor for PLC activation (Yablonski et al., 2001).

Stimulation of the TCR and BCR results in a rapid and sustained increase in $[Ca^{2+}]_i$. The immediate increase in $[Ca^{2+}]_i$ is the result of the release of intracellular stores of calcium through the action of IP_3 on IP_3 receptors in the ER (Sugawara et al., 1997). Release of the intracellular stores of calcium, however, results in only a transient rise in $[Ca^{2+}]_i$. The sustained increase requires an inward transmembrane flux of extracellular calcium ("store-operated calcium entry"), which occurs through plasma membrane Ca^{2+} channels that contain the ORAI1 calcium channel. ORAI1 was identified in an siRNA screen carried out with a Drosophila cell line, and, in addition, a mutation in this protein was discovered to be the cause of a defective calcium response in T cells from a patient with severe combined immunodeficiency (Feske et al., 2006); see also Chapter 20. Similarly, ORAI1 deficiency in mice results in immunodeficiency (Oh-hora and Rao, 2008). The human genome has two close homologs of ORAI1, called ORAI2 and ORAI3, but ORAI1 is the major isoform expressed in T cells. The "calcium-release activated calcium" (CRAC) channels containing ORAI1 are regulated by a transmembrane ER protein STIM1, which contains an EF hand, a sensor for calcium levels, in the part of the protein localized to the inside of the ER (Liou et al., 2005). A second related protein, STIM2, is also present in lymphocytes but has a different calcium sensitivity and seems to play a greater role in maintaining calcium elevation at later times and also in maintaining basal cytoplasmic calcium levels in the absence of TCR stimulation (Brandman et al., 2007). When calcium in the ER is depleted in response to IP_3 levels in the cytoplasm, STIM1 oligomerizes and now appears by fluorescence microscopy to co-localize with ORAI1 in areas of the cell where the ER and the plasma membrane come very close to one another (Oh-hora and Rao, 2008). Evidence that ORAI1 and STIM1 interact directly has recently been reported (Park et al., 2009). This STIM1/ORAI1 interaction maintains elevated intracellular free calcium levels in the cytoplasm as long as PIP_2 hydrolysis continues because IP_3 prevents refilling of the ER with calcium by maintaining open calcium channels in that organelle. When PIP_2 hydrolysis ceases, the ER refills and STIM1 dissociates from ORAI1, which no longer allows calcium entry across the plasma membrane. These changes, combined with mechanisms that pump calcium out of the cytoplasm, return the level of cytoplasmic calcium to that of the unstimulated state. The sequence of events in B cells is thought to be very similar.

The increase in $[Ca^{2+}]_i$ triggered by the TCR or BCR has effects on several downstream events, including the activation of calcium/calmodulin-dependent kinase II and calcineurin, a calcium/calmodulin-regulated protein serine/threonine phosphatase (also called PP2B). These events inhibit migration of T cells, promoting stable interactions with antigen-bearing antigen-presenting cells, promote degranulation of cytotoxic T cells, and promote the activity of a series of transcription factors. The activation of calcium/calmodulin-dependent kinase II has been implicated in T-cell anergy (Nghiem et al., 1994) and in activation of the CREB transcription factor, whereas the function of calcineurin has received considerably greater attention. Calcineurin function has been implicated in T- and B-cell responses that depend on TCR and BCR functions in a wide variety of experimental systems. This connection was made possible through the use of the immunosuppressives

cyclosporin A and FK506, which, when bound to their cellular receptors (cyclophilin and FKBP, respectively), function as specific inhibitors of calcineurin (Crabtree, 1999). Among the best examples illustrating the importance of calcineurin in lymphocyte responses are the studies of its role in the activation of a family of transcriptional factors, nuclear factor of activated T cells (NFAT), which plays an important role in the regulation of most cytokine genes, including IL-2. Calcineurin catalytic function has been shown to be required for the transformation of inactive cytoplasmic NFAT into active nuclear NFAT, where it interacts with AP-1 transcription factors (made up of Fos and Jun family members) at composite elements in the upstream IL-2 regulatory region (Crabtree, 1999). This requirement involves dephosphorylation of the inactive cytoplasmic NFAT, exposing its nuclear localization sequence (Oh-hora and Rao, 2008). Thus, by virtue of its regulatory influence on multiple cytokine genes, an increase in NFAT activity resulting from a calcium elevation can have profound effects on the subsequent immune response.

The other second messenger released by PIP_2 hydrolysis is DAG, which is an activator of RasGRP, which activates Ras, and also is an activator of protein kinase C (PKC) isozymes. Some PKC isoforms expressed in lymphocytes are calcium- and DAG-dependent enzymes (PKCα, β1, and β2), whereas others are DAG-dependent but calcium-independent (PKCε, δ, η, and θ) (Baier and Wagner, 2009). These functions of DAG can be mimicked by addition to cells of the much more stable pharmacological activators of the phorbol ester family. While different PKC isoforms likely have many functions, clearly two important functions are in the activation of the transcription factor NF-κB and in the activation of Ras, as described below.

SIGNALING PATHWAY LEADING TO ACTIVATION OF NF-κB

Lymphocyte survival and activation are highly dependent on NF-κB function (Gerondakis et al., 2006). Recent studies have greatly increased our understanding of the signaling pathway connecting antigen receptors to NF-κB activation. NF-κB is typically composed of a heterodimer of p50 and either p65 (also called RelA) or c-Rel, although homodimeric forms are known, as is an alternative complex made up of p52 and RelB, which is activated by some TNF receptor superfamily members. A small family of inhibitors, collectively called I-κB, maintain NF-κB in an inactive state until the IκB kinase (IKK) complex becomes activated. Active IKK phosphorylates I-κB, which leads to its ubiquitinylation and degradation by the proteasome. This releases NF-κB, which then translocates to the nucleus and activates transcription of NF-κB-responsive genes. NF-κB plays a key role in the induction of many genes involved in inflammation and immunity, including many cytokines, chemokines, and intracellular survival factors of the Bcl-2 family (Sen, 2006).

Essential to BCR- and TCR-induced NF-κB activation are three proteins that form a complex following antigen receptor engagement, CARMA1, Bcl10, and MALT1. Mice defective in any of these components have severe defects in antigen receptor-induced NF-κB activation but still activate NF-κB downstream of TNFR superfamily members or downstream of Toll-like receptors (Rawlings et al., 2006). CARMA1 is a large scaffold protein with multiple protein–protein interaction domains that regulate membrane localization, oligomerization, and Bcl10 binding. Recent genetic and biochemical studies support the hypothesis that select protein kinase C isoforms, PKCθ in T cells and PKCβ in B cells, are responsible for phosphorylating CARMA1 and causing a shift from an autoinhibited configuration into the active configuration, which binds to membrane lipid rafts, oligomerizes, and recruits Bcl10, which in turn recruits MALT1 and TRAF2 and/or TRAF6. TRAF family members are required components for the activation of NF-κB by most and possibly all receptors. TRAFs interact with the IKK complex and with the protein kinase that is believed to directly activate it, TAK1. These interactions, promoted by the TAK1-associated proteins TAB1, TAB2, and TAB3, transmit the information of Bcl10 and MALT1 oligomerization into IKK activation. NF-κB activity is also modulated by phosphorylations of the p50 and p65 subunits, but the exact details are not well understood.

RAS ACTIVATION IN T AND B CELLS

Ras proteins have been implicated in a wide variety of growth and differentiation responses in many cell types. The activation of Ras proteins following antigen receptor stimulation has similarly been shown to be a critical event in lymphocyte development and activation. The Ras proteins are a small family of 21 kDa GTP-binding proteins with GTPase activity. The activation state of Ras is determined by the form of guanine nucleotide bound to it; GTP-bound Ras is active and GDP-bound Ras is inactive. GDP-bound Ras becomes activated by interacting with guanine nucleotide exchange proteins (GEFs), which cause it to release GDP, allowing it to bind GTP (Fig. 6.6). Conversely, GTP-bound Ras is inactivated by hydrolyzing the GTP to form GDP and PO_4, a reaction stimulated by GTPase activating proteins (GAPs). Thus, the activation of Ras could be a consequence of GEF stimulation, GAP inhibition, or a combination of both. The activation of Ras can lead to a variety of downstream events, including (1) the activation of the Erk/MAPK pathway; (2) the activation of PI 3-kinase; and (3) the activation of other small-molecular-weight, GTP-binding proteins such as Rac and CDC42 (McCormick and Wittinghofer, 1996).

Initial studies of growth factor receptor protein tyrosine kinases (PTKs) in Drosophila, *C. elegans*, and mammalian fibroblasts identified an adaptor molecule called Drk, Sem 5, or Grb2, respectively, in the different species, that interacts with both the stimulated receptors and with a guanine nucleotide exchange factor called SOS (son of sevenless) to activate Ras. Subsequently, in some systems another adaptor, called Shc, was found to function in linking Grb2/SOS to the activated receptor PTKs. Genetic and biochemical studies indicate that Grb2/SOS proteins couple the stimulated PTK receptors to the activation of Ras. SOS action on Ras is

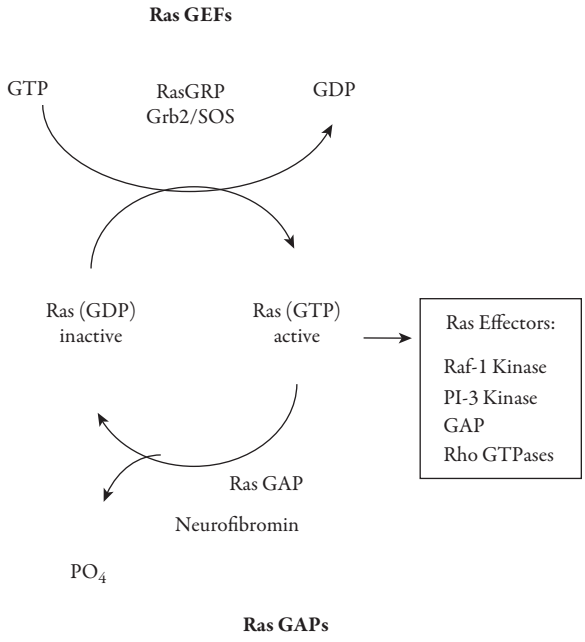

Figure 6.6 ***Regulation of Ras activation and its effector functions.*** Ras cycles between an active form in which GTP is bound and an inactive form in which GDP is bound. Conversion to the active form involves dissociation of bound GDP, catalyzed by Ras GEFs (guanine nucleotide exchange factors), followed by binding of GTP, whereas conversion to the inactive form involves hydrolysis of GTP, stimulated by RasGAPs (GTPase activating proteins), to yield free phosphate, which dissociates from Ras, and GDP, which stays bound to the now-inactive Ras.

regulated, in part, by intracellular localization: receptor signaling induces a translocation of Grb2/SOS from the cytosol to the plasma membrane by virtue of the binding of Grb2 to tyrosine phosphorylated sites on the receptor itself or on adaptor proteins such as Shc. Shc phosphorylation and interaction with Grb2/SOS has been observed after TCR or BCR stimulation (Crowley et al., 1996; Ravichandran et al., 1993; Saxton et al., 1994). Conditional deletion of the *Shc1* gene in developing thymocytes indicates that the majority of Erk activation at the TCR β-selection checkpoint is dependent upon ShcA (Trampont et al., 2006), although the importance of Shc for activation of Ras and ERK in mature lymphocytes is unclear.

Activation of GEF function is probably the primary mechanism responsible for the positive activation of Ras by the TCR and BCR (Ravichandran et al., 1993). In T cells, the Grb2/SOS complex associates with the TCR-induced phosphorylated LAT, which would serve to translocate these complexes to the membrane and can stimulate Ras activation (Wange, 2000). However, optimal Ras activation in T and B cells appears to involve another family of Ras GEFs that are activated downstream of PLCγ1 or 2 activation and activate Ras in concert with SOS proteins (Dower et al., 2000; Ebinu et al., 2000). RasGRP proteins have calcium-binding EF hands and, more importantly, a C2/DAG-binding domain. Thus, the activity of PLCγ1 may be directly translated into Ras activation through the recruitment of RasGRP. In addition, PKC enzymes, which are also activated by DAG together with calcium in the case of the classical PKC isoforms, play a role in activating RasGRP GEF function by phosphorylating RasGRP.

Regulation of Ras activation through RasGAPs also occurs to some extent. For example, RasGAP is tyrosine phosphorylated following BCR stimulation and to a lesser extent following TCR stimulation (Gold et al., 1993). In B cells, it is recruited to the membrane via the negative coreceptor FcγRIIB, SHIP, and the adaptor protein $p62^{dok}$ (Tamir et al., 2000; Yamanashi et al., 2000), so it appears to function to limit Ras activation at least in this context.

Why should lymphocyte antigen receptors utilize two families of Ras GEF, SOS proteins and RasGRP proteins, for the activation of Ras? Recent studies suggest very dynamic and synergistic functional interactions between SOS and RasGRP proteins (Das et al., 2009). SOS proteins can interact with Ras via two sites. One binds to the GDP-bound form of Ras and induces exchange with GTP. The other site, the so-called allosteric site, binds preferentially to the active GTP-bound form of Ras proteins, and this interaction greatly stimulates the GEF activity of the other Ras-binding site of SOS (Boykevisch et al., 2006). Thus, there is the potential for positive feedback influencing SOS activity. Recent studies suggest that RasGRP may facilitate the activation of SOS activity following TCR engagement by providing the initial low levels of RasGTP that can boost the activity of SOS, which is also recruited to the membrane (Das et al., 2009). Moreover, the coordinated activation of both of these two GEFs exhibits hysteresis, or a type of biochemical memory, which prolongs Ras activation even after a stimulus is removed. This memory can facilitate Ras activation in lymphocytes in the setting of transient cell–cell interactions in secondary lymphoid organs.

As listed above, there are several reported downstream effectors of Ras (Alberola-Ila and Hernandez-Hoyos, 2003). The effectors responsible for Ras function in different systems are not fully established and no single effector can usually substitute for the activated form of Ras in experimental models. The best-characterized Ras effector is the Raf-1 kinase (Morrison and Cutler, 1997). GTP-bound Ras interacts directly with the serine/threonine kinase Raf-1, translocating it to the membrane. The translocation of Raf-1 to the membrane can increase its activity, although other mechanisms have been implicated in Raf activation, including its tyrosine phosphorylation and transphosphorylation by dimerization. The translocation to the membrane by Ras may simply concentrate Raf-1 there and allow it to dimerize and transphosphorylate. In any case, Raf-1 is activated in T and B cells in response to TCR and BCR stimulation or phorbol ester stimulation, corresponding to signals activating Ras (Genot and Cantrell, 2000). The activation of Raf-1 leads to its direct interaction and activation of a dual specific tyrosine/serine/threonine kinase, MEK-1, that in turn activates the Erk1/Erk2 MAP kinases. MAP kinases have numerous functions, including the phosphorylation and activation of transcription factors such as serum response factor, which can regulate c-fos and Egr-1 transcription (Raman et al., 2007). Thus, this antigen receptor-regulated cascade of events ending in MAP kinase

activation can function to regulate transcriptional events leading to lymphocyte differentiation and activation.

Ras plays a critical role in lymphocyte development and activation. For example, expression of activated Ras as a transgene can promote early T-cell developmental transitions in recombinase activating gene (RAG)-deficient mice, which cannot express the pre-TCR (Swat et al., 1996). Similarly, blockade of the Ras pathway with inactivating mutants can interrupt normal thymic development (Alberola-Ila and Hernandez-Hoyos, 2003). The magnitude of Ras activation may be very critical for determining whether TCR peptide/MHC molecule interactions lead to positive or negative selection in the thymus. Negative selection has been correlated with strong but transient Erk activation, whereas positive selection requires a lower but sustained elevation of Erk activity (McNeil et al., 2005). In addition, the localization of activated Erk within the developing thymocyte also differed between thymocytes undergoing negative selection and those undergoing positive selection (Daniels et al., 2006). Recent modeling studies suggest mechanisms whereby a sharp threshold of TCR peptide/MHC molecule affinity can result from the extent of LAT phosphorylation and properties of the Grb2/SOS and RasGRP GEFs (Prasad et al., 2009), which may contribute to the sharp affinity cutoff between positive selection and negative selection in the thymus (Naeher et al., 2007).

Ras activation is also critical for T-cell activation. Dominant negative mutants of Ras can partially block IL-2 gene activation in T cells and completely block NFAT-based transcription (Genot and Cantrell, 2000). This is probably explained by the involvement of Ras in regulating the AP-1 components involved. Conversely, an activated form of Ras, which cannot hydrolyze GTP, can synergize with calcium ionophores to induce NFAT-directed transcription.

Similarly, Ras plays important roles in B-cell development and activation. Specific inhibition of the Erk MAPK by using pharmacological inhibitors of MEK1 and MEK2 blocked BCR-induced proliferation of mature B cells but did not block apoptotic responses of immature B cells and an immature B cell line, indicating that Erk MAPK mediates some effects of BCR signaling but not others (Richards et al., 2001). BCR-induced transcription of the *egr*-1 early response gene is mediated by Ras (McMahon and Monroe, 1995). The Egr-1 promoter contains five serum response elements (SREs), sites of action of SRF, which is activated downstream of Ras, Raf, and Erk. Egr1 appears to mediate BCR-induced upregulation of ICAM-1 and CD44 expression, molecules that are important for B-cell adhesion to other cells (Maltzman, Carman et al., 1996; Maltzman, Carmen et al., 1996).

VAV PHOSPHORYLATION AND FUNCTION IN T AND B CELLS

Among the many TCR- and BCR-induced tyrosine phosphoproteins is the proto-oncogene Vav (Margolis et al., 1992). The original cellular Vav is now called Vav-1, as mammals additionally express two related molecules. Vav-1 is expressed exclusively in hematopoietic cells and trophoblasts, whereas Vav-2 and Vav-3 are expressed more widely (Swat and Fujikawa, 2005). Vav-1 contains multiple distinct domains, including a leucine-rich domain, a domain related to GEF domains of Rho family GTPases (Dbl-homology domains), a pleckstrin homology (PH) domain, a zinc finger domain, two SH3 domains, and an SH2 domain. Deletion of the N-terminal 65 residues of Vav leads to a protein with transforming ability in NIH 3T3 fibroblasts (Katzav et al., 1991).

Vav-1 appears to be a direct substrate of the TCR- and BCR-dependent Src family kinases and Syk family PTKs (Swat and Fujikawa, 2005). Phosphorylation of tyrosines near its N-terminus seems to play a role in activating the GEF function of the Dbl-homology domain. Its SH2 domain has a consensus binding specificity for the sequence adjacent to Y315 (YESP) in ZAP-70 (Songyang et al., 1994). Both the binding of the SH2 domain of Vav-1 and the tyrosine phosphorylation of Vav-1 depend on this site in ZAP-70 (Wu et al., 1997). Moreover, the functional activity of ZAP-70 is reduced by mutation of this site in a reconstitution system where NFAT activity is assessed. These results suggest that the interaction of ZAP-70 with Vav is an important event in antigen receptor signal transduction.

The importance of Vav in TCR and BCR signaling is underscored by the phenotype of mice lacking one or more Vav family members (DeFranco, 2001). The Vav-1-deficient mice show defects in thymic cellularity, thymocyte positive and negative selection, peripheral T-cell numbers, and peripheral T-cell responses (Swat and Fujikawa, 2005; Tybulewicz et al., 2003). While the deficiency of Vav-1 does not have any serious defects in the B-cell compartment other than loss of the B-1 subtype of B cells, evidence from genetic knockouts of the Vav-2 gene alone or in combination with Vav-1 deficiency shows that Vav-1 and Vav-2 have both unique and redundant roles in BCR-mediated signaling (Doody et al., 2001; Tedford et al., 2001). The development of T and B cells in Vav-2-deficient mice is largely unaffected; however, these mice show a decrease in antibody responses to T-independent type 2 antigens and also a partial defect in T-dependent IgG production. Suboptimal stimulation of the BCR revealed defects in BCR responses such as calcium flux and proliferation in these mice. Vav-1 and Vav-2 double knockout mice, by contrast, had impaired B-cell development and greatly diminished BCR responses, similar to the substantial effects of the Vav-1 knockout on T cells. Deletion of all three Vav proteins leads to a severe impairment in T- and B-cell development (Swat and Fujikawa, 2005).

Considerable evidence suggests that the GEF-dependent function of Vav regulates Rho, Rac, or Cdc 42 GTP-binding proteins (Bustelo, 2001; Swat and Fujikawa, 2005). The primary role of these Ras-like small-molecular-weight GTPases is to orchestrate changes in the actin cytoskeleton. Such changes are likely important for effective interactions of T cells with antigen-presenting cells (Dustin, 2009) or of B cells with membrane-bound antigen (Harwood and Batista, 2008). In one model system used to probe Vav-1 function, overexpression of Vav in Jurkat T cells led to potentiation of TCR-mediated IL-2- and NFAT-regulated reporter constructs (Wu et al., 1995). This functional activity, which depends on TCR-specific signals, is also dependent on Ras,

Lck, and calcineurin function. This suggests that Vav may function very proximally within the TCR pathway or in an alternate signaling pathway that, together with Ras- and calcineurin-regulated pathways, contributes to IL-2 gene expression. This is most likely to involve increased Rac and Cdc42 activity, as evidenced by studies of Vav-deficient cells. The most prominent signaling defect in these cells is a failure of actin polymerization and antigen receptor clustering or cap formation (Fischer et al., 1998). These effects suggest that the regulation of Rac and Cdc42 by Vav GEF function is a critical event in TCR signal transduction.

Surprisingly, biochemical defects in TCR signaling in Vav-1-deficient T cells include defects in phospholipase C tyrosine phosphorylation and Ca^{2+} mobilization (Tybulewicz et al., 2003). This global effect of Vav deficiency suggests that Vav may have roles in T-cell activation beyond Rac or Cdc42 activation. It is possible that Vav plays an important role in the formation or stability of TCR-induced multicomponent signaling complexes (signalosomes). Vav interacts with the TCR- and BCR-induced adaptors, SLP-76 (Wu et al., 1996), and BLNK (Fu et al., 1998). The Vav SH2 domain is required for these interactions. As has been seen with Vav, overexpression of SLP-76 markedly potentiates TCR-mediated IL-2 promoter and NFAT-driven gene expression (Motto et al., 1996). Furthermore, overexpression of both Vav and SLP-76 synergistically induced basal and TCR-stimulated NFAT activity (Wu et al., 1996). These results suggest that a signaling complex containing Vav and SLP-76 plays an important role in T-lymphocyte activation. At least part of this function may be GEF-independent and may relate to an adaptor function of Vav (Kuhne et al., 2000). Hence, the defects in MAPK activation and in PI 3-kinase activation that have also been observed in Vav-1-deficient T cells may relate to such adaptor functions.

In B cells, all three Vav isoforms seem to participate in BCR signaling (Kurosaki and Hikida, 2009). Syk contains a sequence homologous to the Vav-1 binding site of ZAP-70, and in addition, the cytoplasmic domain of CD19 has a binding site for Vav. Recent studies suggest that while CD19 appears to be dispensible for early BCR signaling in response to soluble ligands, it is essential for robust signaling in response to membrane-bound ligands, which are likely to be important in many circumstances in vivo (Harwood and Batista, 2008). Genetic experiments in mice and in DT-40 chicken B cells demonstrate that CD19, Vav, and Rac2 are all essential for actin-based spreading of B cells following contact with antigen on a cell surface. This spreading allows the B cell to sense the presence of antigen with much greater sensitivity and thereby enable signaling and also antigen uptake for presentation to helper T cells. Thus, as is the case in T cells, Vav is likely to play a critical role in B-cell activation via its ability to promote actin polymerization to support cell–cell contact.

ANTIGEN RECEPTOR-MEDIATED ACTIVATION OF INTEGRINS

A key function of antigen receptors is to regulate the adhesion of T cells and B cells to cells presenting antigen to them, and this is largely accomplished via regulation of the adhesive properties of integrins (Evans et al., 2009). Integrins are a family of αβ heterodimeric transmembrane proteins that on their intracellular side bind to actin cytoskeleton components and on their extracellular side bind either to cell-surface ligands on other cells, or less importantly in the case of lymphocytes, to extracellular matrix ligands. Hence, they "integrate" cell binding to their environmental cues with binding to the cytoskeleton. Their affinity is regulated in two major ways: by their conformation and by their lateral mobility as controlled by the actin cytoskeleton. In their low-affinity conformation, integrin extracellular domains are bent sharply in the middle, with the end of the molecule pointing back toward the cell expressing the integrin. Signaling events induced by the TCR or BCR signaling, or alternatively by chemokine receptors, induce a straightening of the molecule so that the end is now farther away from the cell and in a better position to bind its ligand. Integrins appear to exhibit two higher-affinity states, referred to as an intermediate-affinity state and a high-affinity state, but what controls the shift between intermediate-affinity and high-affinity states is not well understood. So, here we focus on the shift between the low-affinity and one or the other of the higher-affinity states. In addition to this affinity regulation, integrins generally are fixed to the cytoskeleton, and this limits their ability to bind to ligands that may also be fixed in position (in the extracellular matrix) or at least somewhat limited in their mobility (on the surface of antigen-presenting cells or endothelial cells). TCR or BCR signaling induces dramatic remodeling of the actin cytoskeleton, and this causes a transient release of integrins from being tethered to the actin network. Once these molecules bind to their ligands using their newly acquired higher-affinity conformation, they again become fixed to the cytoskeleton and mediate strong adhesion to the antigen-presenting cell, at least temporarily. This rapid and dramatic alteration in their contribution to cell-to-cell or cell-to-matrix adhesion makes integrins well suited to supporting the function of T cells and B cells. In the integrin field, the ability of other receptors (TCR and BCR in this case) to promote integrin-based adhesion is referred to as "inside-out" signaling, whereas the ability of integrins that have bound their adhesive ligands to signal that fact to the cell and thereby alter cell behavior (survival, activation, etc.) is referred to as "outside-in" signaling.

Both the TCR and the BCR mediate powerful inside-out signaling to induce integrin adhesion. Current understanding of the molecular mechanisms is moderately well advanced, but some questions remain and it is unclear at this time how directly analogous are the molecular mechanisms in T cells and B cells. In T cells, genetic evidence has demonstrated that TCR-induced integrin adhesion depends on the phospholipase Cγ1 signaling pathway, including activation of PKCθ, and also protein–protein interactions emanating from SLP-76 (Baker and Koretzky, 2008). Upon TCR engagement, SLP-76 associates with an adaptor called ADAP (adhesion and degranulation promoting adaptor protein), which in turn associates with an adaptor called SKAP-55 (Src kinase-associated phosphoprotein of 55kDa). SKAP-55 in turn associates with

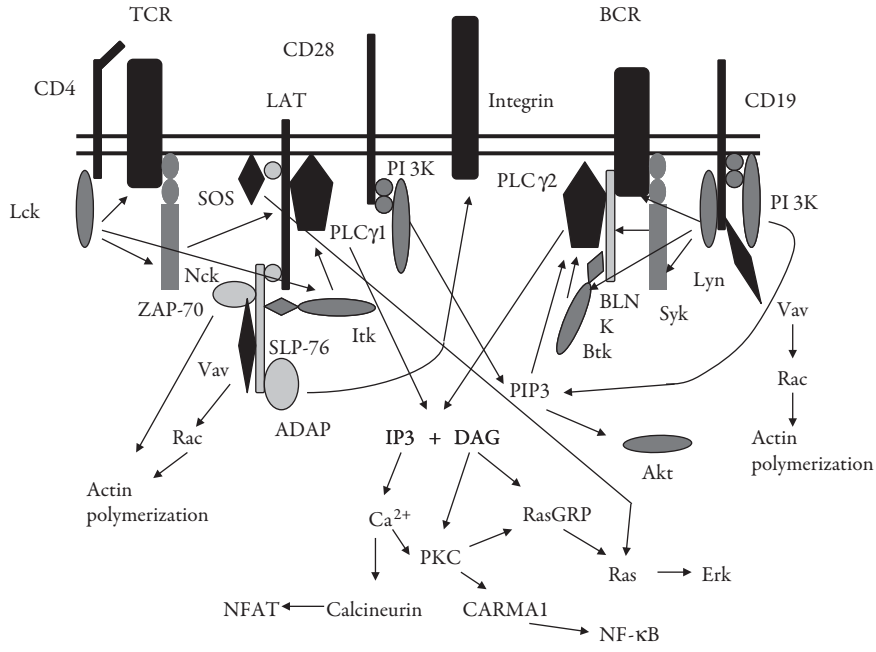

Figure 6.7 *Antigen receptor signaling induces formation of signaling complexes.* See text for details. Not all known interactions could be shown for sake of clarity.

RIAM (Rap1-interacting adhesion molecule). This complex is thought to localize and activate the small-molecular-weight GTP-binding protein Rap1, which appears to be a key activator of integrin affinity, perhaps via its putative effector RapL. In addition, TCR signaling promotes integrin mobility in the membrane, possibly via PKCθ, but how this occurs is not known.

In the case of B cells, the mechanism by which antigen receptor signaling promotes integrin adhesion is less well worked out, but a central role for Rap1 is well established (Arana et al., 2008; Lin et al., 2008; McLeod et al., 2004). Mature B cells do not express ADAP or SKAP-55 but do express a molecule similar to the latter, called SKAP-HOM, and B-cell integrin adhesion is dependent on this SKAP isoform (Togni et al., 2005). Upstream signaling events that appear to be important include PI 3-kinase activation, Vav1/2 activation, and Rac2 (Arana et al., 2008). How integrin activation is localized is not yet clear in B cells, although CD19 may play a critical role.

The major signaling pathways of TCR and BCR signaling are summarized in Figure 6.7.

COMPARTMENTALIZATION OF T AND B ANTIGEN RECEPTOR SIGNALING

Signaling via the antigen receptors and recruitment of various signaling molecules into a "signalosome" is increasingly being viewed in the cell biological context. Recent studies indicate that the interaction of lymphocytes with antigen bound to cell surfaces results in intriguing cell biological phenomena at the point of cell–cell contact, referred to as an "immunological synapse" (Dustin, 2009).

A ROLE FOR PLASMA MEMBRANE MICRODOMAINS IN SIGNAL TRANSDUCTION?

A controversial area in the signaling by antigen receptors has been the role of microdomains in the plasma membrane called "lipid rafts," or more recently and more accurately "membrane rafts" (Dykstra et al., 2003; Gupta and DeFranco, 2007; Shaw, 2006). These subdomains of the plasma membrane are rich in cholesterol, sphingomyelin, and glycosphingolipids with saturated fatty acyl chains, which gives them a less fluid, more structured character referred to as "liquid ordered." These subdomains are enriched in a subset of membrane proteins, including those with particular lipid modifications, such as glycosylphosphatidylinositol (GPI)-anchored proteins, palmitoylated proteins such as members of the Src kinase family, heterotrimeric G proteins, some adaptors such as LAT, and isoprenylated proteins, including Ras family small G proteins. In resting cells, membrane rafts are small (5 to 200 nm in diameter), highly dynamic structures, but upon activation, these microdomains coalesce into structures large enough to be visible by fluorescence microscopy (Viola and Gupta, 2007). Controversy surrounding their role in antigen receptor signaling largely stems from the methods that were commonly used in early studies, namely cholesterol depletion and biochemical isolation by differential detergent solubility (Shaw, 2006). Cholesterol depletion of cells with agents such as methyl-β-cyclodextran causes the remaining membrane-raft components to dissociate and become incorporated into the bulk membranes of the cell. Clearly many membrane functions are perturbed by cholesterol depletion, not just membrane-raft association, so interpreting the results of cholesterol-depletion experiments is not straightforward.

Putative membrane rafts can be isolated for biochemical analysis by taking advantage of their resistance to extraction

by nonionic detergents at low temperature, a feature that is believed to result from the more stable packing of the lipids in these microdomains. While there is some concern that this procedure could create structures that do not exist in the cellular membranes, a greater uncertainty for interpreting data from this approach is that the protein composition of these "detergent-resistant membranes" (DRMs) varies depending on the concentration of detergent used, so whether or not some proteins are components of membrane rafts is not clear. In general, antigen receptors are found to be largely absent from DRM preparations prior to antigen engagement but present in such preparation soon after antigenic stimulation is initiated (Dykstra et al., 2003). This change in localization of antigen receptors upon engagement has been verified by fluorescence microscopy in living B cells by using fluorescence resonance energy transfer (FRET), which showed a rapid association of the BCR with membrane-raft structures identified by the presence of a fusion protein between the membrane-raft targeting N-terminal sequence of Lyn fused to GFP (Sohn et al., 2006, 2008). Moreover, lipid rafts appear to be home to a number of proteins important for antigen receptor signaling, including the co-receptors CD4 and CD8, Src family kinases Lck, Lyn and Fyn, and transmembrane molecules that participate in signaling such as LAT and PAG-1 (Dykstra et al., 2003). In addition, CARMA1, which is essential for antigen receptor activation of NF-κB, is induced to associate with membrane rafts upon stimulation (Rawlings et al., 2006).

Despite these suggestive observations, direct evidence for the role of membrane rafts in antigen receptor signaling is scant. Efforts were made to test the role of localization of LAT to membrane rafts for supporting TCR signaling by mutation of the two LAT juxtamembrane Cys residues. These residues are palmitoylated, and these modifications are likely to target LAT to membrane rafts. Mutation of these residues abolished the ability of the mutated LAT to participate in TCR signaling. It is now apparent, however, that this experiment did not test the role of localization of LAT to membrane rafts for its participation in TCR signaling because the mutated LAT no longer trafficks to the plasma membrane (Hundt et al., 2009; Zhu et al., 2005). Morover, LAT does not need to be targeted to membrane rafts to participate in TCR signaling effectively, as determined using a chimeric molecule containing the cytoplasmic domain of LAT and targeting signals that take it to the plasma membrane but not to membrane rafts. Nonetheless, the approach of altering the localization of key antigen receptor signaling components from membrane rafts to the non-raft membrane is promising and likely could provide additional insights into the role of membrane-raft compartimentalization.

Membrane rafts are linked to the actin cytoskeleton, and this association appears to maintain these structures in a dispersed state. This linkage depends in large part on the ERM proteins (ezrin, radixin, moiesin), which are cytosolic proteins that in the active configuration bind to a variety of plasma membrane proteins and also to the actin cytoskeleton, linking the two. Stimulation of the BCR or the TCR results in a rapid dephosphorylation of ezrin, converting it to the inactive confirmation, with the result that there is dissociation of ezrin and a decreased linkage of the plasma membrane to the actin cytoskeleton. This release was shown to improve the ability of T cells to interact with antigen-presenting cells, probably by reducing the rigidity of the plasma membrane (Faure et al., 2004). In B cells, the release of ezrin was found to permit reorganization of membrane rafts within the plasma membrane, allowing for the coalescence of small lipid rafts into larger structures (Gupta et al., 2006). One interesting hypothesis is that these larger rafts now contain at least one of each required signaling component and thereby can efficiently support signaling.

Interestingly, the developmental stage of B and T cells influences the ability of the BCR or TCR to enter membrane rafts upon engagement. Whereas antigen receptors translocate to membrane rafts in mature lymphocytes, they fail to do this in immature B cells or T cells (Viola and Gupta, 2007). In the case of immature B cells, this was shown to be due to a lower level of cholesterol in the plasma membrane of immature B cells relative to mature B cells (Dykstra et al., 2003). Moreover, supplementation of the membranes of immature B cells with cholesterol restored the ligand-induced association of the BCR with membrane rafts (Karnell et al., 2005). These observations indicate that membrane rafts are unlikely to play an essential role in antigen receptor signaling. It is possible that they serve to amplify signaling or even may be required for a subset of signaling reactions. In agreement with the later idea, immature B cells were poor at activating Rac1 in response to BCR cross-linking, whereas cholesterol-supplemented immature B cells activated Rac1 similarly to mature B cells (Brezski and Monroe, 2007). An alternative and not mutually exclusive possibility is that the dispersion of signaling components in small membrane rafts inhibits signaling at low levels of antigen receptor engagement and creates a greater threshold for signaling in mature B cells compared to immature B cells, consistent with observations in the literature (Gross et al., 2009). Additional experiments will be needed to address these possibilities.

ORGANIZATION OF ANTIGEN RECEPTORS IN THE IMMUNOLOGICAL SYNAPSE

Efficient T-cell activation requires sustained interaction between the TCR and MHC/peptide complex. Recent imaging studies of regions of contact between T cells and antigen-presenting cells have described the following sequence of events occurring at the plasma membrane: T-cell polarization, initial adhesion, TCR microcluster formation, and formation of a highly organized immunological synapse. T cells use the leading edge of the cell, the lamellapodia, to contact the surface of the antigen-presenting cell and test for the presence of antigen. Once TCRs in the lamellapodia become engaged by their cognate peptide/MHC complex, they organize into small aggregates called "microclusters," which are visible by using a high-resolution form of fluorescence microscopy called total internal reflection fluorescence (TIRF) microscopy, together with an artificial lipid bilayer containing peptide/MHC complexes and ligands for integrins (Dustin, 2009). These TCR microclusters are highly active in signaling

and are connected to the actin cytoskeleton, which sweeps them to the center of the contact region. Within minutes of a stable T cell–APC interaction, the molecules in the contact zone organize themselves into a bull's-eye arrangement of molecules with the TCR and MHC/peptide complexes clustering in the center (central supramolecular activation clusters, c-SMACs) and the adhesion molecules, LFA-1 and ICAM-1, forming a ring around the periphery (p-SMACs).

The functional significance of the c-SMAC/p-SMAC organization of the immunological synapse has been a matter of great debate. When a strong antigenic stimulus is provided to the T cell, microclusters outside of the p-SMAC exhibit strong signaling, whereas signaling in the c-SMAC area is attenuated (Varma, 2006), arguing that inhibitory mechanisms limiting or terminating signaling are favored in the c-SMAC in this circumstance. In agreement with this interpretation, the use of a patterned artificial membrane that allows formation of TCR microclusters but does not allow them to be swept into the c-SMAC results in enhanced TCR signaling compared to a nonpatterned bilayer (Mossman et al., 2005). In contrast, when a weak antigenic stimulus is provided to the T cell, more TCR signaling is evident within the c-SMAC region than in the peripheral regions (Cemerski et al., 2007, 2008), suggesting that attenuation of signaling in the c-SMAC is dependent on the level of signaling. Mathematical modeling based on these observations suggests that for this reason the c-SMAC/p-SMAC organization of the immunological synapse serves to broaden the responsiveness of T cells to allow them to respond to weaker antigens as well as stronger antigens.

Co-stimulation via CD28 also affects aspects of the immunological synapse. When CD80 and/or CD86 is expressed on the antigen-presenting cell, then CD28 is observed to be present in the early signaling TCR microclusters, and it is brought to a region adjacent to but outside the c-SMAC region containing the TCR (Yokosuka, Kobayashi et al., 2008). The participation of CD28 seems to provide qualitatively unique aspects to the immunological synapse, including efficient recruitment of PKCθ (Altman and Villalba, 2003) and also efficient recruitment of membrane-raft microdomains (Viola and Gupta, 2007). The latter function is mediated by the actin filament cross-linking protein filamin A, which associates with the cytoplasmic domain of CD28 in the c-SMAC and promotes association with membrane rafts via the actin cytoskeleton (Tavano et al., 2006).

The immunological synapse is usually thought to be a property of a T cell interacting with an antigen-presenting cell, but a similar cell biology is seen in the interaction between B cells and antigen-bearing follicular dendritic cells (FDCs) or antigen- and integrin ligand-bearing artificial membrane bilayers (Harwood and Batista, 2008). B cells contacting a membrane-bound antigen initiate a spreading response that extends the area of membrane contact between the B cell and the bilayer. Microclusters of signaling BCRs are rapidly formed, highly analogous to what is seen in T cells. These microclusters are swept into a c-SMAC area of contact and the B cell contracts its membrane, retaining contact with the antigen-bearing membrane in the central area. As in T cells, the antigen receptor-rich cSMAC is surrounded by a ring of LFA-1. This sequence of events is dependent on BCR signaling reactions, including those downstream of Vav and PLC-γ2 (Weber et al., 2008), and facilitates uptake of the bound antigen, allowing the B cell to then process the antigen and load it onto its class II MHC molecules for presentation to helper T cells.

The demonstration that B cells and T cells interacting with membrane-bound antigen exhibit nearly identical cell biological organization of their antigen receptors and integrins suggests that this behavior reflects the biophysical and cell biological nature of the events. For example, the molecular sizes of integrin-ligand extracellular domains and of TCR-MHC extracellular domains are different enough that it has been proposed that the size differences provide a force for segregating these molecules into distinct zones (Choudhuri and van der Merwe, 2007). On top of this biophysical force, the actin cytoskeleton together with myosin IIA (Ilani et al., 2009) actively moves TCR microclusters to the center of the contact region, which may be responsible for forcing integrins to a ring surrounding the c-SMAC.

CONCLUSIONS

Although T and B cells use distinct receptors to recognize completely different forms of antigens, the signal transduction machinery regulated by their antigen receptors shows many similarities. Differences may reflect the different form or context in which antigen is recognized. The signaling machinery includes lymphocyte-specific components that interact with signaling components that are more ubiquitously expressed and used in a wide variety of cellular systems. Lymphocyte function may be impaired by interruption of any of the critical components in these signaling cascades. However, discrete immune deficiency states are likely to result from alterations in the critical known and unknown components that are lymphoid-specific.

LYMPHOID ORGAN DEVELOPMENT, CELL TRAFFICKING, AND LYMPHOCYTE RESPONSES

Sirpa Jalkanen and Marko Salmi

A productive interaction between a lymphocyte and its cognate antigen is required to trigger an adequate immune response. Thus, it is not only the defects in the production and maturation of lymphocytes or in the activation machinery that can result in immunodeficiencies, but the same outcome can be seen if otherwise normal cells do not migrate properly within the body in search of foreign antigens. The best-known examples of this class of diseases are leukocyte adhesion deficiencies (LAD, see Chapter 38). The impact of proper lymphocyte recirculation between blood and different tissues and within the tissue stroma for eliciting an immune response already becomes evident by looking at the physical dimensions of our immune system.

Humans have approximately 10^{12} lymphocytes, each of which normally expresses receptors for only one antigen. Thus, for most antigens only some 100 to 1,000 specific lymphocytes reside anywhere in the body. Moreover, at any moment only about 1 percent of these lymphocytes are in blood circulation, whereas the rest are in tissues. The freely mobile cells in the blood travel at high velocity for their size. Even in small-caliber venules, where the extravasation takes place, an 8-μm-diameter cell moves about 500 μm/sec in the blood flow. Moreover, the total length of the circulatory tree has been estimated to exceed 100,000 km in an adult. These constraints make it very challenging for a specific cell to leave the blood at a desired site. At the same time, enormously large body surfaces are exposed to antigen invasion. The total area of the principal entry ports for antigens is about 2 m^2 in the skin, 400 m^2 in the gut, and 100 m^2 in the respiratory system. The antigens, on the other hand, can be minute particles such as viruses or short foreign peptides. Thus it is clear that a highly efficient, adaptive immune response cannot rely on chance for random contact between the antigen and a specific lymphocyte anywhere in the body.

An elaborate system of lymphocyte recirculation has evolved to address these challenges (Butcher and Picker, 1996; Salmi and Jalkanen, 1997; Springer, 1994). Different functions of the immune system are compartmentalized to specific organs and tissues, and these units are then interconnected by lymphocyte trafficking via trees of vascular and lymphatic vessels (Fig. 7.1). Thus, primary lymphoid organs are specialized for the production of huge numbers of lymphocytes. The specificity of a lymphocyte is also determined in these organs. The mature but antigenically inexperienced cells are then released into the circulation. These naïve cells extravasate from the blood into secondary lymphoid organs (such as peripheral lymph nodes, Peyer's patches of gut). Simultaneously, antigens are concentrated into these very same organs from large epithelial surfaces (via an afferent lymphatic system to peripheral lymph nodes and via M cells into Peyer's patches). The secondary lymphoid organs are thus designed to collect and concentrate lymphocytes on the one hand and antigens on the other and to provide an optimal microenvironment for launching a productive immune response. Finally, the effector lymphocytes leave the secondary lymphoid organs, equipped with a capacity to migrate to the peripheral sites of inflammation. All the rest of the organs and tissues in the body can be regarded as tertiary immune tissues, which harbor significant numbers of lymphocytes only during an active immune response.

LYMPHOCYTE MIGRATION TO PRIMARY LYMPHATIC ORGANS

Lymphocyte trafficking first takes place during early ontogeny, when lymphoid precursor cells populate the lymphocyte-forming organs (Cumano and Godin, 2007; Ueno and

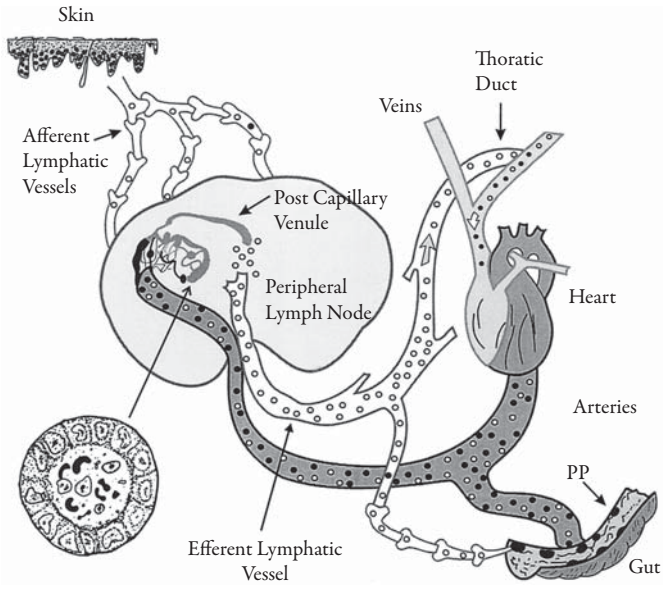

Figure 7.1 Lymphocytes recirculate between the blood and lymphoid organs. Most lymphocytes enter the peripheral lymph nodes or organized lymphoid tissues of the gut (Peyer's patches [PP] and appendix) via high endothelial venules. A low-level, continuous migration of lymphocytes from vascular beds such as skin to lymph nodes takes place via afferent lymphatics. The incoming lymphocytes migrate through the tissue parenchyma, enter the lymphatics, and are then carried within the efferent lymphatics back to the systemic blood circulation. Most of the venous circulation has been omitted for clarity. (Reproduced with permission from Salmi and Jalkanen, 1997.)

Weissman, 2007). Initially, precursor cells from the yolk sac and/or aorta–gonad–mesonephros area migrate to the fetal liver. Later, the spleen and bone marrow become the main targets for these precursor cells. After this stage the fate of B and T lymphocytes differs. B lymphocytes undergo their entire development in the cavity of bone marrow in contact with stromal cells. T-cell precursors, by contrast, move further on to the thymus. They enter the thymus through cortical vessels and gradually migrate toward the medulla during the maturation processes. Finally, immunocompetent but naïve B and T lymphocytes join the circulating pool of lymphocytes in the blood. Although these early migratory events are crucial for the development of the immune system, many of the molecular determinants involved in the trafficking remain to be elucidated.

Development of the lymphoid organs and their population of lymphocytes is regulated in a highly time-dependent manner (Bailey and Weiss, 1975; Bofill et al., 1985; Campana et al., 1989; Spencer et al., 1986; Vondenhoff et al., 2007). In humans, the first CD3-positive thymocytes are found by week 10 of gestation. Anlage of secondary lymphoid organs have already started to develop earlier. Peripheral lymph nodes developing from a lymphatic plexus become recognizable around week 10, but development of high endothelial venule (HEV)-like vessels (the specialized vessels for lymphocyte recruitment, see below) and accumulation of early lymphocytes in these nodes can be seen only in 15- to 18-week-old fetuses. In gut, mucosal villi appear around weeks 9 to 10 of gestation. By week 14, clusters of lymphocytes can be detected in the lamina propria, and by 19 weeks well-organized Peyer's patches appear. The 12-week-old fetal spleen contains few lymphocytes, but at 14 weeks T and B cells are scattered throughout the organ. The early seeding of lymphocytes takes place in the absence of any external antigenic stimulation.

It is intriguing that the endothelial adhesion molecules, which govern lymphocyte trafficking in the adult, are expressed in a functional form very early during human development but in a remarkably different manner in terms of tissue specificity (Salmi et al., 2001). The gut addressin MAdCAM-1 (see below) is widely expressed in fetuses already at week 7. In fetuses, not only is it crucial for lymphocyte adhesion to vessels in gut, but it is also the most important determinant for lymphocyte binding to HEVs in peripheral lymph nodes. Although the adult peripheral node addressin, PNAd (see below), is expressed in humans at week 15, it only gradually starts to dominate in mediating lymphocyte trafficking to peripheral lymph nodes during early childhood. On the basis of these findings it is likely that efficient lymphocyte recirculation takes place already in utero.

TRAFFICKING OF LYMPHOCYTES TO SECONDARY LYMPHOID ORGANS

Peripheral lymph nodes, Peyer's patches, and spleen are the prime target organs for naïve lymphocytes. In lymph nodes, HEVs, based on the characteristic cuboidal morphology of endothelial cells, allow efficient recruitment of bloodborne lymphocytes (Kraal and Mebius, 1997; von Andrian and Mempel, 2003). In these postcapillary venules, the shear stress is relatively low, and the endothelial surfaces protruding into the lumen of the vessels are rich in specific molecules needed for efficient adhesion. Moreover, the junctions between endothelial cells in these vessels are not typical tight junctions; rather, a flap-valve–like mechanism is operative at this site, which also facilitates cellular transmigration. Consequently, when the lymphocytes flow into HEVs they undergo the different steps of the classical extravasation cascade very efficiently. It has been estimated that up to 50 percent of incoming lymphocytes make contacts with the HEV lining in Peyer's patches, and that even one cell in four can ultimately extravasate in these specialized organs (Bjerknes et al., 1986). On the basis of calculations in sheep, up to 15,000 lymphocytes can be expected to be transmigrating through HEVs in a single lymph node every second (Girard and Springer, 1995).

Antigens are concentrated to lymph nodes through the other vessel systems draining into these organs (Randolph et al., 2005). Free antigens or antigens taken up by dendritic cells enter lymph nodes from the periphery via afferent lymphatic vessels. These vessels empty into the subcapsular sinuses, from which cells and antigens can penetrate into the lymphoid areas while flowing through the fine lymphatic channels within the tissue. The dual vessel supply bringing in lymphocytes by blood and antigens by lymph maximizes the likelihood for lymphocyte–antigen contacts in lymph nodes.

When lymphocytes enter the lymphoid tissue they are further guided by chemotactic gradients into specific intra-

organ locations. Most notably, different chemokines secreted by many cell types help to segregate lymphocytes into discrete T- and B-cell areas within the lymph node (Sallusto and Baggiolini, 2008). Thus B cells preferentially accumulate into cortical B-cell follicles, whereas T cells are recruited into more diffuse subcortical T-cell areas. While percolating through the tissue stroma the lymphocytes constantly search for their cognate antigens presented by different types of professional antigen-presenting cells also concentrated in lymph nodes. If they fail to find a specific antigen in the lymph node, they enter the lymphatic sinuses and leave the organ via efferent lymphatic vessels. These cells are then carried back to the blood system, since the main lymphatic trunks (such as the ductus thoracicus) open into the major veins near the heart. Then these cells are free to move on in the circulation and to enter any other lymphoid tissue in the body during their continuous recirculation (Gowans and Knight, 1964). One cycle from the blood back to the blood takes about 1 day, so any single lymphocyte has time to percolate through hundreds of lymph nodes until it dies. This patrolling behavior of a lymphocyte is interrupted and retargeted only if it encounters its specific antigen within a lymphoid tissue (see below).

Lymphocyte recirculation through the spleen is profoundly different from that in the lymph nodes (Mebius and Kraal, 2005). Notably, HEVs are absent from the spleen and lymphocytes enter the white pulp via marginal-zone sinuses, where macrophage-like cells surrounding the endothelial cells may be important for recruitment. In the splenic parenchyma, lymphocytes again migrate toward specific guidance molecules. However, here T cells migrate into confined T-cell areas around the central arteriole, whereas B cells remain scattered in the corona. Splenic lymphocytes also seem to leave the organ via the splenic vein rather than via lymphatics. Although the spleen contains more lymphocytes than all the lymph nodes together, the migratory pathways in this organ specialized for concentrating blood-derived antigens remain rather poorly characterized.

TISSUE-SELECTIVE HOMING OF ACTIVATED LYMPHOCYTES

When a lymphocyte meets its cognate antigen in lymph nodes, its migratory properties change profoundly (Gowans and Knight, 1964; von Andrian and Mempel, 2003). The activated lymphocyte undergoes proliferation and differentiation in the lymph node. Thereafter, its progeny cells leave the node via the efferent lymphatics together with other naïve lymphocytes. However, upon re-arrival into the circulation, the antigen-activated effector cells no longer randomly recirculate to other lymph nodes. Instead, they have become imprinted so that they can preferentially traffic into the peripheral epithelial tissues through which the inciting antigen penetrated the body surfaces. This reprogramming is mainly instructed by local dendritic cells, which adapt external cues into signals giving information on the tissue localization (Sigmundsdottir and Butcher, 2008). The imprinting involves at least changes in the expression profile of adhesion molecules and receptors for chemokines as well as effector functions of lymphocytes. These effector cells can leave the blood via the normal flat-walled postcapillary venules in the periphery and navigate into areas of microbial or other inflammatory stimuli. Hence, the effector cells are efficiently targeted to those locations, where they can do the most good to defend the body.

A small population of effector cells ultimately turns into memory cells. Should the same antigenic exposure reoccur, the memory cells can evoke a rapid response against it. These cells can be divided into central memory and effector memory cells, which have different abilities to migrate into lymphoid and nonlymphoid tissues (such as epithelial surfaces). The central memory cells can home back to lymph nodes via HEVs, whereas the effector memory cells have mainly lost this ability and migrate to the peripheral tissues instead. Again, the phenotypic changes in the memory cell subsets reflect their recirculation potential.

Under physiological conditions, two main recirculation routes for activated lymphocytes can be distinguished (Fig. 7.1) (reviewed in Agace, 2008; Butcher and Picker, 1996; Salmi and Jalkanen, 1997; Springer, 1994; von Andrian and Mempel, 2003). Immunoblasts activated in peripheral lymph nodes preferentially migrate into the skin, whereas those responding to gut-derived antigens in Peyer's patches tend to return to the gut-associated lymphatic tissues. The gut-seeking immunoblasts enter mainly the intestine in the lamina propria, which is the body's largest nonorganized lymphoid tissue. These cells may also have the capacity to migrate into the respiratory and genitourinary tract, which have traditionally been included in the common gut-associated lymphoid system (Brandtzaeg and Johansen, 2005). Thus, under normal conditions, the gut and nonmucosal lymphoid organs share the total pool of naïve cells with all possible antigenic specificities, but upon activation, the subsequent migratory route sharpens the immune response into the affected tissue.

During pathological inflammation there are characteristic changes in leukocyte trafficking (Butcher and Picker, 1996; Ley et al., 2007; Salmi and Jalkanen, 1997; Springer, 1994). First, in acute inflammation, polymorphonuclear leukocytes invade the affected site very rapidly, and only later are waves of monocyte and lymphocyte influx seen. In a primary challenge it takes about 3 days before antigen-specific immunoblasts enter the peripheral lesion, but during a secondary response the influx of memory-derived cells occurs much faster. Second, the exposure of flat-walled venules to proinflammatory mediators at a site of acute inflammation makes them much more adhesive toward different classes of leukocytes. Bathing of the affected tissue in inflammatory cytokines, microbial products, and other pro-adhesive compounds results in the rapid synthesis of many endothelial adhesion molecules that are absent from non-inflamed vessels or expressed only at low levels. In chronic inflammation, even an HEV-like transformation of vessels in peripheral tissues is common and is quite often associated with notable lymphoid follicles in these nonlymphoid organs.

Different types of inflammations have typical features that also affect lymphocyte trafficking (Ley et al., 2007). In general, CD8-positive cytotoxic T cells and CD4-positive Th1, Th2,

Th17, and T reg cells, as well as different B-cell subsets, can infiltrate to sites of inflammation, but their relative proportions vary according to the underlying cause. The inflammatory stimulus and/or anatomical location results in a characteristic, although partially overlapping, pattern of expression and/or activation of adhesion molecules and chemotactic systems on both lymphocytes and endothelial cells, which translates into apparently tissue-selective migration patterns into inflamed tertiary sites. For example, inflamed synovial membrane in rheumatoid arthritis displays features of lymphocyte homing, which are clearly distinct from those in peripheral lymph nodes, skin, and gut. In fact, restricted expression of homing-associated molecules on Th1 versus Th2 CD4 lymphocytes may explain the preponderance of Th1 cells in certain inflammatory lesions (D'Ambrosio et al., 2000; Syrbe et al., 1999).

MOLECULAR MECHANISMS IN LEUKOCYTE EXTRAVASATION

THE MULTISTEP ADHESION CASCADE

Lymphocytes and other leukocytes leave the blood in a multistep process that can be visualized both in vitro and in vivo as tethering, rolling, adhesion, crawling, and transmigration (Fig. 7.2) (Butcher, 1991; Springer, 1994; Zarbock and Ley, 2009). Tethering and rolling phases are mainly mediated by selectins and their sialomucin ligands. Transient and weak interactions between lymphocytes and endothelial cells formed by these molecular pairs lead to triggering of an activation step involving chemokines and their receptors. Activation is required for optimal adhesive behavior of leukocyte integrins that are inactive when cells are freely flowing in the bloodstream. However, engagement of other types of molecules, such as glycosyl-phosphatidylinositol (GPI)-linked proteins, on the lymphocyte surface can also result in integrin activation. During activation and firm adhesion, leukocytes change their shape, crawl actively on endothelium, and then start to transmigrate. Molecular mechanisms functioning at the transmigration step have remained poorly known and there has been continuous debate during the past 40 years whether the leukocytes use a transcellular or paracellular route during the transmigration (Engelhardt and Wolburg, 2004). Currently it is thought that in principle the leukocytes are capable of using both transmigration routes, but the leukocyte subtype, the vascular bed, and the inflammatory status of the tissue determine the transmigration route (Sage and Carman, 2009). In both routes the path used by a transmigrating lymphocyte is rapidly closed by unknown repair mechanisms. Movement and final localization of a lymphocyte within the tissue is largely dependent on chemokine receptors and molecules binding to extracellular matrix proteins on its surface (Cyster, 1999, 2005).

The complexity of the multistep cascade functioning in leukocyte extravasation is comparable to blood clotting and complement-mediated killing, in which each step has to be executed correctly to achieve the goal. The extravasation cascade is made more complex by the fact that vascular beds in different organs and inflammatory conditions express some unique homing-associated molecules, and each leukocyte subset displays partially distinct homing molecules on its surface. Because the lymphocyte can enter a particular tissue only if it is equipped by a set of molecules matching the ligands presented on the vascular endothelium of this tissue, the composition of lymphocytic infiltration in each tissue is tightly controlled (Butcher, 1991; Salmi and Jalkanen, 1997; Springer, 1994).

The most relevant homing-related molecules (illustrated in Fig. 7.3) are presented below in more detail and in the order of their principal place in the adhesion cascade. It should be emphasized here, however, that the functions of these molecules overlap in vivo and may depend on the characteristics of the vascular bed, where the interactions take place. For example, integrins are able to mediate rolling under low shear, and in narrow capillaries they may act without a clear preceding, selectin-mediated rolling phase (Salmi and Jalkanen, 1997; Springer, 1994).

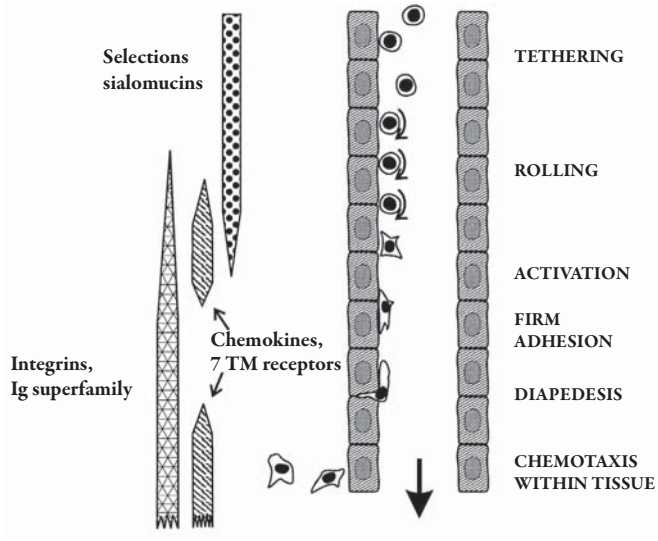

Figure 7.2 The multistep adhesion cascade of lymphocyte extravasation. The freely flowing, bloodborne lymphocyte starts the interaction with vascular endothelium by tethering and rolling; this proceeds to an activation step. Activation is followed by firm adhesion. Thereafter, the lymphocyte seeks an interendothelial junction, through which it penetrates into the tissue. The contribution of major molecular families at each step is illustrated.

TETHERING AND ROLLING

Selectins and Their Sialomucin Ligands

Selectins and their sialomucin ligands are the key players in tethering and rolling steps because the lectin-carbohydrate bonds between these receptor–ligand pairs allow formation of rapid but transient and weak interactions typical of rolling behavior. There are three members of the selectin family that have been named based on their main site of expression: L-selectin (CD62L) is present on different types of leukocytes, E-selectin (CD62E) is on endothelium, and P-selectin (CD62P) is on platelets and endothelium (Rosen, 2004; Vestweber and Blanks, 1999).

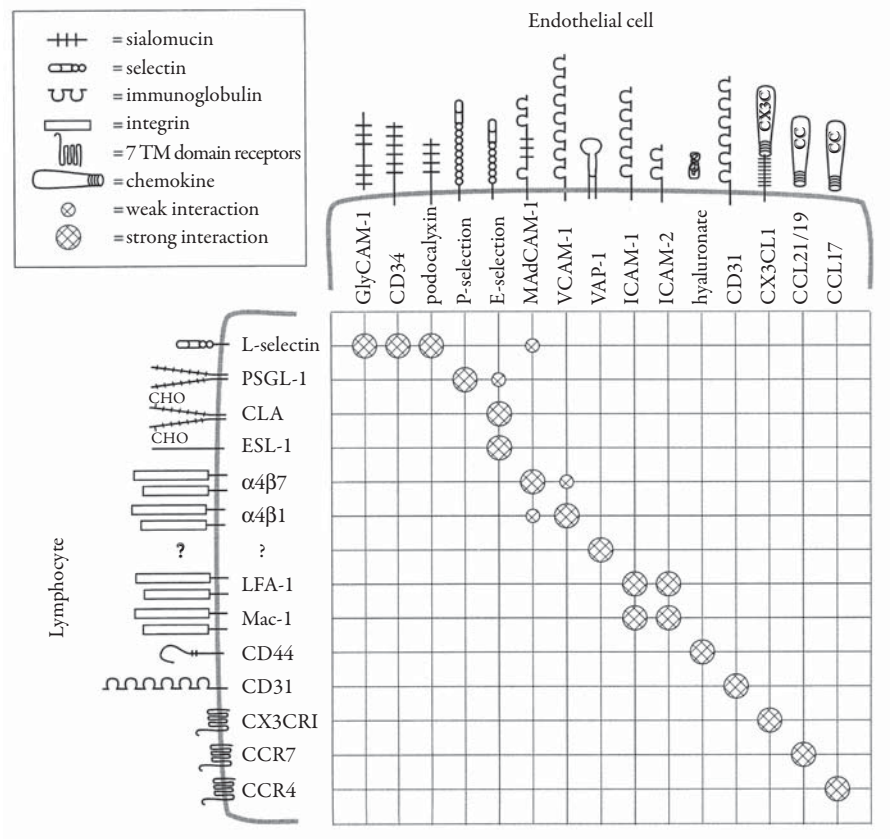

Figure 7.3 Homing-associated molecules involved in leukocyte traffic. The most relevant leukocyte surface molecules and their counter-receptors on vascular endothelium are depicted.

The common structural feature of these molecules is the N-terminal lectin domain, which is of fundamental importance in binding to sialyl Lewis X (sLeX) carbohydrate present on the sialomucin ligands of selectins (Fukuda et al., 1999; Rosen, 2004; Vestweber and Blanks, 1999). The ligand structures for L-selectin are presented by PNAd on HEVs in peripheral lymph nodes; thus, PNAd is fundamental to guiding L-selectin–positive lymphocytes into peripheral lymph nodes. PNAd consists of at least six different proteins, all decorated by a sulfated and fucosylated sLeX. They are glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, podocalyxin, nepmucin, endomucin, and MAdCAM-1. Interestingly, MAdCAM-1 has the proper glycosylation for L-selectin recognition only in organized lymphoid areas of the gut such as Peyer's patches but not in lamina propria vessels, allowing to a certain extent L-selectin–dependent entrance of cells to mucosal sites.

The importance of most homing-related molecules in vivo has been demonstrated by creating knockout mice (Table 7.1). Among the first were L-selectin–deficient mice, which exhibit severely impaired lymphocyte homing to peripheral lymph nodes. In contrast, GlyCAM-1 knockout mice only have enlarged lymph nodes, a result suggesting a regulatory role for the soluble GlyCAM-1 molecule in lymphocyte homing. CD34 knockout mice are seemingly healthy despite defective eosinophil migration. Also, the genes important for proper posttranslational modifications of the selectin ligands have been disrupted. For example, fucosyltransferase VII (FucTVII)–deficient mice are not able to add the critical fucose moiety to the sLeX structure. Hence, they do not glycosylate L-selectin ligands properly and exhibit severe impairment in lymphocyte homing and leukocyte extravasation to sites of inflammation (Lowe, 2003). As another example, lack of a highly HEV-specific sulfotransferase (GlcNAc6ST) leads to inefficient or absent sulfation of the sLeX motif, concomitant disappearance of L-selectin ligand activity, and decreased lymphocyte homing (Hemmerich et al., 2001).

Expression of both P- and E-selectin is induced at sites of inflammation. However, their expression kinetics differs remarkably. P-selectin is released within minutes from intracellular storage granules, Weibel-Palade bodies, and is translocated to the endothelial cell surface, whereas E-selectin requires new protein synthesis, and its maximal expression is seen 4 hours after the induction of inflammation. The primary ligand for P-selectin is correctly tyrosine-sulfated P-selectin glycoprotein ligand-1 (PSGL), which is present on most leukocytes (McEver and Zhu, 2010). Depending on its glycosylation profile it can also bind to E-selectin, which has high affinity particularly toward cutaneous lymphocyte antigen (CLA), a specific glycoform of PSGL-1. Interaction between CLA and E-selectin appears to be important in directing lymphocytes to skin inflammations. In addition, E-selectin

Table 7.1 PHENOTYPE OF GENE-TARGETED MICE MADE DEFICIENT FOR INDIVIDUAL HOMING-ASSOCIATED MOLECULE

MOLECULE	MAIN ABNORMALITIES IN LEUKOCYTE TRAFFICKING
L-selectin	Impaired lymphocyte homing to peripheral lymph nodes
E-selectin	Increased velocity of rolling leukocytes
P-selectin	Decreased leukocyte rolling at early stages of inflammation
GlyCAM-1	Enlarged lymph nodes
CD34	Impaired eosinophil accumulation in allergen-induced lung inflammation
PSGL-1	Decreased leukocyte rolling at early stages of inflammation
Fuc-TVII	Reduced leukocyte migration to sites of inflammation
	Reduced lymphocyte homing to peripheral lymph nodes
C2β GlcNAcT	Reduced leukocyte emigration to sites of inflammation
GlcNAc6ST	Decreased lymphocyte homing
ICAM-1	Impaired neutrophil migration to sites of inflammation
ICAM-2	Stimulus-specific decrease in granulocyte transmigration
VCAM-1	Embryonic lethal
ESAM	Reduced neutrophil extravasation to sites of inflammation
JAM-A	Increased dendritic cell homing to lymph nodes and reduced transendothelial cell migration of JAM-A–negative neutrophils
JAM-C	Reduced leukocyte adhesion to inflamed endothelium and transmigration
CD31	Deficient migration through basement membrane
CD11a	Reduced lymphocyte trafficking to lymphoid organs Decreased leukocyte trafficking to sites of inflammation
CD11b	Decreased leukocyte trafficking to sites of inflammation
CD11c	Decreased leukocyte trafficking to sites of inflammation
β2-integrin	Decreased leukocyte migration to sites of inflammation
α4-integrin	Embryonic lethal, chimeric mice have reduced lymphocyte homing into Peyer's patches
β7-integrin	Impaired lymphocyte migration to Peyer's patches
CD43	Increased lymphocyte homing to secondary lymphoid organs
CD44	Decreased lymphocyte migration to peripheral lymph nodes and thymus
VAP-1	Diminished leukocyte infiltration to sites of inflammation
CD73	Increased leukocyte traffic to sites of inflammation
CD38	Defective chemotaxis of leukocytes to severe inflammations
CCR4	Impaired T-cell trafficking to mesenteric lymph nodes and lung
CCR7	Defective lymphocyte entry to lymph nodes and formation of T-cell areas
CCR9	Reduced number of intraepithelial T cells and IgA-positive plasma cells in lamina propria
CCL19/CCL21	Impaired homing of lymphocytes (especially T cells) to lymph nodes
CXCR5/CXCL13	Defect in formation of follicles in lymph nodes
CX3CL1	No obvious defects in leukocyte trafficking

binds to a non-mucin-like E-selectin ligand-1 (ESL-1) and CD44 on leukocytes (Hidalgo et al., 2007; Vestweber and Blanks, 1999).

E-selectin knockout mice are apparently healthy, but their leukocytes roll faster than in normal mice, indicating that E-selectin is an important molecular brake at early steps of leukocyte–endothelial cell interactions. P-selectin–defective mice are also viable and fertile. They show neutrophilia due to a longer half-life of neutrophils. After induction of inflammation, leukocyte rolling is impaired for less than 2 hours in these mice. This finding suggests that P-selectin is indispensable only at early phases of inflammation (Frenette and Wagner, 1997). PSGL-1 knockout mice largely resemble P-selectin–deficient mice, thus confirming the importance of PSGL-1 at the rolling step (Yang et al., 1999). Mice deficient for both E- and P-selectin have also been generated. These mice exhibit much more profound defects than those of single knockouts, indicating that E- and P-selectin have overlapping

functions and that they compensate each other (Frenette and Wagner, 1997). Furthermore, mice whose core 2β 1, 6-*N*-*acetylglucosaminyl* transferase (C2-β-ClcNAcT) gene has been disrupted have a defect in the early step of branching of LeX oligosaccharide and therefore lose proper glycosylation of their E- and P-selectin ligands. These mice show normal lymphocyte homing to lymph nodes, but their leukocytes cannot efficiently enter the sites of inflammation (Etzioni et al., 1999; Vestweber and Blanks, 1999). A human immunodeficiency disease, leukocyte adhesion defect 2 (LAD2), resembles characteristics of these knockout animals: LAD2 patients do not have functional selectin ligands because of a glycosylation defect. Leukocytes of these patients have decreased rolling capacity, although in static conditions leukocytes adhere efficiently to endothelial cells. Patients with LAD2 suffer from recurrent bacterial infections and also have other developmental abnormalities (Etzioni, 2007; Notarangelo and Badolato, 2009). This disease is presented in detail in Chapter 38.

CD43, CD44, and Vascular Adhesion Protein-1

Other (nonselectin) molecules have also been shown to directly mediate rolling or tethering or to indirectly regulate this step. An example of a regulatory molecule is CD43, a long and negatively charged glycoprotein on lymphocytes that inhibits engagement of L-selectin, thus blocking the homing of lymphocytes. Its role is clearly demonstrated in CD43-deficient animals, which show enhanced lymphocyte homing to secondary lymphoid organs (Stockton et al., 1998). Although neutrophil CD43 generally serves as an antiadhesive molecule to attenuate neutrophil-endothelial interactions, it may have a proadhesive role as an E-selectin ligand (Matsumoto et al., 2008).

CD44 is a multifunctional member of the proteoglycan family that can mediate rolling of lymphocytes on endothelial hyaluronan and E-selectin (Hidalgo et al., 2007; Siegelman et al., 1999). It can be physically associated with VLA-4 on activated T cells to mediate efficient rolling and subsequent firm adhesion (Steeber et al., 2005). In addition, triggering of CD44 activates lymphocyte function–associated antigen-1 (LFA-1), which may strengthen lymphocyte adhesion to endothelium. In vivo experiments using function-blocking antibodies suggest that CD44 is important in lymphocyte trafficking to sites of inflammation. Moreover, lymphocytes of CD44-deficient mice show impaired lymphocyte homing to peripheral lymph nodes and thymus and diminished granulocyte influx to arthritic joints (Protin et al., 1999; Sarraj et al., 2006).

Vascular adhesion protein-1 (VAP-1) is a dual-function homing-related molecule, because in addition to its adhesive function at an early phase of the multistep cascade it possesses intrinsic enzymatic activity. The end products of the reaction catalyzed by this amine oxidase are aldehyde, ammonium, and hydrogen peroxide. All of them are potent compounds that may regulate the entire scene of inflammation by, for instance, aberrantly glycosylating endothelial proteins (aldehydes) or by upregulating other adhesion proteins and metalloproteinases and inducing apoptosis (hydrogen peroxide). Regulation of VAP-1 function appears to involve its sequestration into intracellular granules, from which it is rapidly translocated to the endothelial surface upon induction of inflammation. Mice lacking VAP-1 show mild impairment in lymphocyte homing to mucosal sites and reduced response to oral immunization. Moreover, leukocyte migration to sites of inflammation is diminished (Salmi and Jalkanen, 2005).

ACTIVATION

Chemokines and Their Receptors

Certain endothelial chemokines and their interaction with the seven pass transmembrane receptors on leukocytes are considered to be of fundamental importance at the activation step of the adhesion cascade. Chemokines are small molecules divided into the following families on the basis of their structural cysteine motifs: C, CC, CXC, and CX3C, where *C* is cysteine and *X* is any amino acid residue.

Chemokines are typically heparin-binding soluble molecules, and many of them are not even produced by endothelial cells. Nevertheless these molecules can exert their function at the luminal surface of endothelial cells, where blood constantly flushes away any soluble gradients. It seems that these molecules are carried via a specialized reticular conduit through the lymph node to the abluminal side of the vessels. They can then be transcytosed to the luminal side of the endothelial cell, where they become immobilized by an avid binding to surface-expressed glycosaminoglycans. In fact, chemokines injected subcutaneously can find their way to the luminal surface of HEVs in the draining lymph nodes, and hence selectively enhance lymphocyte recruitment to the draining node. After chemokine binding, activation signals are transduced from the serpentine receptors via guanine nucleotide-binding (G) proteins via complex signaling routes that eventually result in affinity/avidity changes of leukocyte integrins (Bromley et al., 2008; Colditz et al., 2007; Sallusto and Baggiolini, 2008).

Different leukocyte subsets possess alternative sets of chemokine receptors, which determine whether they are allowed to exit from the blood—for example, at HEVs in peripheral lymph nodes or in vasculature at sites of inflammation. For instance, T cells bearing CCR7 receptor become recruited to peripheral lymph nodes and mucosal sites where its ligands, CCL21 and /or CCL19, are expressed on HEVs. B cells, in contrast, use CXCR4 and 5 to bind CXCL12 and CXCL13, respectively. CX3CL1 (Fractalkine) is structurally very different from other endothelial chemokines because in addition to a soluble form it has a transmembrane form with a long stalk of sialomucin-like structure. CX3CL1 has a strong affinity toward CX3CR1-expressing leukocytes. Tissue selectivity among chemokines has been demonstrated to exist at least in the skin, where endothelial CCL17 and CCL22 attract CCR4-bearing lymphocytes, and in the small intestine, where CCR9-positive lymphocytes seek for CCL25 (Salmi and Jalkanen, 2005).

CCR7 knockout mice demonstrate the importance of this chemokine in lymphocyte trafficking, as these mice have defective T-cell entry to lymph nodes (Cyster, 2005). CCR9-deficient mice have a reduced number of mucosal lymphocytes, and mice lacking CXCR4 or CXCR5 have defects

in the formation of lymphoid follicles (Salmi and Jalkanen, 2005). In contrast, no obvious homing defects have been found in CX3CL1 knockout mice. The only abnormality discovered in CX3CL1$^{-/-}$ mice is the diminished number of cells belonging to the monocyte/macrophage lineage in the blood. In CX3CR1 deficiency the accumulation of dendritic cells is diminished in atherosclerotic lesions. CCR4-deficient T cells show impaired homing to mesenteric lymph nodes and inflamed lungs.

CD73 and CD38/CD157

Engagement of several other leukocyte surface molecules can lead to activation of LFA-1, CD 11 a/CD 18. However, only a few of them have been directly shown to result in increased leukocyte binding to endothelium. One of the molecules having this property is CD73, a GPI-linked molecule that is expressed on endothelium and on a small subset of lymphocytes and has ectonucleotidase activity catalyzing conversion of extracellular AMP to adenosine (Colgan et al., 2006; Jalkanen and Salmi, 2008). Adenosine regulates E-selectin expression, integrin function, and endothelial permeability (Cronstein, 1997; Cronstein and Weissmann, 1993). Interestingly, lack or diminished expression of CD73 is linked to a variety of immunodeficiency diseases, such as Wiskott-Aldrich syndrome, severe combined immunodeficiency, common variable immunodeficiency, primary hypogammaglobulinemia, selective IgA deficiency, and Omenn syndrome. Mice lacking CD73 are prone to more severe vascular leakage in hypoxic and ischemic conditions than their wild-type counterparts, confirming the role of CD73 in maintaining endothelial cell barrier function (Jalkanen and Salmi, 2008).

CD38 and CD157 are close relatives and have both ADP-ribosyl cyclase and NAD-hydrolase activities. They are expressed in most human leukocytes and can modulate leukocyte trafficking by regulating the sensitivity of cells to chemokines, calcium influx, and thus integrin function through inside-out signaling. CD38-deficient mice have defective chemotaxis. Patients suffering from paroxysmal nocturnal hemoglobinuria lack CD157 and their neutrophils have constant defects in adhesion and migration (Deaglio and Malavasi, 2006).

FIRM ADHESION

Integrins and Their Immunoglobulin Superfamily Ligands

Certain integrins participate effectively in the arrest of leukocytes on the endothelium through use of members belonging to the immunoglobulin superfamily as their vascular ligands (Denucci et al., 2009). They can also function at the earlier steps of the cascade, even during rolling. Typical for integrins is that they are heterodimers consisting of α and β chains. Important integrins for leukocyte extravasation are α4β7, LFA-1, and α4β1. α4β7 is a principal homing receptor for MAdCAM-1 and directs lymphocytes to mucosa-associated lymphatic tissues (Butcher, 1999). Its role as a mucosal homing receptor has been clearly demonstrated by β7 knockout animals. They have rudimentary Peyer's patches and their lymphocyte homing to mucosal sites is severely impaired. In contrast, lymphocyte homing to peripheral lymph nodes in these mice is intact (Butcher, 1999).

α4β1, in contrast, exerts its role mainly at inflammatory sites, where it binds to its ligand, vascular cell adhesion molecule-1 (VCAM-1, CD106). Both VCAM-1 and α4 knockout animals are embryonically lethal, indicating that besides homing they have more fundamental roles in embryonic development. Mice that are chimeric regarding the deletion of α4 show diminished lymphocyte trafficking to Peyer's patches but not to other secondary lymphatic organs, a finding compatible with the phenotype of β7 knockouts (Butcher, 1999).

LFA-1 (CD11a/CD 18) is a member of the group of four leukocyte integrins sharing the same β chain, β2 (CD 18), while having unique α chains (CD 11a, b, c, and d). LFA-1 is present on practically all leukocytes and mediates their binding to intercellular adhesion molecules 1 and 2 (ICAM-1 [CD54] and ICAM-2 [CD 102]) in its active form (Alon and Dustin, 2007). Mac-1 (CD11b/CD18) also participates in leukocyte migration, but its role is overshadowed by LFA-1. The role of leukocyte integrins in leukocyte trafficking is evident through the dramatic defects in leukocyte extravasation in patients suffering from LADI or LADIII. LADI patients lack the normal β2 chain and consequently surface expression of all leukocyte α chains is prevented, or they express LFA-1 in a nonfunctional form. In LADIII all hematopoietic integrin activation processes are defective and besides severe infections the patients suffer from increased bleeding tendency (Etzioni, 2010). These deficiencies are presented in more detail in Chapter 38 in this book.

Mice deficient in CD18 do not show as dramatic defects as LAD1 patients. Their neutrophils do not migrate properly to sites of inflammation. CD1la$^{-/-}$ mice have impaired lymphocyte homing to both peripheral lymph nodes and Peyer's patches, a finding in keeping with the role of LFA-1 as a non–organ-specific homing molecule. In CD11b- and CD11c-negative mice, reduced leukocyte trafficking to sites of inflammation is observed. Mice lacking ICAM-1 have a relatively mild phenotype compared to findings obtained from studies using function-blocking antibodies. These mice have decreased neutrophil migration to tissues in some inflammatory models. Lack of ICAM-2 normally constitutively present on endothelium does not cause any obvious defects in lymphocyte recirculation.

Crawling and Transmigration

Transmigration is the least-analyzed phase in the leukocyte extravasation process, although recent progress has been made (Carman and Springer, 2008). Before actual transmigration the leukocytes crawl on endothelium, actively seeking a proper site to enter the tissue (Kelly et al., 2007). Studies using function-blocking antibodies have shown that CD31 is intimately involved in transmigration. CD31 belongs to the immunoglobulin superfamily and is expressed by several leukocyte subsets and continuous endothelium of all

vessel types. On the vascular endothelium its expression is concentrated on intercellular junctions. Unexpectedly, CD31-deficient mice show a normal overall transmigration capacity. However, the polymorphonuclear leukocytes are arrested between the endothelium and basement membrane, demonstrating that CD31 is needed in migration through the basement membrane (Woodfin et al., 2007). Other molecules such as junctional adhesion molecules (JAMs) and their close relative endothelial cell-selective adhesion molecule (ESAM), as well as CD99, LFA-1, and the ICAMs, have been implicated in transmigration via the paracellular route (Ley et al., 2007; Weber et al., 2007). Also matrix metalloproteinase-2 (MMP-2), which is induced in T cells upon binding to endothelium, and MMP-9 play a role in this invasive process. Overall, the current evidence suggests that also the transmigration requires stepwise and carefully regulated interactions of the molecules involved.

There are still limited amount of data about the molecular mechanisms operating in the transcellular transmigration route. ICAM-1 and VCAM-1 are both participating in formation of the transmigratory cap around the extravasating leukocyte (Carman and Springer, 2008). Also plasmalemmal vesicle-associated antigen (PV-1) functions in the transendothelial route (Keuschnigg et al., 2009).

LYMPHOCYTE TRAFFIC VIA THE LYMPHATICS

The molecular mechanisms mediating leukocyte migration via the afferent lymphatics into the draining lymph nodes and lymphocyte exit via the efferent lymphatics are less well known than those controlling leukocyte extravasation from the blood into the tissues. Recently, however, several molecular interactions have been reported to contribute to migration of dendritic cells and lymphocytes through afferent lymphatics. Those include CCL21 chemokine presented on lymphatic endothelium, sphingosine 1 phosphate receptor 1 ($S1P_1$) expressed in many different cell types, JAM-A, ICAM-1, VCAM-1, Clever-1/Stabilin-1 and MR. CCL21 attracts CCR7-positive dendritic cells and lymphocytes into the afferent lymphatics and further to the draining lymph nodes. $S1P_1$, on the other hand, plays a dual role: it participates in lymphocyte entrance into the draining lymph nodes via afferent lymphatics and in their exit from the nodes via efferent lymphatics. It also regulates emigration of thymocytes from the thymus (Debes et al., 2005; Rosen and Goetzl, 2005). The SIP_1-deficient mice are embryonically lethal due to defects in vascular development. However, conditional knockout mice have confirmed the role of SIP_1 in lymphocyte egress from the lymph nodes into the efferent lymphatics. Recent studies suggest that SIP_1 controls lymphocyte trafficking by regulating endothelial permeability and/or suppressing lymphocyte chemotaxis in SIP gradients (Cyster, 2005; Rosen and Goetzl, 2005). Clever-1/Stabilin-1, a scavenger present both on afferent and efferent lymphatics, contributes to lymphocyte traffic via the lymphatics. Junctional adhesion molecule-A (JAM-A) is also involved in cell trafficking within lymphatics as dendritic cells from JAM-A–deficient mice show an increased capacity to transmigrate across lymphatic endothelial cells and altered trafficking to the lymph nodes. Interestingly, the altered migration was found only when the dendritic cells lacked JAM-A but not in the case of endothelium-restricted deficiency of JAM-A. Moreover, ICAM-1 and VCAM-1 are induced on lymphatics upon inflammation and mediate dendritic cell trafficking into the draining lymph nodes (Johnson and Jackson, 2008). CCR7, $S1P_1$, JAM-A, Clever-1/Stabilin-1, VCAM-1, and ICAM-1 are all expressed on a wide variety of other cell types in addition to lymphatic endothelium, and they all are also involved in leukocyte extravasation through the vascular endothelium. In contrast, macrophage mannose receptor (MR) is one of the few adhesion molecules that is expressed on lymphatic but not on blood vessel endothelium. Mice lacking MR have impaired lymphocyte trafficking via afferent lymphatic vessels into the draining lymph nodes, demonstrating the role of MR in lymphocyte migration via lymphatics (Marttila-Ichihara et al., 2008).

INTRAORGAN LOCALIZATION OF LYMPHOCYTES

Subsequent to entry into the lymphoid organs, lymphocytes start their ameboid voyage within the organs. For the migration, lymphocytes need balanced function of adhesion molecules capable of binding to extracellular matrix molecules (ECMs), such as fibronectin, laminins, and collagens, and mechanisms to detach from the anchorage to ECMs (Friedl and Weigelin, 2008). β1-integrins are essential for binding to several ECMs, and lymphocytes can use CD44 to bind to fibronectin and collagens. Detaching mechanisms are poorly understood. Controlled and directional migration also needs proper chemokine receptors on the lymphocyte surface that respond to chemokines secreted by different cell types within the tissues. These interactions are important both in early phases of lymphocyte maturation, for example in the thymus, and later during physiological lymphocyte recirculation and leukocyte movement at sites of inflammation (Bonecchi et al., 2009; Bromley et al., 2008). During normal recirculation, CCL21 and CCL19 guide T cells to interfollicular areas within the nodes, whereas CXCL13 produced by follicular dendritic cells attracts B cells expressing CXCR5 into the follicles (Fig. 7.4).

In addition to cell-surface molecules mediating adhesion–de-adhesion steps in the intraorgan movement of lymphocytes, the pathways that transduce these surface signals into the locomotory machinery are important for proper localization (Barreiro et al., 2007). Hence, specific receptors are clustered at the leading edge and trailing edge of the crawling lymphocyte. These molecules signal to the actomyosin and microtubuli networks within the cell, and translate the surface signals into polarized cell crawling. Just one example of the importance of these steps for proper immune defense is Wiskott-Aldrich syndrome, in which a defect in one of these effector signaling proteins, WASP, leads to a severe immunodeficiency (Bosticardo et al., 2009).

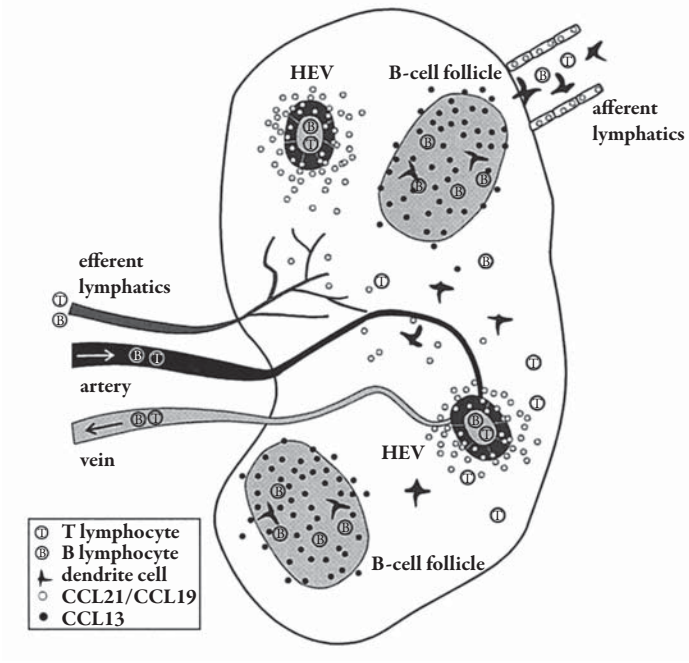

Figure 7.4 Chemokines contribute to both entrance and intraorgan localization of lymphocytes. CCL19 and CCL21 are involved in T-lymphocyte entrance via high endothelial venules (HEVs) into the node. They also guide T cells to the interfollicular areas in the lymph node. CXCL13, by contrast, directs B lymphocytes into the follicles.

Dendritic cells entering the lymph nodes via afferent lymph and bringing antigens are key players in the immune response as antigen-presenting cells. CCL21 expressed in lymphatic endothelium assists dendritic cell entrance into the T-cell areas, allowing these two cell types to interact with each other. B-cell collaboration with T cells is ensured by upregulation of CXCR5 on a subset of T cells and CCR7 on B cells. This makes it possible for B and T cells to move to the boundary of the B- and T-cell zones and interact with each other. A spontaneously mutant mouse strain, *plt*, which has decreased expression of both CCL21 and CCL19, demonstrates the importance of these chemokines in intraorgan localization (and entry) of lymphocytes, as these mice have defective organization of T-cell areas within lymph nodes. The phenotype of these mice is thus comparable to that of mice lacking the receptor for these chemokines (CCR7). In contrast, in CXCR5-negative mice development of B-cell follicles is defective—again, in keeping with the function of this chemokine in B-cell localization (Okada and Cyster, 2006).

Intraorgan localization also shows remarkable tissue specificity, best exemplified in the gut. Practically all lymphocytes in the small intestine have CCR9, whereas in the colon these cells are less frequent. Importantly, lymphocytes in most other tissues (excluding thymus) are CCR9 negative. CCR9 ligand, CCL25, is produced by gut epithelial cells and guides CCR9-positive lymphocytes, especially to the epithelium of the small intestine (Agace, 2008).

CONCLUSIONS

Optimal lymphocyte entry to primary lymphoid organs during development and to secondary lymphoid organs during recirculation and efficient leukocyte trafficking to sites of inflammation are the key elements in adequate functioning of the immune system. The molecular mechanisms mediating lymphocyte contacts with the vascular wall and governing the intraorgan localization of lymphocytes are relatively well known. Knowledge on the mechanisms functioning during diapedesis through the vascular wall, leukocyte entry to afferent lymphatics at different vascular beds, and lymphocyte exit via efferent lymphatics within the lymphoid organs is rapidly increasing.

The importance of leukocyte trafficking to the pathophysiology of human disease is best reflected by the rare genetic disorders of lymphocyte migration, and by the enormous potential of the recently introduced therapeutics modulating adhesion molecules in inflammatory diseases. Thus far, the number of patients diagnosed as having a defect in any of the molecules involved in leukocyte migration has been very small. One reason for this small number may be that many of the defects are not compatible with life. The tools for diagnosing patients who suffer from defective leukocyte trafficking are continuously being developed and may help to reveal many new disease entities. The adhesion and activation molecules have been tempting targets for anti-inflammatory drugs ever since they were discovered. During the past few years this research has translated into clinical success (Luster et al., 2005; Mackay, 2008). A humanized antibody against α4 (natalizumab) has proven to be highly effective, especially in the treatment of multiple sclerosis and Crohn's disease, respectively. Although a few serious side effects have been reported, it is actively and successfully used in clinics. Moreover, dozens of drugs targeting other adhesion molecules and chemokines are in late clinical trials.

Over the past few years, we have gained increasing insight into the salient molecular and physiological mechanisms guiding lymphocyte recirculation from the blood into the tissues and back to the circulation. In terms of our immune defense, this continuous patrolling process is important for guaranteeing maximal efficacy of a lymphocyte meeting its cognate antigen. Failure of this process inevitably leads to some form of immunodeficiency. Thus, a detailed understanding of the multifaceted extravasation cascade will help us to develop new strategies for guiding and redirecting lymphocyte trafficking into locations where the system has gone awry for one reason or another.

INNATE IMMUNITY

Jordan S. Orange, Michael M. Frank, and Stuart E. Turvey

The innate immune system serves as the initial immunological defense against foreign and dangerous material. Innate immunity is required once a challenge to the host organism has managed to penetrate certain physical defenses that the host presents as a barrier between itself and the environment. Examples of these physical defenses in humans include the skin and mucus. While the host physical barriers to danger are essential for survival, this chapter is focused upon the first line of immunological defense—the initial immune elements used in encountering challenges that have succeeded in overcoming the physical divisions between host and environment. As entire volumes are devoted to the topic of innate immunity, the summary provided here is intended to (1) define the general paradigms through which the innate immune system functions; (2) identify key components of the innate immune system and provide some insight into how they function in host defense; and (3) introduce how some of the innate immune elements critically link to the adaptive immune system to coordinate an integrated immunological defense.

PARADIGMS IN INNATE IMMUNITY

Unlike the adaptive immune system (see Chapters 4 and 5), the innate immune system is "hardwired" to recognize and respond to danger (Janeway and Medzhitov, 2002). In other words, innate immune elements do not require genetic recombination events or a developmental phase to mediate function. All of the function is encoded within the germline DNA and is poised to exert immediate or near-immediate effects. This includes not only recognizing the dangerous challenge, but also responding to it and acting to contain or eliminate the insult. Based on this immune recognition strategy, there are three important paradigms of the innate immune system that in some way apply to the majority of its components: recognition, amplification, and response.

In essence, each of these paradigms represents a phase of an innate immune response. During the recognition phase, danger is specifically identified within a complex environment containing endogenous and nondangerous materials. An example would be recognizing a bacterium that penetrates the skin on the surface of a sewing needle. In the amplification phase, the recognition of danger leads to the generation of a discernable signal. This can be intracellular, and occur within the same cell that had recognized the dangerous element, or extracellular. Extracellular amplification can occur at the level of direct intercellular contacts, or through soluble mediators that act at long distances. The amplification phase serves the purpose of expanding a one organism versus one defense interaction into an immune response potentially involving multiple defenses. The response phase of innate immunity depends on the amplified signal leading to a function directed at the offending stimuli. In the case of the bacterium, this could be its ingestion and destruction inside a phagocyte, or its direct dissolution through a soluble antibacterial molecule. Before defining the individual components of the innate immune system, the fluid concept of these three paradigms will be further discussed with specific reference to the types of immune elements responsible for each phase. While not exhaustive, the objective is to introduce the concept of the innate immune response so that the breadth and specificity of innate immunity can be appreciated (Beutler, 2009).

RECOGNITION PHASE OF INNATE IMMUNITY

A central function of the innate immune system is the rapid recognition of potentially harmful materials. These can

originate from the environment, as in the case of a pathogenic bacterium, or from within the host itself, such as a cancerous cell; in addition, the innate immune system has the capacity to sense tissue damage and some of the common biochemical consequences of infection. While the recognition of the element may immediately lead to its eradication, in some cases it represents only the very beginning of a multifaceted response aimed at containing and ultimately eliminating the threat. Two major strategies are used by the innate immune system in recognition: pattern recognition and danger sensing.

PATTERN RECOGNITION

Pattern recognition represents the ability of the innate immune system to recognize molecular motifs inherent to something challenging the host and to differentiate signals from motifs normally present throughout the host organism. As such, this is an essential feature of recognition within the innate immune system. It was originally defined by Janeway through his concept of *pathogen-associated molecular patterns* (PAMPs) (Janeway, 1989). PAMPs are characteristic hallmarks of pathogenic organisms that the immune system can exploit to distinguish them immediately from self-tissues. By definition, PAMPs are not a product of host DNA. Some examples include lipopolysaccharide (LPS) and double-stranded RNA. PAMPs technically fall into the broader category of *microbial-associated molecular patterns* (MAMPs). The distinction between a MAMP and a PAMP is useful as not all relevant patterns capable of being recognized are associated with pathogenic microorganisms. MAMPs can still be recognized by the innate immune system and present the ability to facilitate immunological responses and cellular functions. An alternative but equally relevant paradigm is the recognition of *danger-associated molecular patterns* (DAMPs) (Bianchi, 2007). DAMPs are not inherent to a pathogen and are products of host DNA. Because of their ability to elicit an immune response, however, they are generally contained within protected environments and are not routinely exposed to the immune system. DAMPs, however, may be induced directly, or indirectly by a pathogen or other signals of stress such as malignancy. An example of a DAMP would be heat shock protein-70, which is encoded in the human genome and can be induced under a variety of stressful circumstances. Another important example is that of DAMPs derived from mitochondria during celluar injury, which can promote inflammation and under severe circumstances link to systemic inflammatory response syndrome (Zhang, 2010).

A critical element for a molecular pattern to act as a stimulus for innate immunity is the presence of a specific means for recognizing the pattern. In this light, there are a number of host-encoded receptor systems that are used for the recognition of PAMPs, MAMPs, and DAMPs. Collectively, these define a family of innate immune receptors referred to as *pattern-recognition receptors* (PRRs). The best appreciated of the PRRs at this point are the Toll-like receptors (TLRs).

In humans there are 10 TLRs, which have been described to recognize over 45 foreign molecules and 17 endogenous molecules as ligands (well-characterized examples in Table 8.1) (Akira and Takeda, 2004; Beutler, 2009; O'Neill, 2008; Takeda et al., 2003). All TLRs are transmembrane proteins. Some of the TLRs are found on the cell surface, including TLRs 1, 2, 4, 5, 6, and 10. TLRs 3, 7, 8, and 9 are found intracellularly and are localized within the endosomal compartment. As a result, different TLRs are specialized in recognition of patterns characteristic of extracellular or intracellular environments. Exemplary microbial ligands of the TLRs include lipoaribinomannan (TLR1/2), fungal zymosan (TLR2±6), double-stranded RNA (TLR3), bacterial lipopolysaccharide, and RSV fusion protein (TLR4), bacterial flagellin (TLR5), mycoplasmal diacyl lipopeptides (TLR6/2), viral single-stranded RNA (TLR7 and 8), and unmethylated CpG islands within bacterial and viral DNA (TLR9). An exemplary host-derived ligand is HSP-70, which is capable of ligating TLR 2/6 and 4. TLRs can also recognize synthetic molecules, such as imidazoquinolines (TLR7 and 8), and this represents a growing field of actual and experimental therapeutics aimed at inducing innate immunity. The signaling that results after TLR ligation is complex and has the objective of inducing transcriptional activation. These signal events therefore represent an amplification and are discussed separately as an amplification paradigm.

Table 8.1 **EXAMPLES OF TLR LIGANDS**

TLR	LIGAND	SOURCE
TLR1/2	Lipoarabinomannan	Mycobacteria
TLR2±6	Zymosan *HSP70*	Fungi Host
TLR3	DS RNA	Viruses
TLR4	Lipopolysaccharide RSV fusion protein *HSP70*	Gram-neg. bacteria RSV Host
TLR5	Flagellin	Flagellated bacteria
TLR6/2	Diacyl lipopeptides	Mycoplasma
TLR7 and 8	SS RNA Imidazoquinolones	Viruses Synthetic
TLR9	Unmethylated CpG motifs	Bacteria and DNA viruses
TLR10	Unknown	

In addition to TLRs, there are a number of other important PRRs, which are increasingly appreciated for their role in host defense. These include the nucleotide-binding oligomerization domain (NOD) family (Benko et al., 2008; Chen et al., 2009; Ting et al., 2008). The best known of these is NOD2, which is mutated in a subset of individuals with Crohn's disease as well as in Blau syndrome (Haskins et al., 1988; Hugot et al., 2001; Masters et al., 2009). NOD2 binds to the muramyl-dipeptide of bacterial peptidoglycan and thus can initiate response amplification after recognizing intracellular bacterial components. Formyl peptide receptors bind formyl peptides such as N-formyl-methionyl-leucyl-phenylalanine (fMLP), which is a recognizable byproduct of bacterial metabolism. Thus, recognition of fMLP can serve as an important chemoattractant

for innate immune cells, such as neutrophills, that express these receptors. The natural cytotoxicity receptors, NKp44 and NKp46, also function as PRRs and are appreciated for their inherent ability to bind viral hemagglutinins. They are expressed on natural killer (NK) cells and in animal models have been shown to be needed for defense against influenza.

In addition to the above-mentioned cell-surface and intracellular PRRs, there are also a number of soluble proteins that have preference for motifs possessed by microorganisms. In a sense these are PRRs as they recognize dangerous material through their inherent specificity and have the ability to access immune function. In some cases these molecules mediate function directly and are introduced as a group. A first example is lectins or collectins, a family of proteins that bind carbohydrates. Some of these have specific utility in binding microbial carbohydrates; a key example is mannan-binding lectin (MBL), which binds to carbohydrate structures containing mannose present on microorganisms. MBL utilizes associated MASP (MBL-associated serine protease) proteins to activate complement and amplify an immune response as well as inducing an antibacterial response. MBL is held by some authors to be important in defense against infection, as individuals deficient in their ability to express the molecule have been found to have infectious susceptibility (Thiel et al., 2006). There are, however, conflicting observations regarding the significance of MBL deficiency in humans. Finally, there are a number of antimicrobial peptides that maintain a selective ability to bind to microorganisms (Hancock and Sahl, 2006). These include the defensins, cathelicidins, and histatins. In general they are 15–45aa positively charged peptides that will preferentially associate with the dense phospholipids characteristic of microbial membranes and cell walls. These peptides can then insert into the microbe and have direct antiproliferative effects. They can in some cases lead to microbial destruction, which will expose other microbial patterns to be recognized. Thus, whether through soluble or cell-anchored means of recognizing microbial-specific components, pattern recognition serves a critical role in innate immune recognition.

DANGER SENSING

While ligands for the PRRs are clear signals of danger to the immune system, there are other important means by which dangerous conditions can be promptly defined by the host. Specifically, receptor systems are in place to recognize and respond to physiological ligands whose expression is reserved for dangerous circumstances. The exposure of these ligands, therefore, acts as a surrogate marker for the presence of danger. If enough ligand is recognized, a critical signal amplification threshold can be achieved to induce a response. There are two broad categories of danger sensing: soluble immune mediators and danger ligands/receptors.

There are a wide variety of soluble immune mediators that, when secreted, can signify danger and induce a protective response. These factors are able to contribute to innate immunity, are encoded in the germline DNA, and are induced under specific stressful conditions. As an example, some are produced by cells that become infected. The purpose of this is to allow for innate immune defenses in the cells of the local environment to respond against the imminent danger. One example is type-I interferon. An infected cell will produce type-I interferons, leading to the induction of antiviral innate defenses in local cells that recognize the type-I interferon via specific receptors. The recognition of type-I interferon induces proteins such as protein kinase R (PKR) and Mx proteins, which slow down the proliferative capacity of the cell and impart specific antiviral properties. PKR inhibits translation by phosphorylation of the transcription factor eIF-2, while Mx proteins are GTPases that prevent nucleocapsid transport and viral nucleic acid replication. Thus, by recognizing a host-encoded soluble signal for danger, an innate immune defense can be initiated.

There are also a number of receptor–ligand pairs encoded in the germline DNA that are specifically accessed in the context of danger. These represent an inherent distress call that a cell can put out in situations of stress to facilitate its recognition as needing to be contained or eradicated. An example is the expression of CD48 on B cells infected by Epstein-Barr virus (EBV). This ligand was originally named Blast-1 for its appearance on EBV-transformed B-cell lymphoblasts. CD48 serves as a ligand for CD244 (2B4), which is a useful activating receptor constitutively expressed on NK cells. Its ability to sense danger through the recognition of CD48 represents an endogenous sensing mechanism that is immediately available to access innate immunity due to the constitutive expression of CD244. Another similar example is that certain infected or malignant cells that will express MICA as a feature of the stress these processes induce. MICA is specifically recognized by the constitutively expressed NKG2D receptor present on NK and T cells and like CD244 can directly induce innate immunity. Thus, while using endogenous receptor–ligand pairs, danger-sensing mechanisms can interpret abnormalities to effectively participate as elements of innate immune recognition.

AMPLIFICATION PHASE OF INNATE IMMUNITY

The recognition phase of innate immunity is central to the identification of danger, but in most cases does not directly include function that is relevant to host defense. To enable an effector response, the recognition of a danger signature needs to be amplified. This typically includes amplification events inside the cell recognizing the initial danger, as well as subsequent communication to the tissues and other components of innate immunity. Thus the amplification phase can be intracellular, extracellular, or both.

INTRACELLULAR AMPLIFICATION

Intracellular amplification follows the recognition of a danger signature by an innate immune receptor, or after the recognition of specific host-derived ligands by a danger-sensing receptor. The amplification typically involves a series of adaptor molecules and signaling effectors such as kinases, phosphatases, and ubiquitin ligases. At least some of these molecules are

recruited to the signaling platform centered around the receptor that has been ligated in order to amplify a signal generated after the recognition. The variety of intracellular signaling pathways and paradigms used by innate immune receptors is extensive and usually specific to a particular receptor system. As there is great diversity of these signaling mechanisms, they will only be illustrated here using the TLR system, which is well defined at the molecular level. There are, however, superb independent reviews of intracellular amplification resulting directly from the recognition of danger (Akira and Takeda, 2004; Beutler, 2009; O'Neill, 2008; Takeda et al., 2003).

The TLR system has been extensively studied for the signaling events that are utilized during intracellular amplification and has been reviewed elsewhere. The intracellular amplification following ligation of TLR is also relevant to consider, since defects in some of the molecules involved have been identified as causing specific primary immunodeficiency diseases (Picard et al., 2003; von Bernuth et al., 2008) (see Chapters 34–36). The TLRs are not entirely overlapping with regard to the amplification events that occur after their ligation (Fig. 8.1). They all, however, share the primary objective of inducing transcriptional machinery to lead to the production of new proteins. These newly synthesized proteins can then act to further amplify the innate response, or to serve roles as innate immune effectors.

The specific amplification pathways used by the TLRs, however, do have some important similarities. Amplification signals resulting from the ligation of all TLRs require the signaling adaptor MyD88 to access transcriptional functions. The exceptions to this rule are TLR3 and 4, which can amplify a signal in a MyD88-independent manner via the use of the TRIF and TRAM adaptor proteins. This MyD88-independent pathway then utilizes TBK to induce further downstream events. Ultimately all of the different amplification pathways will lead to accessing a kinase or kinase complex that induces the activation/phosphorylation of a transcription factor. For TLR this is most notably NF-κB (Fig. 8.1A) but includes others such as AP-1, IRF3, 5, and 7 (Fig. 8.1B). NF-κB is a transcription factor critical for innate immunity that is induced after dimers are released from the hold of the inhibitor of NF-κB (IκB) in the cytoplasm so that they can translocate to the nucleus and promote transcription. IκB is targeted for proteosomal degradation by ubiquitinylation, after it is phosphorylated by the IκB kinase (IKK) consisting of IKKα/β and the NF-κB essential modulator (NEMO). Most TLRs are capable of activating NF-κB in an IRAK4- and TRAF6-dependent manner. TLR3 can also function to activate NF-κB but uses RIP1 instead of IRAK4, and TRAF6. A number of other transcription factors are also induced through TLR signaling via distinct TLR-induced kinase functions. These include the AP1 transcription factor via MAPK by most TLRs; the IRF3 transcription factor via TBK1 by TLR4 and TLR3 (independently of MyD88); the IRF5 transcription factor via TRAF6; and the IRF7 transcription factor via IRAK1 specifically by endosomal TLR.

The transcription factors activated downstream in the process of TLR signal amplification further serve to amplify signals by inducing the generation of new proteins. Some of these proteins serve important intracellular functions and include components of transcription factors themselves (such as IRF and NF-κB), apoptosis regulators, and antigen-processing machinery. Other genes transcribed by TLR-induced transcription factors lead to the production of proteins that serve important roles in extracellular amplifications of the innate immune response and are discussed below. The TLR-induced transcription factors, however, also induce the production of effector molecules that are essential to the response phase of innate immunity and are discussed in the next section.

EXTRACELLULAR AMPLIFICATION

The amplification phase of innate immunity can be initiated extracellularly or it can have extracellular components after an intracellular amplification has occurred. Extracellular amplification can be through soluble mediators and thus lead to the involvement of innate immune elements from a distance. An example of a soluble amplification that is not initiated intracellularly is the fixation and activation of complement (discussed in greater detail in the specific section on innate immune components) (also see Chapter 55). Complement activation has the capacity to generate the chemotactic anaphylatoxins C3a, C4a, and C5a, which recruit other innate immune elements for action. Another example of a soluble amplification is the generation of proinflammatory cytokines and chemokines that are released from a cell after an intracellular amplification following a receptor-based recognition of danger. This example is germane to the theme of TLR as NF-κB activation after TLR ligation will lead to the transcription, translation, and release of soluble mediators, such as the potent chemoattractant chemokine CXCL10 (Kawai et al., 2001; Re and Strominger, 2001). These in turn will induce the activation and attraction of other innate immune cells so that they can participate in the defense.

Extracellular amplification can also occur through cell–cell contacts. In this case, the cell recognizing danger can express other activating ligands, such as co-stimulatory molecules or surface-anchored cytokines. These can then amplify the signal to a neighboring cell, which will then begin the process of intracellular amplification. An example would be that dendritic cells responding to TLR ligation induce cell-surface IL-15, which in turn leads to intracellular amplification in and activation of NK cells (Lucas et al., 2007). Alternatively, the initial innate immune cell can secrete factors in a directed manner onto a neighboring cell to enable its activation specifically. An example is a dendritic cell secreting IL-12 directly onto an NK cell, which in turn amplifies that signal to secrete IFN-γ onto the dendritic cell (Borg et al., 2004). This leads to a locally amplified signal that is now ready to initiate an innate immune effector mechanism.

RESPONSE PHASE OF INNATE IMMUNITY

The response phase of innate immunity is characterized by effector functions that are directly linked to the recognition of danger and pursuant signal amplification. These include (1)

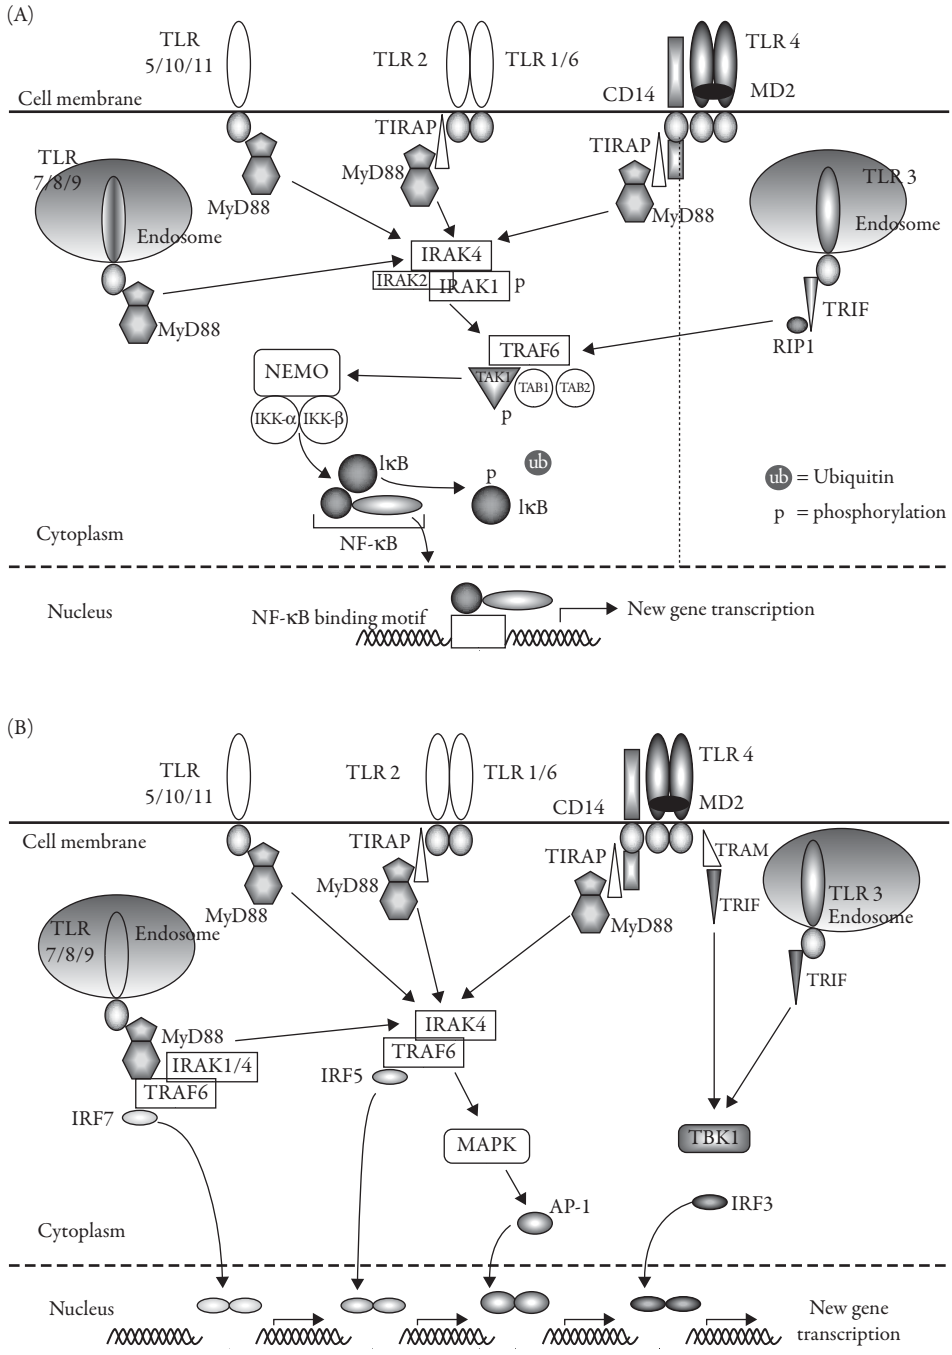

Figure 8.1 *The intracellular amplification phase of innate immunity as demonstrated by TLR signaling.* Ligation of the cell surface or endosomal TLR can lead to induction of NF-κB function (A) or of an assortment of other transcription factors (B). In either case specific adaptor proteins downstream of the TLR are utilized to access intracellular kinases to ultimately activate the transcription factors. These diagrams are not intended to offer an exhaustive scheme of signaling downstream of TLR, but to summarize some of the major routes that signaling can take to induce transcriptional activation. Each independent protein component is shown with a separate labeled shape. The solid horizontal line at the top denotes the cell-membrane boundary between the cell surface and the extracellular environment, and the dashed horizontal line at the bottom specifies the nuclear envelope. The dashed vertical line notes the separation between the MyD88-dependent and -independent signaling pathways. Importantly, TLR4 can amplify a signal in either a MyD88-dependent or -independent manner. With NF-κB activation the combination of NEMO, IKKα, and IKKβ represents the IKK complex, which phosphorylates IκB. This leads to its dissociation from NF-κB as well as targeting it for ubiquitination and proteosomal degradation (not pictured). The horizontal coil in the nucleus represents DNA and the rectangle depicts a promoter sequence in the DNA (not a protein) capable of binding the given transcription factor.

effects upon the physiology and local tissues preparing them for the battle against the pathogen or danger (i.e., inflammation); (2) direct innate effector mechanisms; and (3) communication with adaptive immunity.

LOCAL EFFECTS

Inflammation represents a means of priming the local environment for promoting antimicrobial responses and is one effector mechanism inherent to many innate immune pathways.

The characteristics of inflammation include increased local blood flow, increased vascular permeability, and activation of endothelium to facilitate chemoattraction of other cellular components of innate immunity. Inflammation occurs in response to the release of numerous soluble innate immune mediators, including prostaglandins, leukotrienes, TNF, IL-1, IL-6, and IL-12. To continue with the example of the TLR system, TNF, IL-2, and IL-6 are all produced as a result of the transcriptional activation following TLR ligand recognition. Thus, recognition of a danger motif can directly enable inflammation at the site of recognition.

DIRECT INNATE EFFECTORS

The innate immune system also possesses numerous important direct effector mechanisms that can participate in controlling or containing infection without the need for other factors. Some of these include the soluble effector proteins of the innate immune system such as antimicrobial peptides, and complement. These can mediate the direct destruction of a microbe and thus have an inherent and direct effector function (discussed in greater detail below). Some of these, including several antimicrobial peptides, are synthesized within and secreted by cells of the innate immune system.

The cells of innate immunity can possess their own effector mechanisms, some of which are shared by the adaptive immune system. Mechanisms that are shared with adaptive immunity include perforin-dependent cytotoxicity, contact-dependent cytotoxicity mediated by TRAIL, FAS-L, and surface-bound TNF. Effector mechanisms, which are specialties of certain innate immune cells, include phagocytosis and generation of reactive oxygen intermediates (ROIs) and reactive nitrogen intermediates (RNIs). Phagocytosis generally occurs after an organism is opsonized by complement, or antibody, or ligates a specific PRR. The ingested organism is then destroyed by ROIs, RNIs, acidification of the endosome, or iron restriction via proteins such as natural resistance-associated macrophage protein 1 (Nramp1). ROIs are generated from the NADPH oxidase (phox) complex that can reduce oxygen to superoxide by adding an electron (Fig. 8.2). Superoxide dismutase and myeloperoxidase can then generate hydrogen peroxide and hypochlorous acid (see Chapter 52). RNIs are generated when nitric oxide (NO) synthases (NOS) catalyze L-Arg + oxygen to form L-citrulline and NO. There are three forms of NOS: NOS1 and NOS3 are constitutively expressed and NOS2 is induced.

Although the above-mentioned systems represent only a few examples of effector mechanisms, they illustrate the breadth of means by which the innate immune system can directly mediate function against microbes. While some of these mechanisms are clearly sufficient in their own right to eliminate a challenge, they can also be useful in limiting the spread of a dangerous challenge until the adaptive immune system can be recruited to participate in the response.

LINKS TO ADAPTIVE IMMUNITY

A third and essential response of innate immunity is in its ability to link to the adaptive immune system (Beutler, 2004).

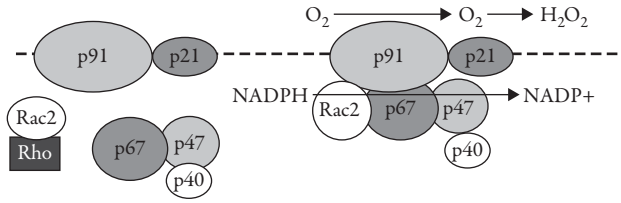

Figure 8.2 *The phagosome oxidase (phox) complex: an essential example of the response phase of innate immunity.* The phox complex consists of numerous components depicted by individual shapes. After recognition and amplification has occurred, the components can assemble to form a functional complex, as represented by the transition from the left to the right of the figure. The dashed line represents the phagosomal membrane. Two components, p91 and p21, are integral to the membrane (left), and the others join the complex at the site of the phagosome after activation has occurred (right). For assembly to occur, Rac2 must become free of Rho, which results as a part of the signal amplification. When assembled, the phox complex reduces NADPH to generate superoxide from oxygen. Using cellular superoxide dismutase, the generated superoxide can be converted to hydrogen peroxide, which has potent antimicrobial function (see Chapter 52 for details).

Through a variety of effector mechanisms, innate immune cells and mediators can constructively communicate with cells of the adaptive immune system. This can serve the purpose of helping to initiate or induce an adaptive immune response, which in turn can allow the adaptive immune system to more specifically target the dangerous challenge. The adaptive immune response can then potentially minimize any collateral damage that the innate immune system may have been responsible for while containing the challenge. Although this topic is rather broad, it is essential to appreciate its existence and relevance. A few important examples are provided.

The innate immune system can produce cytokines that are able to promote the development of adaptive immune cells into functionally specialized cell subsets. Although this has a variety of applications, the classical example is that of polarization of T-helper-cell subsets. If IL-12 is produced by the innate immune system when T cells are developing, they can be biased toward Th1 and away from Th2 differentiation. Clearly, this has important consequences on participation of the adaptive immune system in host defense.

A clear and critical function of innate immunity in interfacing with adaptive immune response is in antigen presentation. The "professional" antigen-presenting cell of the immune system is the dendritic cell (DC), which is an integral part of innate immunity. DCs, described in greater detail in a specific section below, are capable of presenting antigenic peptides to T cells. They perform this function by processing proteins and loading peptides into major histocompatibility molecules (MHC), which are trafficked to the cell surface, where they can be recognized by T cells. Importantly, the antigen-presentation process in DC is facilitated by recognition of TLR ligands and subsequent signal amplification (Blander and Medzhitov, 2006).

Innate immunity is also an essential source of chemokines and chemoattractive factors that can enable the adhesion of and recruit adaptive immune cells to critical sites where antigen can be provided. An example mechanistically defined in

mice is that of NK cells producing the chemokine CCL22 to recruit T cells to tumor microenvironments (Mailloux and Young, 2009).

There are also other important roles for contact-dependent effector functions of innate immunity in linking to the adaptive immune system. An example is the number of co-stimulatory ligands expressed by innate immune cells that provide critical signals to the adaptive cells. An example is the expression of CD86 (B7.2) by DCs after they have been activated. To follow the theme introduced earlier, CD86 can be induced on DCs after they have recognized patterns via TLRs and amplified signal (Hertz et al., 2001). Once expressed, CD86 is recognized by CD28 expressed on T cells, thus generating the essential second signal for T-cell proliferation that is needed in addition to ligation of the T-cell receptor. Thus, interaction between the innate and adaptive immune system is essential for host defense and represents a critical response of innate immunity.

COMPONENTS OF INNATE IMMUNITY

In addition to considering the specific paradigms with innate immunity functions, it is useful to be cognizant of the individual components that make up the innate immune system (Beutler, 2004). On a rudimentary level these can be divided into three categories: physical barriers; proteins and soluble mediators; and cells. Each is introduced below with specific reference to important members of the specific category.

PHYSICAL BARRIERS AND INNATE IMMUNITY

In a sense physical barriers can be viewed as a form of innate immunity. While the majority of cells and tissues that form such barriers are not of immune origin, they do constitute a critical defense against the environment and are essential in protection against infection and other danger. Thus they are at least worthy of mention in the context of innate immunity. Important physical barriers include the cornified epithelium of skin, intestinal epithelium, as well as less well-formed barriers such as mucous linings of various tissues. In addition, the cells of the innate immune system do contribute directly to these barriers in many cases by secreting peptides, enzymes, and other factors to augment the inherent defense functions of physical barriers. An example would be the secretion of defensins (discussed below) into mucus that coats the airway epithelium.

SOLUBLE AND SECRETED COMPONENTS OF INNATE IMMUNITY

Many soluble and secreted molecules are critical components of the recognition, amplification, and effector functions of the innate immune system. Some of these function primarily in amplification and can be considered as mediators, while others possess direct recognition and/or effector functions. Both of these groups of molecules within the innate immune system are extensive, and thus a few key illustrations of soluble and secreted molecules/proteins are given to introduce the major categories.

COMPLEMENT

Complement is a collective term introduced 100 years ago to define a group of factors present in fresh plasma that when activated by specific antibody were able to kill bacteria (Wagner et al., 1998). Later work showed the bacteria studied were lysed and that the killing principle was heat-labile—that is, heated normal serum lost this killing ability. We have come to recognize that this collective term includes at least 30 known proteins and protein regulators, some of which circulate in the blood and some of which are bound to cell membranes. These proteins play a major role in host defense and innate immunity (see Chapter 55). More recently, it has become clear that complement is important also in the generation of a normal immune response. Phylogenetically, the complement proteins are ancient, serving a host defense function in animals as primitive as sea urchins. The adaptive immune system appears in evolution at the level of the jawed fish and, by this point in evolution, all the various complement proteins are arrayed to produce their regulatory and host defense functions. The system clearly follows the pattern of pathogen recognition, amplification, and response.

Three pathways of complement activation are known (Fig. 8.3) (Walport, 2001a, 2001b). The first pathway, defined over a century ago, and therefore termed the classical pathway, appears in phylogeny at the time of antibody and usually uses antibody as its recognition molecule. A second pathway, termed the alternative pathway because it was recognized later, is phylogenetically the oldest pathway and does not require antibody for pathogen recognition. Its recognition mechanism, although complex, is quite primitive and will be described below. The third pathway, the lectin pathway, described in the past two decades, is still being defined in detail (Jensenius, 2005). Its recognition molecules are lectins, mannose binding lectin and the group of ficolins, proteins that recognize repetitive sugar motifs. In this case the sugars are found as part of the capsules or envelopes of most bacterial and viral pathogens and, as such, constitute pathogen-associated molecular patterns. Because normal human proteins and cells do not have repeating sugar patterns, these lectins, which bind to the sugars expressed on the surface of pathogens by multiple low-affinity sugar-recognition sites and activate complement, tend not to bind to host cells. All three pathways proceed by engaging a related series of serine protease enzymes to the activation site and by binding and activating a plasma protein, C3, present at high plasma concentration (1.2 mg/mL), that is central to all three pathways. Upon activation of C3, a fragment, C3a, is cleaved from the molecule and the remaining large fragment of C3, C3b, has a metastable binding site generated that can bind covalently to any nearby cell, bacterium, or virus or can be hydrolyzed by water. Bound C3b can interact with other alternative pathway proteins to initiate further activation of

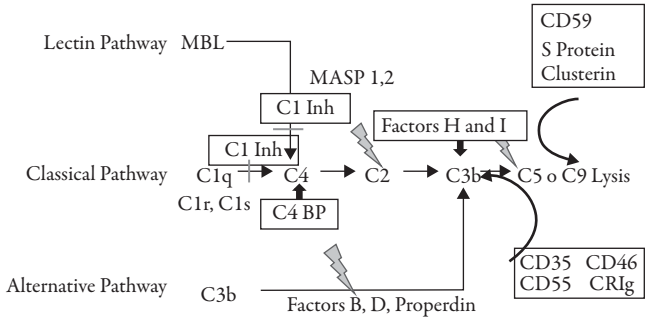

Figure 8.3 *Schematic of complement pathways.* Complement control proteins are listed in boxes. Those proteins that are membrane bound are in bold print; those that are fluid phase are not bolded. The lightning bolts direct attention to those proteins that bind to the assembling complement complex so that an unstable site is formed that decays with loss of ability to continue the cascade. C1 inhibitor controls activation of the classical and lectin pathway. C4 binding protein controls the biological activity of the active fragment of C4, C4b. Factors H and I are the major fluid-phase controllers of C3b. C3b binds preferentially to CD35. Factor H can bind to C3b, allowing it to be cleaved by factor I. Cleavage of the α chain leads to the formation of hemolytically inactive C3b (iC3b). This molecular form of C3 binds preferentially to CD11b/CD18 or CD11c/CD18. CD35, CD46, and CD55 control further aspects of the degradation and cleavage of C3. CRIg is a macrophage C3b receptor found prominently on Kupffer cells in the liver that facilitates removal and phagocytosis of C3b-coated particles from the circulation and aids in the degradation of C3b. CD59 prevents assembly of the membrane attack complex, as do the fluid-phase proteins S protein and clusterin.

the alternative pathway, thus amplifying its effect. If bound to a pathogen surface, C3b and its degradation products can initiate the steps leading to pathogen destruction. C3 undergoes spontaneous activation in the blood, and it is C3 itself that acts to initiate the alternative pathway. Since activated C3 can also bind to host cell membranes, there are proteins that recognize C3b deposited on a host cell surface and cause it to be destroyed without destroying the C3b on a microorganism surface. Nevertheless, it should be clear that more sophisticated mechanisms for pathogen recognition have evolved to facilitate an individual's ability to fight off infection. Because space precludes a discussion of the function of each of the proteins in the various complement pathways, Figure 8.3 illustrates their name designation and place in the various activation pathways. After binding C3, the pathways proceed together through the binding of an additional series of proteins, C5, C6, C7, C8, and C9, to promote the lytic and inflammatory steps in complement action.

There are three major effector functions of complement in host defense. First is its ability to lyse cells. The binding of C3 and the later binding of C5 to C9 leads to the formation of a cylinder-like structure that inserts itself into the surface of complement-sensitive cells, bacteria, or enveloped viruses. The cell or organism cannot maintain its internal stability as its internal environment is in free communication with the external milieu and it dies. The second important function of complement is to opsonize particles. On complement activation, complement fragments, particularly those produced by activation of C3, may bind covalently to an organism surface. These can interact with specific receptors for these fragments on the surface of cells like neutrophils and macrophages, facilitating the ingestion process. The third essential effector function of complement is the ability to generate on activation cleavage fragments that have potent inflammatory activity. For example, the small fragment of C5, C5a, can cause mast cells to degranulate and release histamine as if they were coated with IgE and antigen. C5a can cause migration of phagocytic cells toward the place where the peptide is generated—that is, induce chemotaxis—and it can cause cytokine release from cells (Hugli, 1986; Nordahl et al., 2004).

The complement activation steps are enzymatic and complement activation will continue until the system is specifically turned off. Thus, the system is built to provide massive amplification of small signals. Because activation of complement can induce unwanted widespread inflammatory tissue damage, the system is under tight regulatory control. There are both fluid-phase and cell membrane-bound proteins that function to downregulate or inhibit complement function. Although absence of a complement protein because of a gene abnormality is a very rare event in the case of most of the complement proteins, absence of one of the regulators is more common (see Chapter 55). Such absence, even when the absence is partial, may lead to impressive disease. So, for example, when one of the two gene alleles for factor H, a proteins that in part helps degrade C3b deposited on a host cell surface, is absent, the patient may develop a variant of hemolytic-uremic syndrome with destruction of his or her own kidneys as well as autoimmune erythrocyte hemolysis.

MANNOSE-BINDING LECTIN (MBL)

MBL is an example of the collectin family of calcium-dependent lectins and will bind to terminal mannose groups on many bacteria (Jensenius, 2005). Complement is activated via the MBL-associated serine proteases (MASPs). MASP1 can cleave C3 directly and MASP2 cleaves C4 and activated C2. Thus, MBL represents an additional demonstration of innate recognition, which leads to amplification via complement and effector function via an assembled complement MAC (See Chapter 55). It has been found to have diverse roles in innate immunity (Ip et al., 2009), and animals deficient in MBL are susceptible to staphylococcal infection (Shi et al., 2004). The isolated role of MBL in human host defense, however, is the subject of substantial study and is at present unclear (Casanova and Abel, 2004).

ANTIMICROBIAL PEPTIDES

Endogenous soluble secreted antimicrobials are increasingly appreciated as an effector component of innate immunity. The family of antimicrobial peptides comprises cationic proteins ranging in size from 8 to 45 amino acids in their fully processed forms, which can insert into concentrations of bacterial phospholipids to slow microbial growth (Agerberth and Gudmundsson, 2006). Many of these are synergistic or additive in this action. They include the defensins, cathelicidins, lactoferrins, and histatins.

Defensins are triple-stranded molecules held together by three disulphide bonds. The defensin family includes α-defensin or human neutrophil peptide (HNP), and β-defensin or human β-defensin (hBD). The HNP subfamily consists of HNP1–4 expressed by granulocytes and HNP5 expressed in the intestine. The HBD subfamily consists of hBD1–3 expressed in skin and lung, and hBD-4 expressed in testis. Of particular potential relevance to human disease mechanisms, hBD-2 is decreased in atopic dermatitis relative to levels found in psoriasis lesions or normal skin (Ong et al., 2002).

Cathelicidins are distinguished by possessing a cathelin-like domain at their N-terminus and an antimicrobial domain at their C-terminus. An important member of this subfamily is LL-37, which is expressed by granulocytes and in lung. LL-37 is also found to be decreased in lesions of active atopic dermatitis relative to levels found in psoriasis lesions or normal skin (Ong et al., 2002).

Lactoferrins belong to the transferrin family of proteins and under normal circumstances bind iron. The human lactoferrin (hLF) subfamily consists of hLF1–11, which can be produced by macrophages, among other cells. Importantly, they are also found in tears and in human milk.

Histatins are distinguished by having histadine-rich sequences, and the subfamily contains at least 12 members. The histatins are abundant in saliva and salivary glands and as a result probably serve an important role in defense against microbes entering the oral cavity. They are especially active against fungi.

PROTEOLYTIC ENZYMES

The innate immune system secretes an important variety of proteolytic enzymes that can have critical roles in host defense and the direct elimination of danger. The granzymes are a central example and are serine proteases contained within the lytic granules of cytotoxic cells. When pores are created in pathogens or dangerous cells via molecules such as perforin, granzyme entry and uptake can occur. In humans the granzyme family includes granzymes A, B, H, K, and M, each of which has particular patterns of expression. The cathepsin family also represents an important group of proteases, but these are cysteine as opposed to serine proteases. In addition to roles in host defense, cathepsins serve important functions in antigen-presenting cells to further process entocytosed proteins.

CYTOKINES AND CHEMOKINES

Cytokines and chemokines are a large group of soluble protein messengers that share the common characteristic of having action upon immune cells. They can be produced by immune as well as by nonimmune cells and are characterized by a finite family of structures. They are the subject of many superb reviews that are focusing on nomenclature, origin, and function (Borish and Steinke, 2003; Ransohoff, 2009; Rossi and Zlotnik, 2000; Steinke and Borish, 2006). In some cases these factors can function as cell-surface molecules, but more commonly they are secreted to function in soluble formats in local or distant environments. In either case, they can participate in amplification and response phases of innate immunity, and some specific examples were mentioned above in the section on paradigms in innate immunity.

Some critical innate members of the cytokine and chemokine families are worth specific emphasis. Among the cytokines, these include the members of the proinflammatory cascade, including IL-12, TNF, IL-1, IL-6, and IL-18. These factors are rapidly induced and secreted upon the recognition of danger and serve essential roles in preparing cells and tissues to handle threats as well as further activate and induce immune responses. Together these factors represent a very powerful attempt of the innate immune system to mobilize a response and can be contained on a local level, but can also be pronounced systemically in situations of grave danger. In the most extreme circumstances this can precipitate a "systemic inflammatory response syndrome" in which the host is risking survival with a most aggressive response in order to gain control over danger (Castellheim et al., 2009).

Chemokines are generally more specialized in the recruitment of additional elements of immunity. They can be produced by the innate immune system to recruit additional innate elements, or components of the adaptive immune system. An example of the innate system recruiting more innate immune elements is CXCL8 (also known as IL-8), which is produced by activated macrophages, NK cells, and epithelium (Remick, 2005). It can ligate its major receptor CXCR1 on neutrophils and induce their chemotaxis toward the source of CXCL8. To follow the theme introduced earlier, CXCL8 secretion can be potently induced by ligation of TLR4 by LPS (Sabroe et al., 2003), thus demonstrating an essential role for IL-8 in the amplification phase of innate immunity. An example of the innate immune system specifically recruiting the adaptive immune system is CCL20 (Schutyser et al., 2003). The production of CCL20 is highly induced by ligation of TLRs (Scapini et al., 2001) and facilitates the recruitment of T cells through the CCR6 receptor to the sites of amplification where adaptive immune responses can be propagated.

NEUROPEPTIDES

Neuropeptides are a family of small proteins that by definition are produced by cells of the nervous system. In many cases, however, they can also be produced by cells of the innate immune system and as a group can have numerous and important effects on immune function. Examples include adrenomedullin, proenkephalin A, and neurokinin-1 (also known as substance P). Some of these peptides, such as neurokinin-1, also possess direct antimicrobial functions and thus have significant overlapping function with the antimicrobial peptides discussed above (Brogden et al., 2005). Neurokinin-1 can be produced by and also serve to potently stimulate or inhibit innate immune functions and as such is important to consider as an alternative regulator of innate immunity (Tuluc et al., 2009).

CELLS OF INNATE IMMUNITY

Most cells are capable of innate responses to danger, as having the ability to recognize a challenge to the host is critical

to their survival. Many cells express and can utilize the same pattern recognition, amplification, and response systems discussed above. As an example, TLRs are widely expressed both inside and outside the immune system. They can facilitate the recognition of danger in innate immune cells, but also in cells of the adaptive immune system and in nonimmune cells such as fibroblasts. Thus, innate recognition of danger serves important roles in many contexts. There are, however, cells that should be considered as specialized or "professional" cells of the innate immune system. For the purposes of this discussion they can be considered to include neutrophils, monocytes/macrophages, DCs, eosinophils/mast cells/basophils, and NK cells and are summarized in Table 8.2.

NEUTROPHILS

Neutrophils, also referred to as polymorphonuclear leukocytes, are the chief phagocytes of the immune system (see Chapters 50–53). They develop from $CD34^+$ hematopoietic stem cells in the bone marrow in response to IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF). The later developmental stages of neutrophils, including transition to a granulocyte precursor from one that has the potential to develop into either a monocyte or granulocyte, is especially dependent upon G-CSF. Neutrophils represent more than half of the hematopoietic cells that develop from bone marrow and are relatively short-lived in the circulation ($t_{1/2}$ ~6 hours) as well as in the tissues ($t_{1/2}$ ~24 hours). They are distinguished by cell-surface expression of CD67 (CD66b), also known as carcinoembryonic antigen-related cell adhesion molecule 8, which may be involved in neutrophil aggregation. Neutrophils also express receptors aimed at facilitating their major objective of phagocytosis. These include Fc receptors, and the complement receptors CR1 and CR3 to facilitate phagocytosis through the binding of opsonizing antibody and complement, respectively.

Neutrophils serve essential roles in host defense through their ability to engulf and destroy pathogens (Segal, 2005). They are attracted to sites of danger via an array of chemotactic mechanisms, including the above-mentioned fMLP receptor and CXCL8. They also are potently recruited by C5a, CCL3 (MIP-1α), platelet activating factor, and leukotriene B4, among others. They adhere to their target site using the well-defined mechanism of rolling and tight adhesion dependent upon cell-surface–expressed selectins and integrins, respectively. The destruction of engulfed pathogens can occur via oxygen-dependent (Fig. 8.2) or oxygen-independent systems. The oxygen-independent mechanisms can involve many of the different effector molecules discussed above and include proteins contained in neutrophil granules.

Neutorophil granules represent specifically compartmentalized effector units that are maintained for use in host defense. Their separation from the remainder of the cell allows for the ready storage of highly toxic substances without harming the normal functions of the cell. There are four major types of neutrophil granules, azurophil, specific, gelatinase, and secretory, each having specialized roles. The azurophil granules contain largely host defense molecules, including lysozyme, defensins, acid phosphatase, glucosidases, cathepsins, and elastase. These organelles can contribute to the antimicrobial effect against phagocytosed organisms (contained in a phagosome) by joining the phagosome once it has been formed. The azurophil granule then contributes its contents to the phagosome to provide additional effector mechanisms in the attempted destruction of the pathogen. Neutrophil-specific granules contain the fMLP receptor, integrins, lysozyme, procollagenase, B12 binding protein,

Table 8.2 **THE "PROFESSIONAL" CELLS OF INNATE IMMUNITY**

CELL	KEY FUNCTION	DISTINGUISHING CELL-SURFACE MARKERS	HALF-LIFE	DISTINGUISHING FEATURES	DEVELOPMENT	CHEMOTAXIS
Neutrophils	Phagocytosis	CD67	~6 h (circulation) ~1 d (tissues)	Contain 4 granule types—azurophil, specific, gelatinase, secretory	IL-3, GM-CSF, G-CSF	fMLP, CCL8, CCL3
Monocytes/Macrophages	Phagocytosis, secretion, antigen presentation	CD11b CD14 CD36	~70 h (circulation) Years (tissues)	Potently activated by IFN-γ	GM-CSF M-CSF	CCL4, CCL22, CXCL4
Dendritic cells	Antigen presentation	MHC-II CD11c (most)	~1 d to 2 wks	4 major subsets: myeloid, plasmacytoid, Langerhans, interstitial	GM-CSF IL-4	CCL3 CCL21
Eosinophils/Mast cells/Basophils	IgE-binding, effector secretion	FcεRI (M,B), CD23 (E)	~6 h (E, B) ~21 d (M)	Respond to IgE	SCF (M) IL-3 (B) IL-5 (E)	CCL5 CCL11 (E)
NK cells	Cytotoxicity, secretion	CD56, CD158 CD335 CD337	~10d	Lytic granules containing perforin and granzymes	IL-15	CXCL12

and lactoferrins. By contributing these molecules the specific granule can augment neutrophil chemotaxis, adhesion, and host defense. Their importance is underscored as they are missing in the primary immunodeficiency specific granule deficiency, resulting from mutation of the CCAAT/enhancer-binding protein ε transcriptional regulator (Lekstrom-Himes et al., 1999). Neutrophil gelatinase granules have similarities to specific granules and also contain the fMLP receptor, integrins, and lysozyme, but are distinguished by their gelatinase content. The gelatinase granules are also distinguished by their rapid mobilization after presumed TLR4 ligation by LPS (Almkvist et al., 2001). Neutrophil secretory granules contain many of the same molecules as the specific granules, including those used in chemotaxis and adhesion, but are distinguished by their expression of alkaline phosphatase. Neutrophil alkaline phosphatase is a phosphatidylinositol-linked transmembrane receptor that functions to facilitate dephosphorylation in alkaline environments.

MONOCYTES/MACROPHAGES

Monocytes and macrophages have many overlapping functions with neutrophils as they are active in both phagocytosis and secretion, but also overlap with DCs as they can function in antigen presentation (Auffray et al., 2009; Serbina et al., 2008). Importantly, monocytes are much longer-lived than neutrophils, with a half-life of 70 hours in the circulation. When marginating to tissues, monocytes have the unique characteristic of transitioning into macrophages and can persist for years. This can facilitate tissue-specific immunity but has proven important in disease pathogenesis by serving as long-term reservoirs for the human immunodeficiency virus (Alexaki et al., 2008). Monocytes originate from the granulocyte-macrophage colony-forming unit (GM-CFU) in the bone marrow and require M-CSF and GM-CSF for development. From the circulation, monocytes are attracted to tissues via a number of factors, including CCL4, CCL22, and CXCL4. In tissues, macrophages are capable of performing phagocytosis and generating reactive metabolites similarly to neutrophils. They also secrete over 100 different functionally relevant proteins, including TNF and other proinflammatory cytokines. Monocytes are very potently activated by IFN-γ, which from an innate immune standpoint is derived from NK cells, but of course is also derived from many cells of the adaptive immune system. Distinguishing cell-surface receptors expressed on the monocyte/macrophage include CD11b/CD18 (Mac1), which is also expressed on neutrophils and NK cells; CD14, which is an LPS co-receptor; and CD36, which is an LDL scavenger important for recognizing apoptotic cells. As elements of host defense and promoting immunity, monocytes/macrophages are instrumental, but pure human deficiencies of this lineage have not been defined, except, perhaps, the recently described monocytopenia and mycobacterial infection (MonoMAC) syndrome due to mutations in GATA2. However, MonoMAC patients also have profound NK and B-cell lymphopenia and absent DCs in the circulation, findings that may contribute to the immunodeficiency associated with this syndrome (Hsu et al., 2011).

DENDRITIC CELLS

DCs can be considered as part of the innate immune system, although they perhaps represent the critical link between innate and adaptive immunity. DCs, best known for their function as "professional" antigen-presentation cells, are specialized for presenting peptides in the context of class II MHC to T cells. They facilitate the activation of T cells when antigen is presented along with co-stimulation but can induce anergy when co-stimulation is withheld (Novak and Bieber, 2008). These co-stimulatory molecules include B7.1 (CD80) and B7.2 (CD86), which interact with CD28 on T cells. Importantly, this co-stimulation-dependent link between innate and adaptive immunity can be induced through the innate function of DCs in recognizing danger. Specifically, ligation of TLR on DCs can lead to their upregulation of CD80 and CD86 (Gaddis et al., 2009; Krug et al., 2001). In this sense DCs are innate gatekeepers of the adaptive immune response and depend upon danger sensing to regulate their communication. In addition, the specific conditions of their differentiation and microenvironment can help them preferentially drive T cells to have a polarized functional phenotype, such as to T-helper 1 or 2 cells. DCs additionally interface with the adaptive immune system by their role in the germinal center reaction in the lymphoid follicle required for the generation of an antibody response (Randolph et al., 2008).

DCs develop from bone marrow hematopoietic stem cells facilitated by GM-CSF and IL-4. They are considered immature when resting in tissues and have a high capacity for antigen uptake. DCs are considered mature after activation and have decreased capacity for antigen uptake but increased MHC expression. In this state they migrate to lymphoid organs to facilitate the interface with the adaptive response and can be recruited by CCL3 and CCL21, among others. There are four major DC subsets, myeloid, plasmacytoid, Langerhans, and interstitial, although some focus divisions of DCs more specifically upon myeloid and plasmacytoid.

Myeloid DCs (also known as DC1) develop from a common myeloid progenitor and express characteristic myeloid markers, including CD11b/c, CD13, and CD14. CD13 on DCs likely serves a useful role in reducing the length of peptide presented in class II MHC to facilitate antigen presentation (Larsen et al., 1996). They also express multiple CD1 isoforms to enable alternative antigens to be presented. Myeloid DCs are efficient in phagocytosis, but less so in producing type I interferon.

Plasmacytoid DCs (also known as DC2 and lymphoid DCs) originate from the common lymphoid progenitor and express some characteristic lymphoid markers, including CD4, and the Igλ-like 14.1. Plasmacytoid DCs can produce high levels of type I interferons, which are important in initiating antiviral responses.

Langerhans DCs develop from cutaneous lymphocyte antigen (CLA)-expressing $CD34^+$ precursors originating from common myeloid progenitor cells. They express CD11c and langerin (CD207) and have characteristic Birbeck granules. Langerin functions in the uptake of microbial components as

well as inflammatory cell recruitment. Birbeck granules are tennis racquet-shaped membrane-associated organelles that can be distinguished by electron microscopy. Langerhans cells are often found in the epidermis, excel in $CD8^+$ T-cell priming, and are the longest-lived of the DC subsets.

Interstitial DCs (IDC) develop from CLA^- $CD34^+$ precursors derived from common myeloid progenitor cells. Unlike Langerhans DCs, IDCs express abundant CD2, CD9, and CD68. They do not possess Birbeck granules, do not express CD207, and are found in the dermis. They are effective in macropinocytosis, IL-10 production, and inducing B-cell activation.

EOSINOPHILS, MAST CELLS, AND BASOPHILS

While certainly representative of distinct and important functional units, eosinophils, mast cells, and basophils are discussed collectively due to their common roles in atopic pathogenesis (Blanchard and Rothenberg, 2009; Prussin and Metcalfe, 2003, 2006; Rothenberg and Hogan, 2006). Although atopic diseases present a great burden to the developed world, the major role and likely evolutionary purpose of these cells is in host defense against large extracellular parasitic pathogens such as helminths (Galli et al., 2002). All of these cells have the ability to respond to IgE, which is a characteristic part of the anthelminthic immune response. Basophils and mast cells recognize IgE through the high-affinity receptor (FcεRI) and eosinophils through a lower-affinity receptor (CD23). Each of these cell types is capable of releasing large numbers of soluble mediators that can contribute to amplification and directly to response phases of innate immunity. Important examples of the latter include eosinophil expression of major basic protein (MBP) and eosinophil cationic protein (ECP). Both of these can be secreted and specifically enable the effective participation of eosinophils in host defense (Gleich et al., 1979; Yazdanbakhsh et al., 1987). In particular, both MPB and ECP alter the permeability of membranes and can promote the dissolution of the target; this is especially effective against helminths. Together with basophils, eosinophils also have an important role in resistance against certain ticks (Brown et al., 1982). Mast cells are defined by their tissue localization and are divided into two major subsets based upon whether they contain tryptase, or tryptase and chymase. When secreted in response to IgE in tissues, these components can have a direct ability to exert antimicrobial effects (McNeil et al., 2007), in addition to actively promoting inflammation.

NATURAL KILLER CELLS

NK cells are lymphocytes derived from the common lymphoid progenitor in the bone marrow that require IL-15 for their development (Orange and Ballas, 2006). They have a number of characteristic cell-surface markers, including CD16 (a low-affinity Fc receptor), CD56 (neural cell adhesion molecule), the natural cytotoxicity receptor (NCR—CD335, CD336, CD337) family of molecules, and killer cell immunoglobulin receptors (KIR—CD158 and others). They do not express CD3 and unlike most other lymphocytes do not rearrange their TCR or Ig genes. NK cells are activated by a number of receptors that recognize danger ligands, such as NKG2D recognizing MICA (Raulet, 2003). They also can be specifically induced by their own set of pattern-recognition receptors, such as NKp46 recognizing viral hemagglutinins (Gazit et al., 2006; Mandelboim et al., 2001). NK cells can additionally be activated by the Fc of IgG through their Fc receptor and thus can recognize opsonized materials.

NK cells are inhibited by a number of receptors that recognize characteristics of self, such as the KIR family that recognizes class I MHC. The absence of self-molecules in a target cell, such as in tumor or virus-infected cells, enables NK cell function and has given rise to what is known as the "missing self hypothesis." In combination with the presence of ligands for activation receptors in these target cells, downmodulation of self-MHC can enable NK cell function. Thus, activation and function in NK cells is a feature of a balance favoring activation signaling (Culley et al., 2009; Lanier, 2008).

There are 14 KIR genes in humans on chromosome 19. The genes are highly polymorphic, and there are a large number of distinct KIR haplotypes that can be inherited. As experience with KIR molecules and genotypes has grown, one feature that has become apparent is that like MHC, there are definitive links between the KIR haplotypes and human disease (Parham, 2005). An important example is the presence of KIR2DL3 in the haplotype resulting in rapid clearance of hepatitis C virus when the infected individual is homozygous for the HLA-C1 ligand (Khakoo et al., 2004).

Once activated, NK cells can have three major functions: cytotoxicity, cytokine production, and co-stimulation. NK cytotoxicity is contact-dependent and thus is similar to that employed by cytotoxic T cells. It utilizes perforin and granzymes that are contained within lytic granules. Triggering the NK cell with an appropriate activation receptor results in the intracellular traffic of the lytic granules toward the target cell upon which they are extruded (Orange, 2008). NK cell cytotoxicity is important in eliminating virus-infected cells, especially those infected with herpesviruses as well as hematopoietic tumor cells that have lost expression of class I MHC. In bone marrow transplantation for malignancy, developing donor NK cell cytotoxicity cells is likely responsible for significant graft antitumor effect (Ruggeri et al., 2002). This requires a mismatch between the specificity of the inhibitory receptors present on the donor cells to the class I MHC ligands present in the recipient.

In addition to functioning in cytotoxicity, NK cells are highly efficient in producing IFN-γ and do so to participate in antiviral defense (Orange et al., 1995). NK cell IFN-γ is also very important in facilitating macrophage and DC functions to improve innate immunity. NK cell IFN-γ additionally can directly augment adaptive immune cells. This function overlaps with the ability of NK cells to efficiently provide contact-dependent co-stimulation and can do so through their expression of CD252 (OX40/CD134L) and CD154 (CD40L). Thus, while diverse in their functions, NK cells

are the major lymphocytes of the innate immune system and serve important roles in defense. This is most clearly illustrated by a number of rare human deficiencies of NK cells (Orange, 2006, 2011).

CONCLUSIONS

Innate immunity represents the initial line of defense against danger. There are three phases in innate immunity—recognition, amplification, and response. Each has important elements that relate not only to the generation of host defense, but also to consideration of immunodeficiency. Recognition is focused upon the rapid identification of danger, either the recognition of molecular patterns or by specific danger-sensing mechanisms. TLRs are a major example within innate immunity of pattern recognition and have been used throughout this chapter to illustrate the paradigms of innate immunity. Similar concepts, however, apply to the numerous other systems we did not have opportunity to address in detail. The amplification phase of innate immunity can occur intracellularly via signaling pathways or through extracellular mechanisms. Finally, the response phase of innate immunity is characterized by the specific production of soluble effector molecules, contact-dependent effects, and promoting adaptive immunity. While there are many individual components of innate immunity, it is useful to consider these paradigms when evaluating potential defects of innate immunity that impair host defense (see Chapters 34–36).

INTRODUCTION TO SEVERE COMBINED IMMUNODEFICIENCY (SCID) AND COMBINED IMMUNODEFICIENCY (CID)

Jennifer M. Puck

BRIEF HISTORY OF SCID

The first descriptions of a fatal congenital deficiency of lymphocytes date from the 1950s in Switzerland. Glanzmann and Riniker (1950) described an idiopathic wasting syndrome with fatal *Candida albicans* infection. Hitzig and Willi (1961), following the discovery of agammaglobulinemia by Bruton (1952), reported familial alymphocytosis combined with agammaglobulinemia with a fatal outcome in infancy. The term "Swiss-type agammaglobulinemia" was originally used to distinguish infants with fungal infections, lymphopenia, and early death from the less severely affected children who came to medical attention somewhat later in life with isolated agammaglobulinemia. However, the term was a source of confusion, in part because the "Swiss-type" label was then applied to kindreds in which SCID was inherited as an X-linked recessive trait. "Nezeloff syndrome" was another term originally describing cases of thymus dysplasia with preservation of immunoglobulins (Gosseye et al., 1983; Nezelof, 1968), but the term was no longer used after it became clear that B-cell immunity could not develop in the absence of T cells. In subsequent decades SCID designations have become more precise thanks to improved immunological tools to characterize immune defects plus the identification immunodeficiency genes.

Failure to recognize immunodeficiency as the underlying cause of recurrent diarrhea, pneumonia, septicemia, fungal infections, or failure to thrive is evident in family histories of kindreds in which affected infants have died. In the past and even today many SCID patients have been mistakenly thought to have dietary intolerances or cystic fibrosis because of diarrhea, poor weight gain, and pulmonary infections. Some have received diagnoses such as scarlet fever from the rash of spontaneous graft-versus-host disease from maternally derived lymphocytes; others have been thought to have diphtheria when thrush extending down the throat resembled a diphtheritic membrane. In countries where newborns are routinely vaccinated against tuberculosis with the live attenuated mycobacterial organism bacillus Calmette-Guérin (BCG), infants with SCID may develop fatal disseminated BCG infection, and inadvertent administration of attenuated live poliovirus vaccine, and more recently live rotavirus vaccine, to infants with SCID has led to paralytic polio and severe diarrheal disease, respectively (Bakare et al., 2010). Unfortunately, SCID is frequently not suspected upon presentation to primary physicians or even referral centers; this has spurred recently successful efforts to institute newborn screening for SCID (Chan et al., 2011; Kwan et al., 2013; also see Chapter 57).

Basic and clinical research in SCID has led to fundamental advances in our understanding of lymphocyte development as well as pioneering medical treatments extending far beyond this rare collection of inherited defects. Prior to 1968, patients with SCID died in infancy. However, the pioneering immune reconstitution following bone marrow transplantation (BMT) from an HLA-identical sibling marked the beginning of successful treatment (Gatti et al., 1968; see Chapter 59). The lack of a histocompatible sibling donor led to the use of isolation in a germ-free environment for "David the Bubble Boy," a famous Texas patient who came to represent SCID to the general public. Although David succumbed to complications of newly recognized Epstein-Barr virus lymphoproliferative disease after a BMT at age 12 (Shearer et al., 1985), techniques for transplantation with T cell-depleted haploidentical bone marrow from a parent and with unrelated adult or cord blood hematopoietic cells from well-matched donors have made SCID treatable for all patients (Bortin and Rimm, 1977; also see Chapter 60). Adenosine deaminase (ADA)-deficient SCID was the first disease treated with enzyme therapy (see Chapter 14), and ADA and X-linked

SCID pioneered successful human gene therapy (Cavazzana-Calvo et al., 2000; see Chapter 60). Most recently, the first population-based screening for congenital immune disease was established for SCID (Chan and Puck, 2005; Routes et al., 2009; also see Chapter 57).

Single gene mutations that result in SCID have revealed proteins and pathways that are nonredundant (i.e., essential) for the development and function of human adaptive immunity. Mouse knockouts of the same genes do not reliably produce identical phenotypes, underlying the importance of studying immune defects in humans. While seven genes—*IL2RG*, *IL7R*, *JAK3*, *ADA*, *RAG1*, *RAG2*, and Artemis (*DCLRE1C*)—account for around 90% of SCID cases, many additional genes, even beyond those in Table 1.1 in Chapter 1, continue to be discovered, enriching our understanding of the complex system that provides humans with the ability to recognize and overcome infections throughout life.

LYMPHOCYTE PROFILES AND DIVERSE GENE DEFECTS IN SCID

Table 1.1 lists SCID genotypes and their associated cellular phenotypes. Enumeration of T, B, and natural killer (NK) lymphocytes provides useful correlations of lymphocyte phenotype with genotype (Buckley et al., 2004; Kalman et al., 2004; Stephan et al., 1993), although there are well-documented exceptions (Puck et al., 1997). While all patients with SCID have very few autologous T cells, over half have detectable or even increased numbers of B cells that fail to produce specific antibodies (T^-B^+ SCID). Most of these patients also lack NK cells and are males with X-linked *IL2RG* defects (Noguchi et al., 1993; Puck et al., 1993; see Chapter 10). However, mutations in autosomal *JAK3*, encoding the signaling kinase that interacts intracellularly with the common γ chain, also cause $T^-B^+NK^-$ SCID (Russell et al., 1995; see Chapter 10). Other T^-B^+ SCID genes are *IL7R*, encoding the α chain of the receptor for IL-7 (Puel et al., 1998; see Chapter 10); *CD45*, encoding the cell-surface co-receptor CD45 (Kung et al., 2000; see Chapter 12); and genes encoding components of the CD3 complex (see Chapter 11). In addition, humans with defects in the *FOXN1* transcription factor that is defective in athymic nude mice have autosomal recessive T^-B^+ SCID in addition to alopecia totalis (Frank et al., 1999; see Chapter 21).

SCID with no T or B cells (T^-B^- SCID) occurs in an even ratio of males to females due to autosomal recessive inheritance and is most commonly caused by ADA deficiency (Giblett et al., 1972; see Chapter 14) and also by defects in the proteins involved in the DNA rearrangement of T-cell and B-cell receptor genes, most notably recombinase activating genes *RAG1* and *RAG2* along with the Artemis or *DCLRE1C* gene (Chapter 13).

COMBINED IMMUNODEFICIENCY

Primary immunodeficiency conditions in which T-cell immunity is impaired but not completely absent and B cells are also impaired (due either to intrinsic defects or lack of helper functions supplied by normal T cells) constitute CID. Some patients with CID have "leaky" defects in the same genes in which null mutations produce typical SCID (Table 1.1). A small amount of protein production from these genes, or protein with reduced function, gives rise to a spectrum of phenotypes including susceptibility to infections as well as dysregulated immunity. Disease presentation with infections may occur later in life, or with more mild illness compared to infants with typical SCID, but also distinct syndromes are recognized, including Omenn syndrome, defined as erythroderma rash, eosinophilia, and oligoclonal autologous T cells that cause adenopathy and organ infiltration (Omenn, 1965). A combination of hypomorphic mutations in *RAG1* or *RAG2* genes with overcompensation and dysregulation of other immune reactions can lead to combined T and B cell immunodeficiency with granulomatous disease (Schuetz et al., 2008).

Additional cases of CID are due to null mutations in "variant" SCID genes that generally have a less devastating impact on T-cell production than do typical SCID genes (Puck, 2012); these are also listed in Table 1.1. In these conditions, including Zap70 deficiency, MHC class I or class II deficiency, and others with known and as yet unknown molecular defects, T cells may be produced from the thymus in normal or near-normal numbers, but are impaired in function. In addition, several congenital syndromes with multiorgan involvement such as cartilage-hair hypoplasia, multiple intestinal atresias or CHARGE (ocular coloboma, heart defect, atresia of nasal choanae, retardation of growth and development, genitourinary abnormality, and ear abnormality) syndrome have variable degrees of T- and B-cell immunity, which can be severe.

MAKING THE DIAGNOSIS OF XSCID

A helpful clue from a simple laboratory test is a low absolute lymphocyte count, compared to values for age-matched normal individuals (Shearer et al., 2003; Buckley, 2004). Once the clinical suspicion of an immunodeficiency has been raised, whether by family history, low lymphocyte count, or recurrent or opportunistic infections, the diagnosis of SCID or CID must be pursued by lymphocyte phenotyping by flow cytometry after staining with monoclonal antibodies. Lymphocyte phenotyping in infants can be misleading in the face of maternal T-cell engraftment, transfusion of nonirradiated blood products, certain infections, or expanded populations of oligoclonal cells with poor function. Fewer than 300/μL naïve autologous T cells in peripheral blood strongly suggests SCID. Functional analysis of lymphocytes, such as with proliferation to the mitogen phytohemagglutinin (PHA) is essential to distinguish secondary causes of low T cells from primary SCID diseases, in which proliferation is generally less than 10% of the lower limit of normal for the test. Documentation of a pathogenic mutation by gene sequence should also be sought; increasingly, differences in responses to specific treatments are being recognized dependent on genotype so that molecular diagnosis assists in the selection of an optimal treatment regimen.

Leaky SCID and variant SCID do not demonstrate maternal engraftment and generally have 300 to 1,500 T cells, though oligoclonal T-cell expansion can be associated with higher numbers of memory phenotype cells; nonetheless, responses to mitogens such as PHA and other functional assessments show impairment compared to normal T cells. There are still SCID and CID patients whose molecular diagnosis remains unknown, and additional disease genes are sure to be found.

Because of defective development of T cells, all infants with SCID and many with CID lack T-cell receptor excision circles, or TRECs (Chan and Puck, 2005). TRECs are DNA circles formed by end-joining of genomic DNA segments excised during normal T-cell receptor gene rearrangement; a quantitative PCR reaction across the joined ends is used to measure TREC number (Douek et al., 2000). TREC detection in newborn dried blood spots has formed the basis of population-based newborn screening, now used in a growing number of states in the United States (Chan and Puck, 2005; Puck, 2012; Kwan, 2013; also see Chapter 57). Identification of presymptomatic cases of T lymphocytopenias necessitated development of new classifications and laboratory-based diagnostic criteria because they do not manifest infectious complications of immunodeficiency at birth. Infants with low or undetectable TRECs in dried blood spots and confirmatory flow cytometry evaluations indicating low T-cell numbers may have typical SCID, leaky or variant forms of SCID, syndromes that include low T cells as part of their phenotype—all discussed above—or alternatively may have secondary lymphocytopenia associated with other medical conditions, including vascular permeability, congenital heart defects, extreme prematurity, or other conditions. Whether primary or secondary, these patients should avoid exposure to live vaccines or unirradiated or CMV-positive transfusions and need to be followed by immunologists until their T cells normalize or until definitive therapy for their immunodeficiency is accomplished.

SEVERE COMBINED IMMUNODEFICIENCY AND COMBINED IMMUNODEFICIENCY DUE TO CYTOKINE SIGNALING DEFECTS (*IL2RG*, *JAK3*, *IL7R*, *IL2RA*, *JAK3* AND *STAT5B*)

Jennifer M. Puck, Fabio Candotti, Luigi Notarangelo, and Chaim Roifman

INTRODUCTION

Severe combined immunodeficiency (SCID) and combined immunodeficiency (CID) are the terms applied to a collection of genetic defects that involve both humoral and cellular immunity. All types of SICD and CID are characterized by impaired generation of a diverse repertoire of mature T lymphocytes, and many have additional immune abnormalities. The profound lack of immune function in SCID leads to infections that are generally fatal in infancy unless the immune system can be reconstituted. CID is characterized by somewhat less profound abnormalities and therefore may present somewhat later in life. These are rare disorders, whose precise incidence is unknown because until recently presentation most often occurred with serious infections secondary to the immunodeficiency; therefore, infants who died of infections before a primary immune defect was suspected were not counted (Chan et al., 2011). Now that newborn screening is available for SCID (see below and Chapter 57), the impaired production of T cells can be detected apart from infectious complications (reviewed in Buckley, 2012; Puck, 2012; Verbsky et al., 2012). Over the coming years the new paradigm of presymptomatic diagnosis will no doubt change many aspects concerning the conception, confirmation, treatment, and outcomes for individuals with SCID and CID.

Immunophenotypic and functional analysis of circulating lymphoid cells permits an accessible and useful classification of SCID into distinct subgroups, as presented in Table 1.1 (Fischer, 2001): reticular dysgenesis and adenosine deaminase (ADA) deficiency, generally lacking T, B, and NK cells (T^- B^- NK^-); defects of T- and B-cell antigen receptor recombination (T^- B^- NK^+); defects with low T and NK cells, but normal to increased B cells (T^- B^+ NK^-); and defects predominantly or exclusively restricted to T cells (T^- B^+ NK^+). The subgroups of SCID with B lymphocytes (B^+ SCID) account for over 50 percent of all cases of SCID (Antoine et al., 2003; Bertrand et al., 1999; Buckley, 2000a, Buckley, 2000b, 2004; Fischer et al., 1990; Haddad et al., 1998; Stephan et al., 1993). Most are due to known molecular defects that interfere with signaling of a series of critical hematopoietic cytokines.

DISCOVERY OF THE X-LINKED SCID DISEASE GENE, *IL2RG*

Both a striking male predominance of SCID in all published series and recognition of pedigrees with multiple affected males related through maternal lineages long suggested that X-linked SCID (XSCID, SCIDX1, MIM#300400, MIM*308380) would turn out to be the major form of SCID, and indeed this was the first SCID gene defect to be identified after ADA deficiency, which causes T^- B^- NK^- SCID (see Chapter 14). XSCID was first mapped by linkage to the proximal long arm of the X chromosome by De Saint Basile et al. (1987). Gene mapping studies were hampered by the early lethality of XSCID in males and the lack of any clinical or immunological abnormalities to distinguish carrier from non-carrier females. However, Puck et al. (1987) noted that in contrast to the expected random X chromosome inactivation in female tissues predicted by the Lyon hypothesis, obligate female carriers of XSCID had only the nonmutated X chromosome as the active X in their lymphocytes. This nonrandom X inactivation reflected a selective disadvantage in proliferation, differentiation, or survival of lymphocyte progenitors lacking a normal gene product at the SCIDX1 locus. Nonrandom X inactivation was found in T, B, and NK cells of XSCID carriers. This indirect evidence, 6 years before the underlying molecular defect for XSCID

Table 10.1 CLINICAL FEATURES OF TYPICAL X-LINKED, JAK3-DEFICIENT AND IL7RA-DEFICIENT SEVERE COMBINED IMMUNODEFICIENCY NOT DIAGNOSED BY FAMILY HISTORY OR NEWBORN SCREENING*

Universal Features
Male sex in X-linked SCID; both male and female infants may have JAK3- or IL7rα-deficient SCID
Presentation in first year, usually by age 6 months
Failure to thrive
Oral thrush, candida diaper rash
Absent tonsils
Persistence of infections despite conventional treatment
Common Features
Chronic diarrhea
Respiratory congestion, cough
Fevers
Pneumonia, especially with *Pneumocystis jiroveci*
Sepsis, severe bacterial infections
Viral infections, including cytomegalovirus, adenovirus, Epstein-Barr virus, enteric viruses, varicella, herpes and respiratory syncitial virus
Infections with opportunistic pathogens
No palpable peripheral lymph nodes
Family history of similarly affected maternal male relatives
Less Common Features
Erythematous skin rash (often with hepatomegaly and lymphadenopathy) from spontaneous or transfusion-related graft-versus-host disease
Recurrent bacterial meningitis
Disseminated infections (Salmonella, varicella, vaccine strain [live] rotavirus diarrhea, disseminated Bacillus Calmette-Guérin infection; rarely, vaccine strain [live] polio with paralysis)

*Affected infants who are diagnosed prior to onset of infectious complications (whether by population-based newborn screening or early diagnosis due to a positive family history—see Chapter 57) appear healthy but lack tonsils and lymph nodes.

was identified, showed that the B cells of patients affected with XSCID were intrinsically defective and not merely lacking T cell help. In contrast, random X inactivation patterns were seen in their granulocytes, monocytes, and other tissues (Conley et al., 1988; Puck et al., 1987; Wengler et al., 1993). Thus, the SCIDX1 gene product is necessary for the development and survival of lymphoid but not myeloid cells from bone marrow stem cells.

Nonrandom X inactivation in lymphocytes was used to assign the carrier status of female relatives of XSCID patients, increasing the number of informative individuals for genetic linkage in XSCID pedigrees. Further narrowing of the SCIDX1 region was made possible by the study of males with the eye malformation choroideremia in combination with deafness, but not immunodeficiency, who had interstitial deletions below Xq13 (Puck et al., 1993a). Until this time, no genes related to the immune system were known to reside in the region defined by these mapping studies. However, in 1993, two groups (Noguchi et al., 1993a; Puck et al., 1993b) realized that the γ chain of the receptor for IL-2, cloned the previous year (Takeshita et al., 1992), was located on the X chromosome in the SCIDX1 critical region. Deleterious mutations in *IL2RG*, the gene encoding this receptor, were then found by both groups in XSCID patients, proving that *IL2RG* is the XSCID disease gene.

Only males, who have a single X chromosome, are affected with XSCID. Female carriers, who have a mutated copy of the gene on one and a normal copy on the other of their two X chromosomes, remain healthy. However, carrier females can pass on the disease to their sons and the carrier state to their daughters. When the XSCID genetic locus in Xq13.1 was identified so that mutation diagnosis could be performed, a wide variety of defects were demonstrated (Buckley et al., 1997; Puck et al., 1997a; Niemela et al., 2003; Kellermayer et al., 2006; Lee et al., 2011). XSCID accounts for close to half of all SCID cases in series published from transplant centers, though perhaps a larger proportion in the United States than in European populations (Antoine et al., 2003; Buckley, 2004; Buckley et al., 1997). As newborn screening reveals the incidence of different SCID genotypes in the future, without the bias of clinical detection and referral to transplant centers, the proportion of XSCID may be updated. XSCID appears to occur equally in all ethnic groups.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF SCID

Male infants with XSCID, and males and females with other cytokine pathway SCID defects, appear normal at birth. Unless

Table 10.2 PATHOLOGICAL FINDINGS IN TYPICAL X-LINKED, JAK3-DEFICIENT AND IL7Rα-DEFICIENT SEVERE COMBINED IMMUNODEFICIENCY

Primary absence of T-cell precursors
Markedly small thymus gland
Vestigial thymic stroma present
Absence of lymphocytes in thymus
No Hassall's corpuscles in thymus
No corticomedullary distinction
Evidence of infections secondary to immunodeficiency
Candida pharyngitis, esophagitis
Pneumonia or pulmonary infiltration with:
***Candida*, other fungi**
***Pseudomonas*, other gram-negative bacteria**
Pneumocystis jiroreci
Cytomegalovirus
Evidence of graft-versus-host disease
Lymphocytic infiltration of skin, liver, other organs

preinfectious diagnosis is made either by population-based newborn screening or by testing in the setting of a positive family history, presenting complaints reflect infectious complications and can be highly variable, as summarized in Table 10.2. These features are generally not distinguishable from patients with autosomal recessive (AR) forms of SCID except that female patients are assumed to have AR SCID. Although a family history can lead to laboratory confirmation of SCID before or at the time of birth, over 80 percent of patients have no recognized relatives with diagnosed immunodeficiency or early death consistent with SCID (Chan et al., 2011). Whether due to chance and small sibship sizes or to newly arising mutations, most SCID cases of any genotype are sporadic (Buckley et al., 1997; Conley et al., 1990).

As transplacentally transferred maternal IgG wanes, infants with SCID develop infections that bring them to medical attention, generally by 3 to 6 months of age. Thrush or respiratory and gastrointestinal infections may at first seem routine, but they do not respond to the usual medical management. For example, otitis may not resolve despite several courses of oral antibiotics; respiratory syncytial virus (RSV) may be continuously present in pulmonary secretions for several months; and diarrhea that may follow community exposure or inadvertent administration of live attenuated rotavirus vaccine (Patel et al., 2010) leads to failure to gain weight, or even weight loss. Rashes, either erythematous or maculopapular, have been associated with graft-versus-host disease (GVHD), either from maternal cells transferred to the infant during birth or from transfusion of nonirradiated blood products prior to recognition of the immunodeficiency.

Eventually, a clinical decompensation, diagnosis of an opportunistic pathogen, such as *Pneumocystis jiroveci* (formerly *P. carinii*), or a high index of suspicion leads to consideration of an immune disorder. Decompensating events include bacterial sepsis, meningitis, or deep-seated infections, as well as bacterial, fungal, or viral pneumonias. Series of SCID patients in France (Stephan et al., 1993) and the United States (Buckley et al., 1997) reported a similar large range of infectious agents at presentation: *Pseudomonas*, *Salmonella,* and other gram-negative bacteria; *Streptococcus*, *Staphylococcus* and other gram-positive bacteria; respiratory viruses and viruses of the herpes family; and fungi, primarily *Candida albicans* and *P. Jiroreci*. Infants with SCID who have inadvertently received BCG vaccination may develop disseminated infection with this organism. Live polio vaccination has also caused poliomyelitis and carditis, but this complication is uncommon, probably because most infants have protective transplacentally acquired maternal anti-poliovirus antibodies. Rotavirus live attenuated vaccine can cause diarrhea in infants with SCID.

The hallmark of immunopathology (Table 10.2) is an extremely small thymus gland almost devoid of lymphocytes. Thymic stroma is present but not well differentiated. There are no Hassall's corpuscles and no corticomedullary distinction. Thymic dendritic and epithelial cells are abnormal. Analysis of T-cell receptor (TCR) β chain rearrangement in thymic tissue from infants with XSCID has shown that the initial Dβ-to-Jβ recombination can occur, but subsequent VDJ rearrangement is blocked (Sleasman et al., 1994). Similarly, in extrathymic lymphoid organs, lymph nodes are small and poorly developed, and T lymphocytes cannot be found. Tonsils are absent. Other pathological findings in infants with SCID who do not survive include manifestations of their terminal infections, and in some patients, lymphocytic infiltration of skin, liver, and other organs as a result of GVHD.

Unless treated by hematopoietic cell transplantation (HSC) or experimental gene therapy, infants with SCID generally succumb to infections before 1 year of age, but in rare cases the diagnosis has been made in infants beyond their second birthday. A sheltered home environment may be a factor in late presentation.

LABORATORY FINDINGS IN SCID

Laboratory values that are useful to diagnose all types of SCID are summarized in Table 10.3. A helpful clue from a simple laboratory test is a low absolute lymphocyte count, compared to values for age-matched normal infants. While not universal, this indicator should raise the suspicion of a congenital immunodeficiency in an infant with a significant infection. Because of arrested development of T cells, infants with SCID lack TCR excision circles, or TRECs (Chan and Puck, 2005). TRECs are DNA circles formed by end-joining of genomic DNA segments removed during TCR gene rearrangement; a quantitative PCR reaction across the joined ends is used to measure TREC number (Douek et al., 2000; Schönland et al., 2003). TREC measurement has been developed into a successful population-based method for screening newborns using the dried blood spots obtained routinely to test for a variety of inborn defects (reviewed in Buckley, 2012; Puck, 2012; Verbsky et al., 2012).

Table 10.3 LABORATORY ABNORMALITIES IN INFANTS WITH X-LINKED AND JAK3-DEFICIENT SEVERE COMBINED IMMUNODEFICIENCY*

	SCID PATIENTS	PROPORTION WITH LOW NUMBERS	CONTROL VALUE RANGE, 1ST YEAR*§
Lymphocyte Counts	<2,000	90%	3,400–9,000
Total lymphocytes/μL	200 (0–800, with higher values representing maternal cells)	100%	2,500–5,600
T cells/μL			
B cells/μL	1,300 (0–3,000)	5%	300–3,000
NK cells/μL	<100*	88%	170–1,100
T-cell receptor excision circles (TRECs)	Absent	100%	1 per 10 T cells
Antibody Concentrations§			
IgA, IgM	Extremely low		
IgG	Maternal levels at birth, low by age 3 months		
Lymphocyte Function§			
Mitogen responses	Very poor		
Mixed lymphocyte response	Very poor		
NK cytotoxicity	Usually very poor; rarely intact*		
Specific antibody	Very poor production		
Other Laboratory Tests			
Absent thymic shadow	Universal on chest radiogram		

*Findings are identical in IL-7-receptor-deficient SCID, except that NK cells are generally present in normal numbers and functional in this genotype.

§Control ranges are approximate and age-dependent, and they may vary between laboratories; consult the immunology laboratory performing the test for best interpretation.

Adapted from Buckley et al., 1993, 1997; Chan et al., 2004; Conley et al, 1990; Fischer, 1992; Kalman et al., 2004; Schearer et al., 2003; Schönland et al., 2003; Stephan et al., 1993; Stiehm et al., 2004.

Typically, but not always, the small numbers of lymphocytes found in patients with XSCID are predominantly or entirely B cells, which may be present in normal or even elevated numbers. The B cells in infants with XSCID are immature and resemble the naïve B-cell population of normal cord blood in their expression of cell-surface markers and in vitro antibody production restricted to IgM (Small et al., 1989). Sequence analysis of XSCID B-cell immunoglobulin heavy chains has demonstrated normal VDJ rearrangement (Minegishi et al., 1994). However, there is over-utilization of J_H3 segments, as seen in fetal and neonatal B cells, and a total lack of somatic hypermutation. In XSCID infants whose maternally acquired IgG antibodies have waned, antibody titers to vaccines or infectious agents are low or absent. Other distinguishing characteristics of XSCID are low numbers of cells that bear NK cell markers and poor NK cell cytotoxicity.

Despite the utility of these generalizations, lymphocyte numbers and function are not uniform in all patients and may be subject to modification by genetic factors other than *IL2RG* mutation and by environmental factors. For example, patients with *IL2RG* mutations occasionally have low rather than the typical normal to high numbers of B cells. Also, patients with proven *IL2RG* defects have been reported who have NK cells and intact NK cytotoxicity (Pepper et al., 1995).

Spontaneous engraftment of maternal lymphocytes can be detected in males with SCID by finding XX karyotypes on cytogenetic analysis, by HLA typing or by using DNA polymorphic markers. Maternal cells can be found in almost all SCID patients if sensitive methods are used, and if present in significant numbers they may resist engraftment of allogeneic HSCs. Although there may be no discernible consequences of maternal engraftment, the maternal cells may elevate the lymphocyte counts of an infant with SCID and display some proliferation to phytohemagglutinin (PHA). When sufficient numbers of maternal cells are activated to respond to the infant's paternally derived histocompatibility antigens, a SCID patient may have eosinophilia and circulating maternal, activated, DR^+ T cells. In patients who have iatrogenic GVHD from transfusion of nonirradiated blood products, allogeneic T cells can cause florid, acute GVHD, including gatroenteritis, hepatitis, and lymphocytic infiltrates in skin, liver, and other organs.

MOLECULAR BASIS OF XSCID: THE DISEASE GENE, *IL2RG*

IL2RG encodes the γ chain of the IL-2 receptor; the gene product appears in multiple receptors and is therefore now

called the common γ chain, γc. The α and β chains of the IL-2 receptor were known to exist before the γ chain was identified. The β chain, constitutively expressed on T cells, has intermediate affinity for IL-2; and the α chain, expressed after T-cell activation, boosts the affinity for IL-2 of the receptor complex 100-fold. The existence of a γ chain was postulated when transfection of the α and β chains of IL-2 receptor into fibroblast cell lines failed to produce a receptor that could transmit a signal. A third chain was co-immunoprecipitated with the β chain and purified by two-dimensional gel electrophoresis (Takeshita et al., 1992), permitting determination of the amino terminal sequence and isolation of the cDNA for *IL2RG*. The gene, depicted in Figure 10.1, spans 4.5 kb of genomic DNA in Xq13.1. The coding sequence of 1124 nucleotides is divided into 8 exons. *IL2RG* is one of the transmembrane cytokine receptor superfamily genes. It encodes a 5' signal sequence of 22 amino acids, which is cleaved off while targeting the protein for cell-surface expression. Four conserved cysteine residues at the extracellular amino-terminal end engage in cross-linking for proper conformation; the juxtamembrane extracellular motif WSXWS encoded in exon 5 is a hallmark of all cytokine receptors; the highly hydrophobic transmembrane domain of 29 amino acids occupies most of exon 6; and the proximal intracellular domain in exon 7 contains a Box1/Box2 signaling sequence homologous to SH2 subdomains of Src-related tyrosine kinases.

FUNCTION OF γC, THE *IL2RG* GENE PRODUCT

The first report of γc by Takeshita et al. (1992) showed that it was expressed in T- and B-cell lineages, but not liver or epithelial cells. Subsequent studies have shown expression in human and mouse hematopoietic progenitor cells throughout development of myeloid and lymphoid lineages (Orlic et al., 1997). Expression of γc on murine thymocytes increases as they mature from $CD4^-$ $CD8^-$ double-negative to double-positive and single-positive T cells, and further upregulation occurs after lymphocyte activation (Sugamura et al., 1996). Recognition that γc was a component of the IL-2 receptor explained why mitogen responses were poor in infants with XSCID. DiSanto et al. (1994b) showed absent binding and internalization of IL-2 in B-cell lines from XSCID patients. However, a mouse knockout of the gene for IL-2 manifested immune dysregulation with autoimmune hemolytic anemia and inflammatory bowel disease (Schimpl et al., 1994; Schorle et al., 1991). This apparent paradox may in part be explained if γc were to have additional roles. Indeed, several groups subsequently demonstrated it is part of the receptor complexes for multiple cytokines: IL-4 (Russell et al., 1993; Kondo et al., 1993), IL-7 (Noguchi et al., 1993b), IL-9 (Russell et al., 1994), IL-15 (Giri et al., 1994a), and IL-21 (Habib et al., 2002, 2003; Recher et al., 2011). IL-7 signals are important for moving early multipotent progenitors in the bone marrow into the lymphoid lineages; IL-4 participates in B-cell isotype switching (Kuhn et al., 1991; Matthews et al., 1995; Taylor et al., 1997); IL-15 signals are required for NK cell development (Kumaki et al., 1995; Matthews et al., 1995); and IL-21 signaling is especially important for augmenting T- and B-cell responses to antigens (Habib et al., 2003) and permitting normal B-cell differentiation (Recher et al., 2011).

MUTATION ANALYSIS IN XSCID

Several hundred *IL2RG* mutations have been reported in patients with XSCID from every racial group. A database

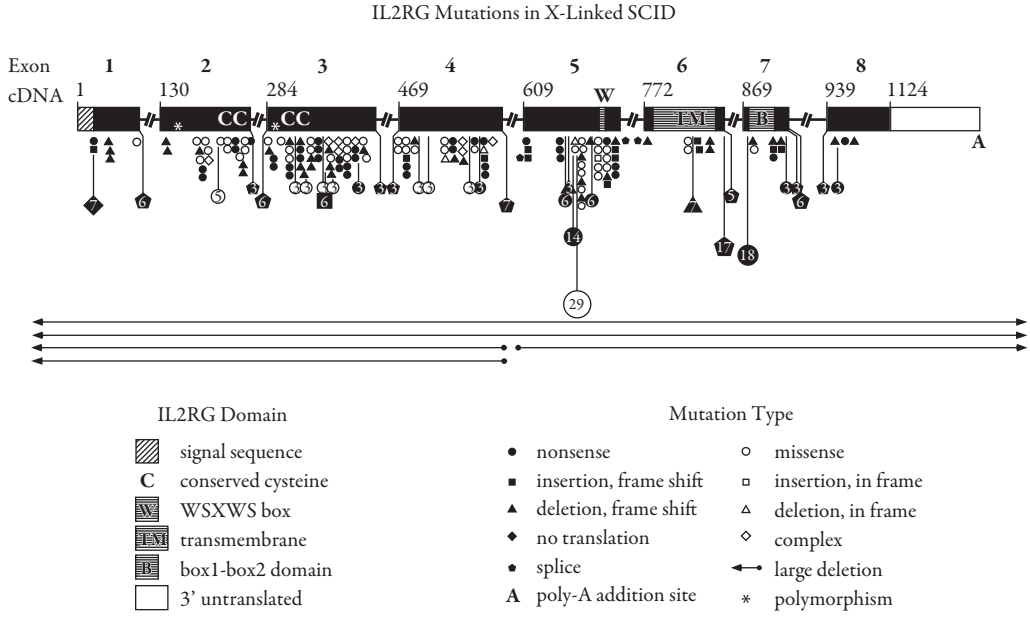

Figure 10.1 Structure of *IL2RG* and mutations found in patients with X-linked SCID and reported to IL2RGbase (http://www.research.nhgri.nih.gov/SCID/; Niemela et al, 2003; Puck et al., 1996); Genbank accession number L19546.

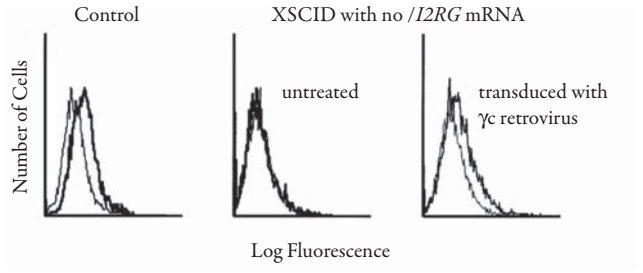

Figure 10.2 Expression of γc in B-cell lines from a healthy control (left), and from an XSCID patient with undetectable *IL2RG* mRNA, before (middle) and after (right) transduction with a retrovirus containing *IL2RG* cDNA under control of the Maloney leukemia virus LTR.

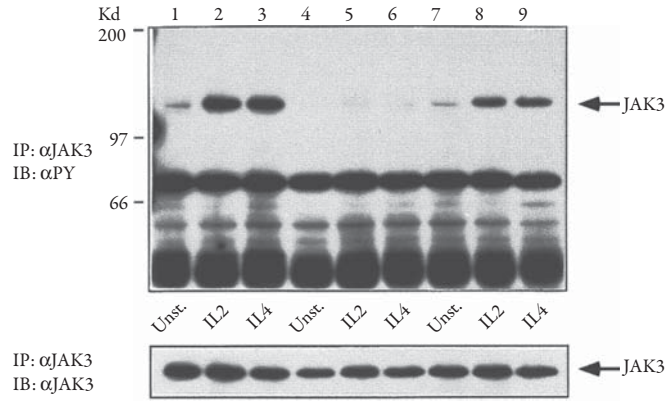

Figure 10.3 Phosphorylation of JAK3 induced by IL-2 and IL-4 in B-cell lines from a healthy control (lanes 1–3) and from an XSCID patient before (lanes 4–6) and after (lanes 7–9) transduction with an *IL2RG* retrovirus (Candotti et al., 1996). After no stimulation or exposure to IL-2 or IL-4, cell lysates were immunoprecipitated (IP) with anti-JAK3 antiserum (αJAK3) and immunoblotted (IB) with anti-phosphotyrosine (αPY), top, or αJAK3, bottom.

of published and verified mutations, IL2Rgbase (Puck et al., 1996), can be accessed at the Leiden Open Variation Database (http://www.lovd.nl/3.0/home). As indicated in Figure 10.1, and as is typical of SCID-causing mutations in other genes in addition to *IL2RG*, SCID-causing mutations occur throughout the entire length of the gene, including exons, splice sites, and even the 3' poly-A addition site. Recurrent mutations have been noted at several positions, or "hot spots," in *IL2RG*. In several instances, the new origin of a mutation has been proven by finding only the normal gene sequence in DNA from parents of female carriers or from mothers of affected males. Five hot spots for mutation involve the well-recognized mechanism of cytosine methylation and deamination to thymidine within a CpG dinucleotide. Almost all *IL2RG* mutations are changes in only one or a few nucleotides, but large deletions have occurred. The number and variety of mutations, including new mutations that continue to be found (Lebet et al., 2008), make gene sequencing imperative.

It is also important to assess the significance of missense mutations. Some are predicted to disrupt known essential elements (Fig. 10.1), such as the first methionine that signals initiation of translation, the four conserved extracellular cysteine residues, the WSEWS motif conserved in all members of the cytokine receptor gene family, or the hydrophobic transmembrane domain. Functional significance is likely for mutations at sites that are conserved not only among mammals, such as mouse, rat, and dog, but also between human and more distant species, such as birds or fish, or between *IL2RG* and other members of the cytokine gene family (Pepper et al., 1995). Amino acid substitutions repeatedly found to be the only change associated with XSCID in unrelated kindreds are more likely to be pathogenic than to be incidental polymorphisms. However, direct proof that a missense mutation is harmful requires testing a cell line from the affected patient for expression of *IL2RG* mRNA and determining whether γc protein is expressed at the cell surface (Fig. 10.2), whether expressed γc can bind IL-2, and whether downstream targets such as JAK3 and STAT5 become phosphorylated (Fig. 10.3) (Puck et al., 1993b, 1997a). Rare or private polymorphisms have been found in *IL2RG*, but none that are common in control populations.

GENOTYPE/PHENOTYPE CORRELATION OF XSCID MUTATIONS

The expression of functional γc is severely compromised by all but a handful of the mutations reported; exceptional cases with atypically mild CID, late presentation, or normal numbers of T cells have revealed important aspects of the molecular biology of γc. In one instance, initially normal T-cell numbers declined with time and TCR diversity was limited by an *IL2RG* substitution of an A residue for the almost invariant G nucleotide at the end of exon 1. While the missense mutation in γc encoded by this change, D39N, appeared not to impair IL-2 binding, the loss of a G terminal nucleotide in exon 1 caused most of the mRNA to be incorrectly spliced (DiSanto et al., 1994c).

In another CID kindred from Galveston, Texas, an intracellular *IL2RG* point mutation L293Q within the Box-1/Box-2 intracellular portion of γc impaired interaction with JAK3, suggesting the importance of JAK3 in the γc signaling pathway (Fig. 10.2) (Goldman et al., 2001; Russell et al., 1994; Schmalstieg et al., 1995).

Another XSCID patient was inexplicably mildly affected despite having inherited an *IL2RG* missense mutation that eliminated the fourth conserved cysteine residue (C115R), required for proper disulfide bond formation and normal configuration of all members of the cytokine receptor family (Bousso et al., 2000). Investigations revealed reversion to wild-type sequence, probably at the level of a T-lymphocyte progenitor, allowing production of functional T cells with normal γc. This case illustrated the powerful selective advantage of gene-corrected cells in XSCID, an argument in favor of retroviral gene therapy for this disease.

Two unrelated patients had XSCID with normal numbers of poorly functioning T cells and shared the missense mutation R222C; one of these had a thymus biopsy demonstrating relatively normal histology with preservation of cortical and medullary regions (Mella et al., 2000; Scharfe et al., 1997).

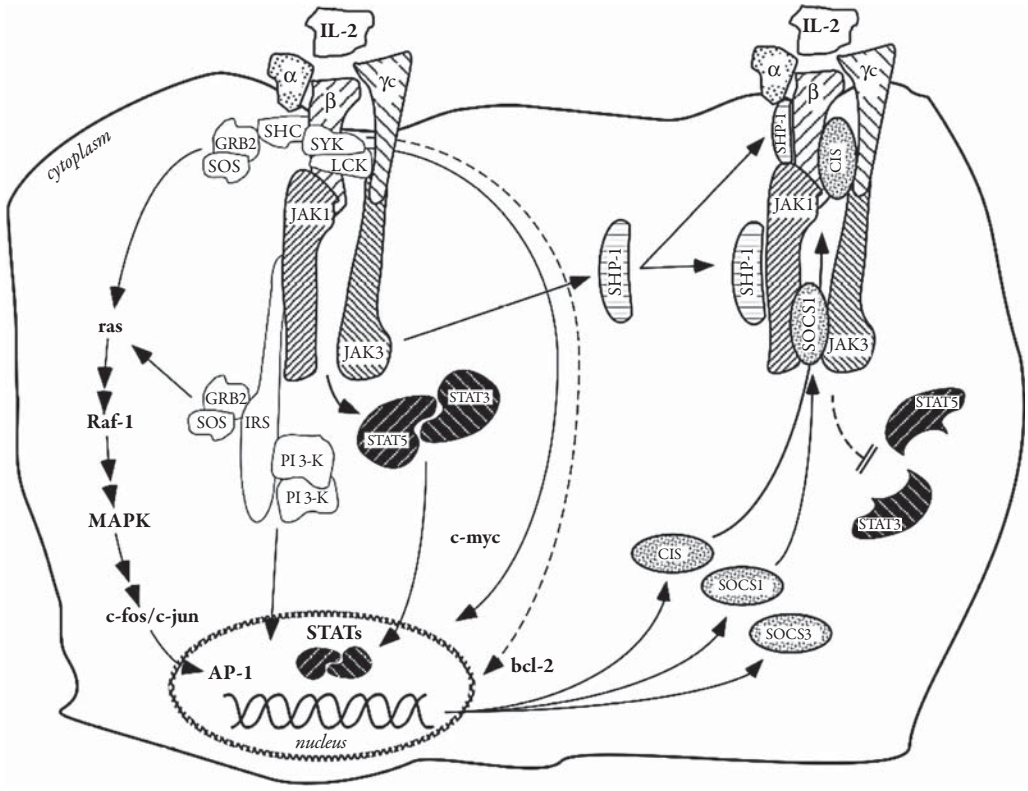

Figure 10.4 Schematic representation of the IL-2-mediated JAK-STAT signaling pathway showing proteins that participate in positive (*solid lines*) and negative (*dashed lines*) regulation.

However four other instances of this mutation have been associated with typical SCID (Clark et al., 1995; J. Puck, unpublished), as have 14 instances of the missense mutation R224W at the same amino position. Patients with CID due to missense mutation L162R (Mella et al., 2000) and a defect in the poly-A addition site of IL2RG mRNA (Hsu et al., 2000) also have been reported. In addition to having more T cells than typical XSCID patients, these individuals survived for over a decade without successful allogeneic transplantation, but resisted engraftment of allogeneic HSC, exhibited activated, DR^+ T cells and immune dysregulation, and suffered from growth delay and chronic pulmonary disease. Taken together, these natural experiments in mutagenesis indicate that low levels of normal γc or mutated γc with residual function can allow some T-cell development to occur, but also are associated with immune dysregulation.

MOLECULAR BASIS OF ADDITIONAL CYTOKINE SIGNALING DEFECTS CAUSING SCID

While the majority of patients with B^+ SCID have mutations at the *IL2RG* locus, the existence of AR B^+ SCID was indicated by the demonstration that B^+ SCID may occur also in females and in infants born to consanguineous parents (Stephan et al., 1993). Immunological and clinical features at diagnosis are similar in X-linked and AR B^+ SCID (Tables 10.1, 10.2). The finding that cytokine receptors utilizing the common γ chain always associate with the intracellular tyrosine kinase JAK3 (Fig. 10.4) and the discovery that the major cytokine receptor transducing subunit binds to another JAK kinase, JAK1 (Miyazaki et al., 1994; Russell et al., 1994), provided a clue as to the molecular bases of AR B^+ SCID. The human CID resulting from a missense mutation in the cytoplasmic tail of γc diminished its interaction with JAK3 (Russell et al., 1994). Based on this information, it was hypothesized that human AR B^+ SCID could be caused by defects of JAK3, encoded on chromosome 19p13.1 (MIM*600802). This hypothesis was proved correct by two groups who reported mutations in the *JAK3* gene in infants with B^+ SCID (Candotti et al., 1997; Macchi et al., 1995; Russell et al., 1995).

The critical role of JAK3 for lymphoid development and function has been further illustrated by the generation of Jak3-deficient mice (Nosaka et al., 1995; Park et al., 1995; Thomis et al., 1995). The immunological phenotype of Jak3 knockout mice is essentially identical to that of γc knockout mice (Cao et al., 1995; DiSanto et al., 1995; Ohbo et al., 1996), substantiating the notion that the γc and Jak3 proteins act together.

Mice with targeted genetic disruption of *Il7r,* the gene encoding the IL-7 receptor α chain (IL7Rα), also have profound defects in T-cell development similar to γc and Jak3 knockout animals (Peschon et al., 1994; von Freeden-Jeffry et al., 1995). This observation led to the additional hypothesis that defects in IL-7 signaling could result in SCID in humans. The search for such patients ultimately demonstrated that mutations of the human *IL7R* gene on chromosome 5p13.2

(MIM*146661) can cause AR B^+ SCID. Importantly, and in contrast to patients with γc and Jak3 deficiency, such patients retain residual development of NK cells and also have B cells that are intrinsically functional (Puel et al., 1998).

Further cases of SCID and CID were subsequently recognized in patients with mutations in intracellular mediators of cytokine signals, STAT5b, Lck (see below), and Tyk2 (see Chapter 38); additional patients with B^+ SCID have defects yet to be characterized and understood at the molecular level.

CYTOKINE SIGNALING THROUGH THE JAK-STAT PATHWAY

The effects of cytokines are mediated through interaction with specific receptors to phosphorylate specific intracellular proteins. Transmembrane receptors of the cytokine receptor superfamily do not have intrinsic kinase activity but recruit intracellular kinases following interaction with their extracellular ligands (Ihle, 1995; Leonard and O'Shea, 1998; Taniguchi, 1995). JAKs couple extracellular cytokine binding with intracellular phosphorylation of protein substrates, and thus induce cell growth and differentiation. The JAK kinases were originally cloned through a PCR-based approach (Wilks, 1989), and their functional role was first demonstrated in response to interferons (Muller et al., 1993; Watling et al., 1993). Four distinct members of the JAK family in humans are JAK1, JAK2, JAK3, and Tyk2.

The JAK family members share a C-terminal kinase domain (termed JAK homology 1, JH1), a more proximal kinase-like domain (JH2) whose function is not completely defined, and five other N-terminal regions of homology (JH3-JH7) (Fig. 10.5) (Ihle, 1995; Leonard and O'Shea, 1998; Taniguchi, 1995). The JH2 domain lacks highly conserved critical residues that are found in other typical kinase domains; when expressed in a recombinant form, JH2 is in fact devoid of kinase activity. The JAK3 cDNA is composed of 4,064 nucleotides and contains an open reading frame that encodes 1,124 amino acids with a molecular weight of 125 kDa (Kawamura et al., 1994). While JAK1, JAK2, and Tyk2 are broadly expressed, JAK3 is largely restricted to the hematopoietic system. The cDNA of JAK3 (originally designated L-JAK) was identified in NK cells and NK-like cell lines, but not in resting T lymphocytes, although expression could be induced following in vitro T-cell activation (Johnston et al., 1994; Kawamura et al., 1994). In B cells, JAK3 expression increases following in vitro activation, and it is high in B-cell malignancies (Tortolani et al., 1995). A splice variant, devoid of kinase activity, has been also identified in epithelial cells (Lai et al., 1995). Studies of murine JAK3 have revealed high levels of expression in fetal and adult thymus and lower levels in fetal liver, adult bone marrow, lymph nodes, spleen, and $CD4^+$ $CD8^+$ thymocytes (Gurniak and Berg, 1996). These data imply a crucial functional role of the JAK3 protein in lymphoid differentiation.

Intracellular signaling from all receptors of the γc superfamily (i.e., IL-2R, IL-4R, IL-7R, IL-9R, IL-15R, IL-21R) involves physical association of γc to JAK1 and JAK3 (Foxwell et al., 1995; Johnston et al., 1995b; Malabarba et al., 1995; Miyazaki et al., 1994; Pernis et al., 1995; Russell et al., 1994; Yin et al., 1995b). The observation that distinct cytokines signal through the same set of kinases indicates that JAKs alone do not control the specificity of the signal. In the IL-2R, JAK1 interacts with the serine region of IL-2Rβ, whereas the 48 C-terminal residues of γc bind JAK3 (Miyazaki et al., 1994). Both regions of the IL-2R chains are critical for JAK activation and signal transduction (Johnston et al., 1994; Miyazaki et al., 1994; Witthuhn et al., 1994). Following cytokine/cytokine receptor interaction and dimerization of the cytoplasmic tails of the cytokine receptor chains, the JAKs are brought in close proximity and may cross-phosphorylate each other. Activation of JAK3 in response to IL-2, IL-4, and IL-7 is more pronounced than that of JAK1 (Foxwell et al., 1995; Johnston et al., 1995b; Malabarba et al., 1995; Sharfe et al., 1995; Witthuhn et al., 1994). In addition, JAKs phosphorylate the membrane distal region of the cytokine receptor chains, thus generating docking sites for SH2-containing proteins (Ihle et al., 1994; Ivashkiv, 1995; Taniguchi, 1995).

Several signaling pathways are elicited by JAK1/JAK3 activation (Fig. 10.4). First, the phosphorylated cytokine receptor may associate with the adaptor SHC (Egan et al., 1993; Karnitz and Abraham, 1995), which is itself phosphorylated and binds to Grb2, which may thus anchor to Sos, the Ras guanine nucleotide exchanging factor (Holsinger et al., 1995; Karnitz and Abraham, 1995; Li et al., 1993). Membrane translocation of the Grb2/Sos complex catalyzes the conversion of inactive, GDP-bound Ras to the active, GTP-bound state. This results in the activation of Raf-1, MAP-kinase, and eventually in induction of immediate-early genes c-fos and c-jun (Blumer and Johnson, 1994). This signaling pathway, however, is apparently not utilized by all γc receptor complexes, and in particular is not triggered by IL-4 (Welham et al., 1994).

Second, JAKs may bind and phosphorylate insulin receptor substrates (IRSs) (Johnston et al., 1995b; Keegan et al., 1995; Sharfe et al., 1995; Yin et al., 1995a). JAK activation by IL-2, IL-4, IL-7, IL-9, and IL-15 results in phosphorylation of IRS-1, whereas evidence of JAK-dependent tyrosine phosphorylation of IRS-2/4PS (which is strictly homologous to IRS-1) has so far been obtained only for IL-2, IL-4, and IL-15 (Johnston et al., 1995b; Keegan et al., 1995). The ability to phosphorylate IRS substrates is restricted to proliferating cells, as IL-4-dependent proliferative responses are not obtained with IL-4R mutants that are unable to recruit IRS-1 (Keegan et al., 1994). Once activated, IRS may bind the SH2 domain of the p85 subunit of phosphatidylinositol 3-kinase (PI3-K) (Myers et al., 1992; Sun et al., 1995), and the catalytic activity of the p110 subunit of PI3-K is eventually elicited. In addition to promoting PI3-K activation, tyrosine phosphorylated IRS may recruit Grb2 and thus amplify the ras/Raf-1 signaling pathway (White and Kahn, 1994).

A third, essential component of the JAK signaling pathway is phosphorylation of signal transducers and activators of transcription (STAT) factors. S (Ihle, 1996; Leonard and O'Shea, 1998; Taniguchi, 1995). STATs contain a tyrosine residue that may undergo JAK-mediated phosphorylation, and they also contain SH2 and SH3 domains. Following cytokine interaction with receptor and triggering of the JAK-mediated signaling

pathway, STATs may interact with the cytokine receptor complex by binding via their SH2 domain to the phosphotyrosine of the cytokine receptor chain. In addition, following STAT phosphorylation, STAT-STAT homo- or hetero-dimerization occurs, with the SH2 domains of each STAT molecule binding to the phosphotyrosines of its partner. Six different classes of STATs have been reported; furthermore, two forms of STAT5 (STAT5a and STAT5b) have been characterized at the molecular level (Lin et al., 1996). The specificity of the response to cytokines is largely dependent on the particular combination of STATs recruited by the different signal-transducing chains of the cytokine receptor (Fenghao et al., 1995; Foxwell et al., 1995; Gilmour et al., 1995; Hou et al., 1995; Ihle, 1996; Johnston et al., 1995a; Taniguchi, 1995). However, three crucial lymphocyte growth factors, IL-2, IL-7, and IL-15, all activate STAT3 and STAT5.

Following dimerization, STATs translocate to the nucleus, where they bind to consensus sequences in the enhancer elements of the promoter regions of target genes and favor gene transcription (Ihle, 1996). Gene accessibility to STAT binding is another mechanism through which specific responses are obtained to distinct cytokines. It has been suggested that JAK-dependent STAT activation is more important to cell differentiation than to proliferation. In fact, deletion of the C-terminal H domain of IL-2Rβ abolishes IL-2-induced STAT5 activation, but not JAK1 and JAK3 activation; nor does it affect cell proliferation (Fujii et al., 1995). However, IL-4-induced thymocyte proliferation is somewhat diminished in STAT6 knockout mice, suggesting that STAT activation contributes to cytokine-induced growth-promoting activity (Kaplan et al., 1996; Shimoda et al., 1996; Takeda et al., 1996).

Additional, possibly JAK-independent, signaling pathways that are elicited following cytokine/cytokine receptor interaction include activation of src-related kinases (Lck, Lyn, and Fyn in response to IL-2) (Taniguchi and Minami, 1993), through their association with the acidic domain of IL-2Rβ. Deletion of this domain abolishes IL-2-induced Lck activation yet does not affect IL-2-regulated cell growth, implying that activation of src-related kinases may not be crucial for cell proliferation. Finally, induction of Syk, c-myc, and Bcl-2 requires the S region of IL-2Rβ (Minami and Taniguchi, 1995). JAK3 mutants devoid of the JH1 kinase domain cause markedly diminished induction of c-myc but intact induction of Bcl-2, indicating that these are independent signaling pathways and that JAK3 may be involved in c-myc transcription (Kawahara et al., 1995).

The need for JAK3 in IL-2-induced cell proliferation has been illustrated by the observation that in the NIH3T3αβγ cell line (which expresses the α and β chains of the IL-2 receptor and γc, as well as JAK1 and JAK2, but not JAK3), IL-2 does not promote proliferation; however, proliferative response to IL-2 is restored after JAK3 is transfected and expressed by these cells (Miyazaki et al., 1994). Furthermore, the requirement for integrity of the structure of JAKs in regulating cell growth and differentiation has been indicated by the fact that JAK3 mutants that lack the JH3-JH7 domains (Fig. 10.5), but not the JH1 protein tyrosine kinase domain, are unable to interact with γc (Taniguchi, 1995), whereas mutants that lack the JH1 kinase domain may bind to γc but are unable to transduce activation signals (cell growth, induction of c-fos and c-myc) in response to IL-2 (Taniguchi, 1995). Finally, overexpression of JAK3 mutants that lack the JH1 kinase domain may inhibit the IL-2-induced phosphorylation of JAK1 and JAK3 (Kawahara et al., 1995). Similar experiments with JAK2 mutants suggest that multiple JH domains are required for functional interaction with the cytokine receptor and target cytoplasmic substrates (Tanner et al., 1995).

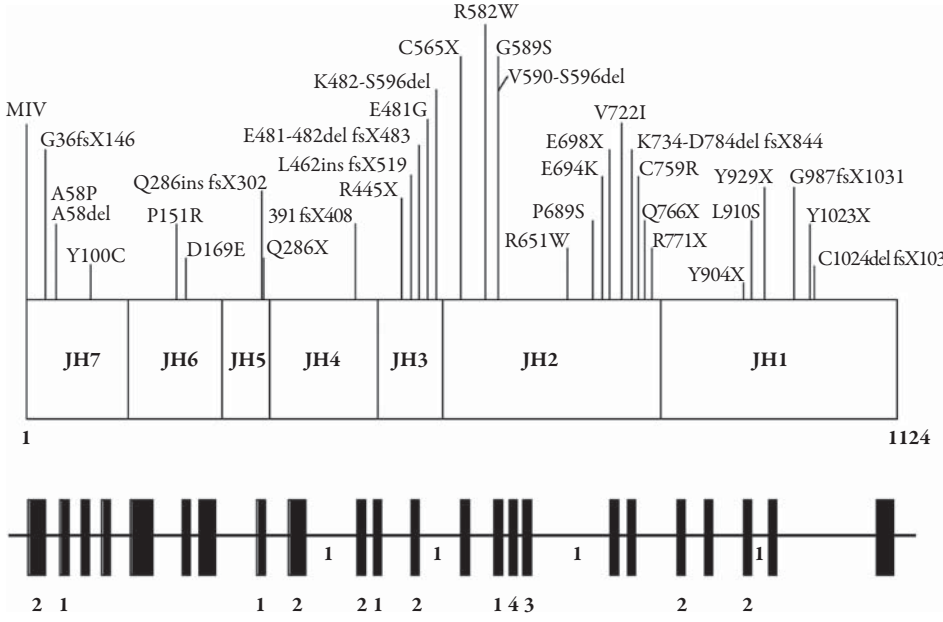

Figure 10.5 Representation of the human JAK3 protein (above), with boxes representing the JAK homology domains (JH1–JH7), observed patient mutations, and *JAK3* gene organization (below), with exons (*vertical rectangles*), introns, and numbers of *JAK3* mutations observed in each as reported through 2006.

A number of mechanisms serve to terminate the activity initiated by cytokine signals (Fig. 10.4). SH2 domain-containing protein tyrosine phosphatases SHP-1 and SHP-2 are important inhibitors of signaling events and are thought to dephosphorylate receptor chains and JAK molecules through SH2–phosphotyrosine interaction (Migone et al., 1998; You et al., 1999). Other mechanisms for attenuation of cytokine signaling involve the members of the suppressor of cytokine signaling (SOCS) family of proteins. These proteins are induced by cytokine stimulation following a feedback mechanism. Eight members of this family are known (CIS and SOCS1-7) (Endo et al., 1997; Hilton et al., 1998; Naka et al., 1997; Starr et al., 1997; Yoshimura et al., 1995). SOCS proteins appear to inhibit cytokine signaling by a variety of mechanisms, including competition with STATs for the phosphorylated docking sites on receptor chains and inhibition of kinase activities.

CLINICAL FEATURES AND LABORATORY FINDINGS OF SCID DUE TO MUTATIONS OF JAK3

By 2004, many publications described SCID patients with JAK3 defects (Bozzi et al., 1998; Buckley et al., 1999; Candotti et al., 1997; Frucht et al., 2001; Macchi et al., 1995; Mella et al., 2001; Roberts et al., 2004; Russell et al., 1995; Schumacher et al., 2000). Their clinical features were indistinguishable from those of infants with X-linked SCID (Tables 10.1 to 10.3). In two cases, the diagnosis of SCID was established in healthy infants immediately after birth, either because of family history of SCID or because of fortuitous recognition of reduced circulating T cells. Most patients, however, were diagnosed following development of upper and lower respiratory tract infections, chronic diarrhea, central nervous system involvement, and failure to thrive during the first few months of life. In all cases, peripheral lymph nodes were undetectable. Although splice variants of JAK3 mRNA have been identified in nonhematopoietic human tissues (Lai et al., 1995), no unique manifestations of primary organ dysfunction unrelated to immune deficiency have been detected in JAK3-deficient infants. Parental consanguinity was documented in several cases.

The clinical and pathological features as well as laboratory findings of JAK3-deficient patients are very consistent with X-linked SCID (Tables 10.1 to 10.3). In addition to being severely reduced in number, T cells from JAK3-deficient infants are functionally impaired. The proliferative responses to PHA and other mitogens, antigens, and alloantigens are abolished or severely reduced. Despite the increased proportion of circulating B cells, serum immunoglobulin levels are low (with the exception of IgG that is maternally derived during the early months of life), and no antibody responses are elicited following antigen stimulation. Failure to generate antibody responses is partly due to lack of effective helper T-cell activity, but it also reflects an intrinsic B-cell defect. In fact, defective induction of STAT activation has been reported following cytokine stimulation in Epstein-Barr virus (EBV)-transformed B cells from these patients (Candotti et al., 1996; Frucht et al., 2001; Oakes et al., 1996; Russell et al., 1995).

As with XSCID, the immunological phenotype, lack of circulating T cells, and increased proportion of B cells may change during the course of JAK3-deficient SCID. One infant who had a typical $T^- B^+ NK^-$ phenotype during the first month of life had a rapid appearance of T cells, up to 41 percent of total circulating lymphocytes, that were oligoclonal, $CD4^+$ $CD45R0$ DR^+ cells that failed to respond to PHA or CD3 stimulation alone, but showed some response to the combination of anti-CD3 and IL-2 (Brugnoni et al., 1998). At the same time that these T cells were found, the patient developed elevated IgE (1,000 IU/mL, with normal levels being <100 IU/mL). This phenotype of partial preservation of the responsiveness to IL-2 by activated T cells correlated with *JAK3* gene mutations (A1537G and deletion of exons 10–12) that permitted residual protein expression and function (Candotti et al., 1997). On the other hand, the contributory role of residual functional activity of JAK3 is less clear if one considers that Jak3 knockout mice develop activated CD4 T cells (see below). It is therefore possible that the T-cell differentiation defect imposed by human JAK3 deficiency allows changes of the immunological phenotype with time or that some degree of T-cell development is possible independently from JAK3.

It is also recognized that JAK3 is expressed in myelomonocytic cells, including human monocytes (Musso et al., 1995; Witthuhn et al., 1994); in vitro stimulation with lipopolysaccharide (LPS) and interferon increases JAK3 expression in monocytes (Musso et al., 1995). Furthermore, IL-2 and IL-4, two cytokines that signal through γc-bearing receptors, have profound effects on cells of the monocyte–macrophage lineage (de Waal Malefyt et al., 1993; Fenton et al., 1992; Vannier et al., 1992) and induce tyrosine phosphorylation and activation of JAK3 in these cells (Musso et al., 1995; Witthuhn et al., 1994). The possibility that mutations of the *JAK3* gene might affect the differentiation and/or function of the myelomonocytic lineage has been considered, but monocyte numbers are normal in JAK3-deficient SCID infants and showed normal responses to IL-2 (measured as release of TNF and IL-8) and to IL-4 (release of IL-1R antagonist) (Villa et al., 1996), indicating that JAK3 is dispensable for monocyte differentiation and responsiveness to cytokines that interact with γc-user receptors.

MOLECULAR BASIS OF JAK3 DEFICIENCY

As with XSCID, there is great diversity in *JAK3* gene mutations, which include missense, nonsense, and splice site mutations as well as less common genomic deletions and insertions. Most *JAK3* mutations drastically affect the expression of the protein; however, a number of missense or small in-frame deletions have been identified that permit near-normal levels of expression of the protein (Notarangelo et al., 2001; Roberts et al., 2004). The analysis of the effect of these mutations has provided important insights on the function of the different JAK3 domains (Fig. 10.5).

Not unexpectedly, mutations of the kinase domain (JH1) can affect phosphorylation of JAK3 and its substrates IL2Rβ

and STAT5, as was demonstrated in patients with nonsense and frameshift mutations (Notarangelo and Candotti, 2000; Schumacher et al., 2000). More interesting have been the consequences of the frequent mutations in the pseudokinase domain (JH2). Constitutive phosphorylation of JAK3 was detectable in a patient with a C759R missense mutation in the JH2 domain, yet IL-2 stimulation did not result in upregulation of JAK3 phosphorylation, nor did it induce STAT5 phosphorylation.

The functional effects of mutations have also been evaluated with heterologous systems. Mutant JAK3s were normally expressed after cDNA transfection, but their kinase activity was undetectable in vitro (Chen et al., 2000). Moreover, JAK3 mutants were unresponsive to IL-2 stimulation, even though they could normally bind to γc. Surprisingly, however, the mutated JAK3 appeared in some cases to be hyper-tyrosine phosphorylated compared with wild-type JAK3, and suggesting that the physiological role of the JH2 pseudokinase domain is to regulate kinase activity and therefore substrate phosphorylation by directly interacting with the JH1 kinase domain. To confirm this relationship, it was shown that, whereas the wild-type JAK3 pseudokinase domain modestly inhibited the JAK3-mediated signaling pathway, JAK3 with the mutated JH2 pseudokinase domains from two patients had an increased capacity to inhibit kinase activity. Thus, kinase dysregulation in these patients appeared likely to have contributed to their disease pathogenesis (Chen et al., 2000).

Mutations in the JH3 domain are also compatible with residual JAK3 expression, as in the case of a patient who carried one missense mutation (E481G) and one deletion (K482-S596del) in this domain predicted to result in both a normal-sized and a low-molecular-weight mutant JAK3 product. In EBV-B cells from this patient, IL-2 induced some residual phosphorylation of the normal-sized mutant JAK3 product. Furthermore, STAT5 phosphorylation was also detected (although at reduced levels), indicating that the glutamic acid-to-glycine substitution at codon 481 in the JH3 domain did not completely abrogate JAK3 function. Interestingly, the immunological phenotype of this patient was atypical, as he developed a substantial number of autologous T cells (although with abnormal phenotype and function) and NK lymphocytes (Brugnoni et al., 1998; Candotti et al., 1997).

Mutations in the N-terminal of JAK3 have indicated the important role that this portion of the protein plays for receptor interaction. Cells from patients with single amino acid substitution or deletion in the JH7 domain express JAK3 mutants whose interaction with γc is severely affected (Cacalano et al., 1999) and with abrogated in vitro catalytic activity. Similar results were observed in the presence of missense mutations affecting the JH2 domain (Roberts et al., 2004). A detailed molecular analysis utilizing constructs carrying the SCID-associated FERM mutation has shown that the JAK3 FERM and kinase domains associate and reciprocally influence each other's function and structure. Thus, in SCID patients with FERM mutations, two mechanisms contribute to the disease pathogenesis: impaired γc/JAK3 association and inactivation of catalytic activity.

SCID DUE TO MUTATIONS OF IL-7 RECEPTOR α CHAIN (IL7Rα)

Patients with IL7Rα deficiency present with classical signs and symptoms of SCID as listed in Tables 10.1 and 10.2. The only difference in laboratory abnormalities is that patients with IL7Rα defects generally have normal numbers of functional NK cells (Table 10.3). The original report (Puel et al., 1998) described two patients with $T^- B^+ NK^+$ SCID characterized by failure to thrive, recurrent otitis, viral infections, candidiasis, diarrhea, and fever. A subsequent report described three affected subjects in an additional consanguineous family; the infants had thrush, absence of palpable lymph nodes, and no thymus shadow on a chest radiograph (Roifman et al., 2000). In a series of 169 SCID cases diagnosed at Duke University Medical Center, 16 (9.5 percent) had IL7Rα-deficiency, making this the third most common cause of SCID in that series after X-SCID and ADA deficiency (Buckley, 2004).

MOLECULAR BASIS OF IL7RA DEFICIENCY

IL7Rα (CD127) is, like γc, a type 1 cytokine receptor chain. This 460 amino acid protein can bind IL-7 with consequent dimerization with γc, which in turn results in JAK3-mediated phosphorylation of IL7Rα and recruitment of JAK2 and STAT5. The *IL7R* gene, like *IL2RG*, is organized into 8 exons and 7 introns, with exons 1 through 5 encoding the extracellular portion of the receptor, and exon 6 and exons 7 and 8 encoding the transmembrane region and the intracellular tail, respectively. The cDNA is 1,380 nucleotides long and encodes a protein of the estimated molecular weight of ~90 kDa. The expression of *IL7R* mRNA can be detected in the earliest stages of lymphocyte differentiation ($CD4^- CD8^-$ double-negative thymocytes and $c\text{-}kit^+ B220^+$ B-cell progenitors) (Orlic et al., 1997; Sudo et al., 1993).

Mutations of the *IL7R* gene are heterogeneous and include missense, nonsense, and splice mutations as well as an intron mutation that introduced a cryptic splice site (Butte et al., 2007).

MURINE MODELS OF IL7Rα DEFICIENCY

IL7Rα participates in both the IL-7 and thymic stromal lymphopoietin (TSLP) cellular receptors, in association, respectively, with γc and TSLPR, a receptor chain with 24 percent homology to γc (Pandey et al., 2000; Park et al., 2000). IL7Rα knockout mice, therefore, lack both IL-7 and TSLP signaling. These mice are viable and fertile, and retain normal proportions of all major thymocyte populations during fetal life (Crompton et al., 1998). Adult IL7Rα-deficient mice, however, have ~20-fold reduction of thymic precursors and decreased peripheral lymphocyte numbers (Peschon et al., 1994). Thymocyte development is arrested at the $CD4^- CD8^-$ double-negative stage, before the occurrence of TCR gene rearrangement (Candeias et al., 1997; Crompton et al., 1997;

Maki et al., 1996a; Perumal et al., 1997). The reduced numbers of T cells that populate the periphery are characterized by impaired survival and reduced proliferation to mitogens and alloantigens (Maraskovsky et al., 1996). Development of γδ T cells is also blocked in IL-7Rα-deficient mice, while NK cells develop normally (He and Malek, 1996; Kang et al., 1999; Maki et al., 1996b). Interestingly, thymocyte development can be restored by the introduction of a transgenic TcR, suggesting that IL-7Rα is needed to initiate TcR gene rearrangement (Crompton et al., 1997). On the other hand, T lymphopoiesis is also restored in IL-7Rα-deficient mice by the transgenic expression of the anti-apoptotic molecule bcl-2 and ameliorated by the concomitant absence of the Bax pro-apoptotic protein, indicating that the critical consequence of engagement of IL-7Rα in T-cell development may be the integration of cell-survival signals (Akashi et al., 1997; Khaled et al., 2002; Maraskovsky et al., 1997).

IL7Rα-deficient mice also show an incomplete block of B-cell development at the transition from the pro-B to pre-B cell stage, which results in a 10-fold reduction in precursor B cells and severely decreased numbers of mature, peripheral B lymphocytes expressing surface Ig (Peschon et al., 1994). This defect is not corrected by transgenic expression of Bcl-2 (Maraskovsky et al., 1998) and is characterized by normal D-J segment joining but impaired recombination of antibody heavy-chain V segments (Corcoran et al., 1998). The reduction of B-lymphocyte numbers in IL7Rα-deficient mice does not parallel the human phenotype. This contrast may be attributable to the fact that the essential role of TSLP in maturation of pre-B cells in mice (Friend et al., 1994; Levin et al., 1999) is not conserved in humans (Reche et al., 2001; Soumelis et al., 2002).

STRATEGIES FOR DIAGNOSIS OF SCID OR CID

Once the clinical suspicion of a combined T- and B-cell immunodeficiency has been raised, whether by population-based screening, family history, low lymphocyte count, or recurrent or opportunistic infections, the diagnosis of SCID or CID must be made by lymphocyte phenotyping and functional tests, with specific mutation diagnosis highly desirable. Clues as to the specific *IL2RG*, *JAK3*, or *IL7R* genotype can be gleaned from the immunological tests, but atypical profiles of lymphocyte subsets can occur. Males with very few T cells, high proportions of B cells, and absent NK cells are likely to have *IL2RG* defects, although AR *JAK3* mutations have an identical clinical and immunological picture.

Lymphocyte phenotyping can be misleading in the face of maternal T-cell engraftment, transfusion of nonirradiated blood products, and/or infectious agents. Deficiency of naïve versus memory phenotype of CD3 T cells, assessed by using the cell-surface markers such as CD45RA and CD45RO, respectively, is characteristic of SCID or CID. Additional testing of the isolated T-cell population with DNA markers can distinguish autologous from allogeneic cells.

The availability of an anti-γc monoclonal antibody makes it possible to evaluate patient peripheral blood lymphocytes for γc expression (Puck et al., 1997a; Gilmour et al., 2001a). If γc is clearly absent from patient cells as compared to controls, XSCID can be suspected. However, the presence of γc may indicate that the patient's *IL2RG* gene is encoding an expressed but nonfunctional protein, or that maternal or other foreign cells in the infant's peripheral blood are positive for anti-γc staining.

Molecular testing for XSCID in the past used indirect methods, linkage and maternal lymphocyte X chromosome inactivation, and even after identification of *IL2RG* as the XSCID disease gene, mutant exons were identified by differential annealing of wild-type and variant strains. At this time, however, indirect methods are complex, expensive, time-consuming and not always interpretable or definitive. Although critical for the gene hunt that identified *IL2RG*, they are now appropriately replaced by DNA sequence-based analysis (Puck et al., 1997b). Genomic sequence analysis of PCR-amplified DNA reveals the specific mutation in patients and carrier relatives. If a mutation has been previously published with functional data, no further workup is needed, while new variants in sequence require validation as disease-causing mutations.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

Females who carry an *IL2RG* mutation on one of their X chromosomes are immunologically indistinguishable from controls. However, they can be identified by nonrandom X chromosome inactivation, which is seen in their lymphocytes but not in their granulocytes or nonlymphoid cells (Conley et al., 1988). This skewed X inactivation is a result of the selective disadvantage of lymphocyte precursors that have inactivated the X chromosome with an intact *IL2RG* gene early in embryogenesis. While X inactivation was formerly used as a carrier test, direct detection of mutations by sequencing for all SCID genes is now preferred. Females carrying a pathogenic *IL2RG* mutation have a 50 percent risk of XSCID for each male pregnancy and a 50 percent risk that each female pregnancy will also carry the mutation. However, as expected with X-linked lethal disorders, new mutations are common and failure to find a mutation in maternal blood does not preclude a mutation in the germline that may be inherited by multiple offspring. Such female germline mosaicism has been documented in XSCID (O'Marcaigh et al., 1997). In 13 percent of 85 mothers of sons with proven XSCID mutations, the mutations were not present in maternal blood samples (Puck et al., 1997a). Because the mutations in such cases may have existed in only a single maternal oocyte or may represent extensive maternal mosaicism, the recurrence risk for these mothers must be given as between 0 and 50 percent for a subsequent male pregnancy. New mutations have also been documented to occur in AR SCID.

Prenatal diagnosis can be performed by several methods, depending on the amount of information available about the genotype of the family requesting it. If specific mutation information is known, sequencing can be performed using chorionic villus sample (CVS) or amniocyte DNA prepared directly or

obtained from cultured cells (Puck et al., 1990, 1997b). When the genotype of a deceased SCID proband is not known, fetal blood sampling has also been used. Although this procedure must be done later in pregnancy and entails more risk than CVS or amniocentesis, lymphocytopenia, low numbers of T cells, and poor T-cell blastogenic responses to mitogens can be definitively demonstrated in affected fetuses by week 17 of gestation (Durandy et al., 1986).

No carrier or prenatal testing should take place without genetic counseling. In considering prenatal diagnosis, the diagnostic options should be weighed against testing at birth for families who would not terminate an affected pregnancy. Regardless of whether prenatal testing is undertaken, education and counseling can clarify the potential benefit of early HCT for affected infants. Relatives of SCID patients who did not survive in the past may not be aware of the medical advances in transplantation therapy.

Puck et al. (1997b) studied the utilization of prenatal diagnosis for XSCID. The great majority of families at risk for having an affected pregnancy desired prenatal testing, whether or not termination of pregnancy was a consideration. In fact, in only 2 instances out of 13 predicted affected male fetuses did families terminate a pregnancy. To prepare for optimal treatment of an affected newborn, families and their medical providers selected bone marrow transplant centers, undertook HLA testing of family members, and even began a search for a matched, unrelated bone marrow donor.

TREATMENT AND PROGNOSIS

SCID is generally fatal unless the immune system can be reconstituted, either by allogeneic transplantation or correction of autologous hematopoietic cells by gene therapy. Infants receiving allogeneic HCT soon after birth are less likely to have serious pretransplant infections or failure to thrive. They also appear to have more rapid engraftment, fewer posttransplant infections, less GVHD, and shorter hospitalizations than those whose transplants are delayed (Antoine et al., 2003; Buckley, 2004; Giri et al., 1994b; Meyers et al., 2002). Supportive care and management of infections from the time of diagnosis through the transplantation period are essential. Intensive monitoring, parenteral nutrition, immunoglobulin replacement, and antibiotics, including antifungal and antiviral agents, have dramatically improved the survival of infants with SCID. Patients should be isolated from exposure to infectious agents in the environment and should not receive live vaccinations. Attempts to maintain a totally aseptic "bubble" environment are not indicated; instead, prompt immune reconstitution should be the goal.

The best current treatment for SCID is HCT from an HLA-matched related donor, but unfortunately most patients lack such a donor. Haploidentical, T-cell-depleted HCT has proven successful (see Chapter 60). Transplantation protocols using matched unrelated adult bone marrow or cord blood stem cells are also successful. The techniques for eliminating mature T cells from the donor-cell population and enriching for stem cells vary between centers. Similarly, different centers have had different approaches regarding pretransplant chemotherapy or posttreatment GVHD prophylaxis for SCID patients. The potential advantages of controlling GVHD from donor immunocompetent cells and clearing out host bone marrow in the hope of improving donor stem-cell engraftment and B-cell production must be weighed against the risks of cytotoxic treatment.

Previously there were few useful data to compare the regimens used, but now increased numbers of treated patients and specific mutation diagnosis for most infants with SCID allow these questions to be addressed. Nevertheless, it is not yet possible to predict which patient may develop GVHD, fail to make adequate antibodies and require long-term immunoglobulin replacement, or eventually develop T-cell dysregulation or decreased T-cell function. Some of the oldest surviving individuals with SCID received HLA-matched related bone marrow transplants and are now in their forties and in excellent health. As larger numbers of children are now growing up after transplantation for SCID, long-term outcome data are becoming available (Antoine et al., 2003; Buckley, 2004, 2011). While a large proportion of subjects remain healthy, some continue to require immunoglobulin replacement, and some eventually experience declines in thymic output, decreased naïve T-cell numbers, and diminished TCR diversity (Antoine et al., 2003; Buckley, 2011; Buckley et al., 2004; Railey et al., 2012). Multicenter collaborative efforts, including that of the Primary Immune Disease Treatment Consortium in the United States, are engaged in prospective, retrospective, and cross-sectional research to probe which treatments are most successful for particular patients with SCID and CID (Griffith et al., 2008).

The concept of prenatal treatment for XSCID has been controversial due to the risk of invasive procedures during pregnancy. Advantages of in utero treatment include early reconstitution, a protected intrauterine environment, and the possibility of introducing normal bone marrow stem cells at the gestational age when fetal hematopoiesis is shifting from fetal liver to bone marrow. Early attempts at human in utero bone marrow transplantation were compromised by technological limitations, septic complications, and GVHD. In at least two patients with XSCID, these difficulties have been overcome (Flake et al., 1996). Fetuses shown by molecular diagnosis to be affected with XSCID were infused intraperitoneally with haploidentical, T-cell-depleted, $CD34^+$ positively selected paternal bone marrow cells between 17 and 20 weeks of gestation. In each of these two cases, infants were born with engrafted, functional T cells from their donors, whereas the XSCID mutation could still be confirmed in the infants' granulocytes. In long-term follow-up both children were reported to have fully reconstituted immunity without requiring immunoglobulin supplementation (Bartolomé et al., 2002; Beggs et al., 2003).

NEW THERAPIES FOR SCID

XSCID and ADA SCID have been successfully treated by gene transfer therapy to hematopoietic stem cells, but serious

adverse events have also occurred (Haeren-Bey-Abina et el., 2002). Advantages of SCID as a pilot disease for gene therapy as well as complications that have come to light since initial positive results are discussed in detail in Chapter 61.

The first clinical trials of human XSCID gene therapy at the Necker Hospital in Paris by Cavazzana-Calvo et al. (2000) enrolled infants with no available HLA-matched donor. Bone marrow from the affected patients was aspirated, enriched for stem cells by positive selection with the cell-surface marker CD34, cultured in activating cytokines, exposed to a retrovirus encoding a correct copy of *IL2RG* cDNA, and reinfused into the patients, who received no myelosuppressive treatment (Cavazzana-Calvo et al., 2000; Hacein-Bey-Abina et al., 2002; Fischer et al., 2011). Although several of the first patients treated became fully reconstituted with T cells and some also developed the ability to make antibody responses, an unanticipated adverse event, leukemic proliferations of T-cell clones bearing *IL2RG* retroviral insertions near a T-cell oncogene, developed. Retroviral vectors have been redesigned to improve safety, and new clinical trials have been undertaken.

Another promising technology is gene correction in autologous patient HSCs. Zinc finger nucleases, and more recently TALEN nucleases, have been designed to excise mutant DNA from patient HSCs, replacing it with the correct gene sequence (reviewed in Porteus, 2011). This approach is still in preclinical trials to optimize efficacy and safety but may offer potential for correction of any SCID genotype.

IL-2R/IL-15Rβ DEFICIENCY

IL-2 and IL-15 signal through cellular receptors that share both γc (CD132) and IL2Rβ/IL5Rβ chain (CD122). Their receptors are distinguished by their ligand-specific partners, IL2Rα (CD25) and IL15Rα, respectively. IL-2 is predominantly produced by activated T cells and plays an essential role in control of peripheral self-tolerance (Nelson, 2002) through activation-induced cell death (Frucht et al., 2001), thymic selection (Bassiri and Carding, 2001) and maintenance of regulatory T cells (McHugh et al., 2001; Shevach, 2000; Shevach et al., 2001). After binding to its receptor, IL-2 activates JAK1, JAK3, and STAT5.

Despite its shared receptor usage with IL-2, IL-15 has a quite distinct function, maintenance of $CD8^+$ memory T cells that gradually decline after viral infections in the absence of IL-15 (Becker et al., 2002; Goldrath et al., 2002; Schluns et al., 2002). IL-15 is also important for the development of NK cells, as illustrated by the lack of NK cells in IL-15 knockout mice and IL-15Rα knockout mice (Becker et al., 2002; Goldrath et al., 2002; Mohamadzadeh et al., 2001). Thus, the NK-cell deficiency observed in XSCID and JAK3-deficient patients is thought to be due to lack of IL-15 signaling.

One patient with T^{low} B^+ NK^- CID presented with undetectable expression of the β chain of the cellular receptor used by both IL-2 and IL-15 (Gilmour et al., 2001b). The infant had severe infections, including respiratory syncytial virus bronchiolitis, *Candida* enteritis, and meningoencephalitis. He had failure to thrive, hepatomegaly, and moderate lymphopenia. Immunophenotype analysis showed markedly reduced T-cell numbers and absent NK cells, with B lymphocytes within normal range. Serum immunoglobulin levels were normal, although the patient failed to produce specific antibodies following immunization with tetanus toxoid and *Haemophilus influenzae* vaccines. The patient underwent allogeneic bone marrow transplantation with good immune reconstitution and resolution of clinical symptoms.

Flow cytometry and Western blot analyses showed a significant decrease of IL-2Rβ/IL-15Rβ expression in the patient's PBMCs. No abnormalities of the *IL15R* sequence were demonstrated, and whether this clinical presentation was due to undetected mutations of the IL-2Rβ/IL-5Rβ chain *IL15R* itself or a secondary defect remains unclear. It is interesting to note that mice lacking IL-2Rβ/IL-5Rβ have defective NK-cell development, as observed in this patient. In contrast, T cells of IL-2Rβ/IL-5Rβ-deficient mice are abnormally activated, resulting in dysregulated differentiation of B cells into plasma cells and consequent high levels of serum immunoglobulins, as well as autoantibodies that cause hemolytic anemia (Suzuki et al., 1995).

LCK DEFICIENCY

Lck (p56lck) is an intracellular protein tyrosine kinase that is critically involved in TCR-mediated signaling. Its N-terminal region associates with the cytoplasmic tail of the CD4 and CD8 co-receptors (Chow and Veillette, 1995), thus bringing Lck into close proximity with the TCR. Lck is known to contribute to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motifs (ITAMs) of the TCR complex (Iwashima et al., 1994; van Oers et al., 1996). In keeping with the role played by Lck in early steps of TCR-mediated signaling, targeting of the Lck gene (Molina et al., 1992), or expression of a dominant negative Lck transgene (Levin et al., 1993), results in a severe T-cell developmental defect, with profound thymic atrophy, a dramatic reduction in the number of double-positive thymocytes, and only few circulating mature T cells.

One infant with a putative Lck defect has been reported to date (Goldman et al., 1998). The patient presented with chronic diarrhea and failure to thrive at 1 month of age and developed *Enterobacter cloacae* sepsis, cytomegalovirus infection, and persistent oral candidiasis. Laboratory investigation disclosed panhypogammaglobulinemia, lymphopenia with a low proportion (9–22 percent) of $CD4^+$ T cells, and a progressive decline in T-cell proliferation to mitogens and anti-CD3 monoclonal antibody. $CD8^+$ T cells, if activated with anti-CD3, failed to express the activation marker CD69, whereas activation with phorbol esthers and ionomycin resulted in normal CD69 expression, indicating a TCR signaling defect proximal to protein kinase C activation. A marked reduction in the level of Lck and an improperly spliced Lck transcript, lacking the exon 7 coding domain, were demonstrated. The milder immunological phenotype observed in the patient when compared with gene-targeted lck knockout mice could be explained by residual, although low, expression of Lck or species differences in redundancy

of related signaling kinases. The clinical course of the infant was typical for SCID; he ultimately required bone marrow transplantation, which was reported to result in a complete cure.

SHORT STATURE AND IMMUNODEFICIENCY DUE TO MUTATIONS OF STAT5b

Six patients in five families, most of them consanguineous, have been reported who had STAT5b deficiency resulting in postnatal growth failure, facial dysmorphism, and immunodeficiency that can be characterized as CID (Bernasconi et al., 2006; Hwa et al., 2005, 2007; Kofoed et al., 2003; Rosenfeld et al., 2004; Vidarsdottir et al., 2006). The original reported case, a daughter of consanguineous healthy parents of normal stature, had severe growth failure with growth hormone insensitivity. By the age of 16.5 years she was the height of an average 6.5-year-old. She also suffered from chronic diarrhea, generalized eczema, and respiratory ailments, periodically requiring oxygen supplementation. A lung biopsy indicated the diagnosis of lymphoid interstitial pneumonia, and the patient was treated with oral steroids. At age 8 she developed severe, hemorrhagic varicella, followed by multiple episodes of herpes zoster. At age 10, progressive worsening of her pulmonary function occasioned a repeat biopsy, in which *Pneumocystis carinii* and *Rodococcus equis* were isolated. Institution of appropriate treatment and chronic management of combined immunodeficiency have resulted in an improved quality of life.

The additional patients all had significant infections and short stature with normal growth hormone, reflecting the critical role of STAT5b in signaling from the growth hormone receptor, which along with γc and IL7Rα is a member of the cytokine receptor family. Other associated features included ichthyosis and juvenile arthritis, each in one patient, and abnormal platelet aggregation in another.

LABORATORY FINDINGS AND MOLECULAR BASIS OF STAT5b DEFICIENCY

High levels of endogenous growth hormone, low insulin-like growth factor, normal growth hormone binding protein, and normal growth hormone receptor (GHR) coding sequence pointed to an intracellular defect distal to the GHR, a member of the cytokine receptor gene superfamily that acts through phosphorylation of STAT5b. Indeed, expression of STAT5b was only poorly detectable in patient fibroblasts, which failed to show phosphorylation of the protein in response to GH. STAT5a expression and ability to be phosphorylated were normal. Details about the patient's lymphocyte profile and immune functional studies have not been published.

This patient was found to be homozygous for the missense mutation in the *STAT5B* gene on human chromosome 17q11.2. The mutation is due to the substitution of C for the G nucleotide at cDNA 2057 in the alanine 630 codon, changing alanine to proline (A630P). The mutation lies in the highly conserved SH2 domain of STAT5b. Although protein is produced (but poorly recognized by some monoclonal antibodies), it is unable to be phosphorylated, preventing dimerization, translation to the nucleus, and activation of transcription.

The coexistence of extreme short stature and combined immunodeficiency may suggest STAT5b deficiency, particularly in a consanguineous family. Because of its extreme rerity, the clinical spectrum of severity of the disease is not known. The multiple roles of STAT5b in many tissues indicate that bone marrow transplantation would not be expected to correct the entire phenotype.

FUNCTIONAL ASPECTS AND ANIMAL MODEL OF STAT5B DEFICIENCY

STAT5a and STAT5b are transcription factors that are 96 percent homologous to each other and are tandemly located in both human and mouse, suggesting that these genes arose by gene duplication. The precise role of each of the two *STAT5* genes is not completely worked out in human or mouse. Mouse knockouts of STAT5a show impaired prolactin-dependent mammary gland development (Liu et al., 1997), while STAT5b knockout mice have a phenotype similar to that observed in GHR-deficient mice (Udy et al., 1997). Deletion of both STAT5a and STAT5b results in a phenotype closely resembling that observed in prolactin receptor-deficient mice, including decreased body size in males, anemia, and impaired mammary gland development, reflecting the roles of STAT5 proteins as intracellular transducers of signals from growth hormone, erythropoietin, and prolactin receptors. In addition, STAT5a and STAT5b double knockout mice show a profound T-cell proliferation defect, similar to that observed in IL2RB-deficient mice (Teglund et al., 1998). Partial T-cell defects can be observed in both STAT5a and STAT5b single knockout mice (Imada et al., 1998; Nakajima et al., 1997), indicating that the two STAT5 proteins play critical, redundant roles in peripheral T-cell activation and proliferation.

IL2RA DEFICIENCY

IL2Rα was the first chain of the IL2R complex to be cloned (Cosman et al., 1984; Leonard et al., 1984; Nikaido et al., 1984). It is a 55-kDa protein with an extracellular portion containing 219 amino acid residues, a transmembrane segment of 19 residues, and a short cytoplasmic portion containing only 13 residues. IL2Rα, unlike the other chains of this receptor, has no similarity to the cytokine receptor superfamily, but it appears to have structural homology to the α chain of the IL-15 receptor (Giri et al., 1995). Of the three chains of the IL2R, IL2Rα shows the most tightly regulated expression. During T-cell development IL2Rα is already expressed on the earliest triple-negative ($CD3^-$ $CD4^-$ $CD8^-$) thymocytes (Godfrey et al., 1993), but subsequently it is dramatically downregulated. In resting, mature T cells IL2Rα is not expressed; it is induced

by stimulation through the TCR or by IL-1 and TNFα (Crabtree, 1989; Rothenberg, 1991). Similarly, mature B cells newly express IL2Rα following stimulation through the B-cell receptor (Jung et al., 1984; Tsudo et al., 1984; Waldmann et al., 1984). IL2Rα is also upregulated in response to IL-2.

CLINICAL AND IMMUNOLOGICAL PHENOTYPE OF IL2RA DEFICIENCY

To date only two human subjects from a single consanguineous family have been identified with IL2Rα deficiency (Roifman, 2000; Sharfe et al., 1997; unpublished observations). The index patient, a male, presented with persistent thrush, Candida esophagitis, and cytomegalovirus (CMV) pneumonitis at 6 months of age. By 8 months, chronic diarrhea and failure to thrive were associated with adenovirus gastroenteritis and frequent hospitalizations for exacerbations of pulmonary disease. Lymphadenopathy and hepatosplenomegaly became increasingly apparent during the second year of life, and by the third year he developed frequent otitis media, gingivitis, and chronic mandibular inflammation. While serum IgM and IgG levels were normal, his IgA level was low. The absolute number of peripheral T cells was reduced, with a significant reduction in $CD4^+$ T cells. In vitro assays demonstrated reduced proliferation after stimulation by anti-CD3 (11 percent of control), PHA (20 percent of control), and other mitogens. Addition of exogenous IL-2 did not significantly rescue these proliferative responses. An allogenic skin graft from a healthy donor (negative for EBV, CMV, HIV, and hepatitis B) was not rejected. Biopsies of lung and upper gastrointestinal tissue revealed dense lymphocytic infiltrates in the absence of infectious agents. Thus, the presentation was of CID with increased susceptibility to viral, bacterial, and fungal infections and evidence of dysregulated lymphocytic inflammatory disease.

The lymphadenopathy and tissue infiltrates of the CD25-deficient patient were partially ameliorated by the administration of corticosteroids. However, to effect a cure an allogeneic bone marrow transplant was performed, using an HLA-matched unaffected sibling as the donor. Engraftment was rapid and a complete resolution of symptoms ensued. On follow-up, the patient was free of symptoms without any treatment with over 95 percent of peripheral blood mononuclear cells of donor origin, and growth and development were appropriate for age.

ABSENCE OF IL2Rα (CD25) EXPRESSION AND MOLECULAR ANALYSIS

EBV-transformed cells from these patients did not express detectable CD25 by flow cytometry, whereas EBV-transformed lines from normal individuals typically contain 20 to 40 percent CD25-positive cells, and Western blot analysis of lysates from peripheral blood lymphocytes confirmed the absence of CD25 protein. In contrast, expression of γc was normal and of IL2Rβ elevated, possibly reflecting compensation for the lack of the α chain, CD25.

Both isoforms of CD25 mRNA had a 4-bp frameshift deletion at cDNA 60–64, resulting in a translational frameshift after 20 codons. The parents each demonstrated a normal and 4-bp-deleted allele.

Atypically for profound cellular immunodeficiency, the thymus in IL2Rα deficiency was of normal size, although Hassall's corpuscles and a distinct corticomedullary demarcation were absent (Plate 10.1). Whereas immunohistochemical staining of thymus sections showed normal expression of CD3, CD2, CD4, CD8, and class I and class II major histocompatibility complex (MHC) proteins, staining for CD1 was completely negative (Plate 10.1). In the normal thymus CD1a is highly expressed on cortical thymocytes and is downregulated upon progression into the medullary antigen-presenting region. Because the *CD1A* gene itself was normal, a failure to provide appropriate signals for CD1 upregulation in thymocytes may explain this phenomenon. CD1 may mediate interactions between thymocytes and thymic epithelium, and absence of CD1 may be related to the loss of the distinct corticomedullary boundary. Normally the induction of CD1 expression in cortical thymocytes precedes a dramatic decrease in the cellular level of the Bcl-2 protein, sensitizing them to undergo apoptosis required for thymic selection (Alvarez-Vallina et al., 1993; Fujii et al., 1994; Gratiot-Deans et al., 1994; Vanhecke et al., 1995).

Whereas normal thymocytes demonstrated distinct areas of low (cortical) and high (medullary) Bcl-2 expression, staining of patient thymus sections revealed that all CD25-deficient thymocytes expressed high levels of Bcl-2 (Plate 15.1). Thus the lack of regulation of Bcl-2 expression in CD25 deficiency suggests dependence upon downstream events following either CD1 or CD25 signaling. Sakaguchi et al. (1995) reported that $CD25^+$ $CD4^+$ regulatory T cells maintain self-tolerance in mice by suppressing autoreactive cells. Indeed, even in the absence of thymic irregularities, autoreactive responses emerged in the absence of $CD25^+$ T cells. This finding suggests that the lymphocytic infiltrates observed in human CD25 deficiency could be autoimmune in nature.

The heavy tissue infiltrates of lymphocytes found in a CD25-deficient patient suggested the involvement of autoreactive oligoclonal expansion observed in multiple autoimmune disorders. Further, the higher-than-normal expression of Bcl-2 in the thymus suggested that such autoreactive clones might escape selection due to reduced ability of these cells to undergo apoptosis. Thus IL2Rα appears to be critical for the physiological negative selection of thymocytes. In its absence, autoreactive clones that normally should die by apoptosis fail to do so, and instead they expand and cause damage to peripheral tissues. In conclusion, a combination of at least two events, one intrathymic and another peripheral, may have combined to create the phenotype observed in humans with CD25 deficiency.

IL2Rα-DEFICIENT MICE

Targeted disruption of IL2Rα in the mouse showed that development of T and B cells appeared intact in these animals, including the distribution of thymocyte subpopulations in the

thymus (Willerford et al., 1995). In addition, NK cells also appeared to be normal (Nelson et al., 1998). However, as with IL-2 deficient mice, older IL2Rα knockout mice developed polyclonal expansion of peripheral T cells that highly expressed CD44 but had a low expression of CD62L. Activated B cells present in young animals initially led to hypergammaglobulinemia, but older animals had progressive loss of B cells. The major phenotype was autoimmune disease, including hemolytic anemia, severe colitis (reminiscent of human ulcerative colitis), and lymphadenopathy.

T-CELL RECEPTOR COMPLEX DEFICIENCY

Jose R. Regueiro and Maria J. Recio

CONCISE DESCRIPTION AND BRIEF HISTORICAL OVERVIEW

Mature T lymphocytes detect the presence of antigens by way of a variable surface heterodimer (either αβ or γδ) termed the T-cell receptor (TCR, Fig. 11.1). In humans, TCR molecules form a complex with two invariant heterodimers called CD3γε and CD3δε and a single invariant homodimer termed CD247 (also called ζζ) (Call et al., 2002). These invariant proteins participate in assembly and surface expression of the whole TCR complex, and in the delivery of intracellular signals that drive T-cell maturation or apoptosis in the thymus, and T-cell activation, proliferation, and effector function or anergy/apoptosis after antigen recognition (Malissen et al., 1999). During early T-cell development, other invariant chains such as the pre-TCR may assist immature TCR ensembles. CD3 and CD247 chains lack intrinsic enzymatic activity for signal transduction. Rather, they relay on conformation- and phosphorylation-dependent recruitment and activation of a number of cytosolic and transmembrane protein tyrosine kinases (PTK) and adaptors such as Zap-70, Fyn, Lck, TRIM, LAT, SLP-76, SIT, and Nck (Schraven et al., 1999). Most TCRαβ-bearing T cells recognize processed peptides associated with major histocompatibility complex (MHC) molecules, whereas the ligands of TCRγδ-bearing T cells are still debated, but include unprocessed bacterial phosphoantigens in humans (Hayday, 2000).

Because of the central role of T cells in adaptive immune responses and the central role of the TCR complex in T-cell selection and function, the description in 1986 of a human familial CD3 expression deficiency in a child with immunodeficiency, but also in his healthy sibling, was in many ways surprising (Regueiro et al., 1986). Four years later, a second CD3 expression deficiency was reported in a healthy child (Thoenes et al., 1990). As it turned out, the former was due to a complete CD3γ deficiency (Arnaiz-Villena et al., 1992) and became the first primary TCR complex immunodeficiency for which the genetic basis was elucidated, while the latter was caused by a partial CD3ε deficiency (Soudais et al., 1993). Further CD3, CD247, and TCR deficiencies followed (Table 11.1), which, keeping with the initial observations, can be classified as complete or partial (also termed leaky) according to the absence or presence of residual levels of the affected protein.

TCR complex deficiencies in humans are very rare autosomal recessive diseases characterized by a selective TCR complex expression defect frequently associated with peripheral blood T, but not B or natural killer (NK), lymphocytopenia and severe combined immunodeficiency disease (SCID) symptoms. TCR complex deficiencies are caused by a range of severe or leaky mutations in the genes encoding for TCR complex chains (to date other than TCRβ, TCRγ or TCRδ). Mutation databases have been established for most of them (http://bioinf.uta.fi/base_root/index.php), as well as diagnostic support websites (http://bioinf.uta.fi/IDdiagnostics).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Reported cases of TCR complex deficiencies have steadily grown to close to 31 patients in 17 families (see Table 11.1), half of them CD3δ deficiencies. Age of onset is generally within the first year of life, essentially with SCID features such as recurrent respiratory infections, chronic diarrhea, and failure to thrive. Chronic pyogenic infections, dysmorphic features, or bone abnormalities were not reported. Unless hematopoietic stem cell transplantation is performed, most

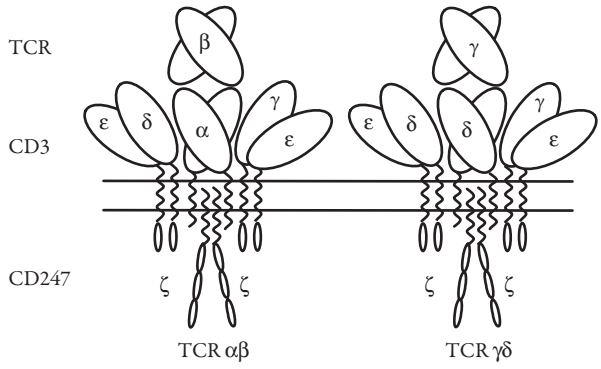

Figure 11.1 *TCR complex isotypes.* Variable TCR heterodimers bind antigens, while invariant CD3 heterodimers (γε and δε) and CD247 homodimers (also called ζζ) undergo conformational changes and recruit intracellular enzymes (such as Fyn, Lck, and Zap) to initiate signal transduction.

patients die early in life as a consequence of viral infections. Omenn syndrome features (hypereosinophilia, hyper-IgE, dermatitis) have been reported in partial CD3δ, CD247, or TCRα defects. In a few cases, notably in complete CD3γ deficiency and in a partial CD3ε deficiency, certain individuals do not show features of immunodeficiency and have reached their third decade in good health without intervention.

LABORATORY FINDINGS

The most consistent laboratory finding is a selective T lymphocytopenia. It may be severe ($T^-B^+NK^+$ immunophenotype), as observed in complete CD3ε or CD3δ defects, with less than 2% peripheral blood T cells, or mild ($T^{+/-}B^+NK^+$), as observed in complete CD3γ or CD247 defects and in most partial TCR complex defects (with >20% T cells, Table 11.2). Overall lymphocytopenia (<3,000 cells/μL in children) is common in the former group, although exceptions due to compensatory B and NK expansions have been reported.

T-lymphocyte functions (anti-CD3 or phytohemagglutinin responses) and B-lymphocyte functions (antibody production following infection or vaccination) are absent when no T cells are detected, although Ig levels may be normal. These functions may be preserved or even normal in partial defects. Autoimmunity and/or immune dysregulation laboratory features may be present, particularly in such leaky defects (see information about Omenn syndrome above).

When T lymphocytes are present, the following laboratory findings have been reported:

1. A TCR complex expression defect is always observed, with 2- to 100-fold less TCR on patient versus normal control T cells using standard CD3ε-specific monoclonal antibodies. It may be severe (more than 10-fold), as observed in CD247 or (partial) CD3ε defects, or mild (less than 5-fold), as observed in CD3γ or (partial) CD3δ or TCRα defects. Thus, a different hierarchy for invariant chain dependence can be proposed for T-cell selection (CD3ε ≥ CD3δ > CD3γ ≥ CD247, see above) as compared with TCR complex expression when some T cells are selected (CD3ε ≥ CD247 > CD3δ ≥ CD3γ). This suggests differential signaling versus structural roles of the different chains during T-cell development.
2. Both αβ and γδ T cells can be detected, but with a restricted repertoire, with few qualifying as recent thymus emigrants (measured using TCR Rearrangement Excision Circles or $CD45RA^+CD27^+$ T cells). However, notable exceptions have been observed, such as partial CD3δ and TCRα defects, which show a $Tαβ^{τ}Tγδ^+B^+NK^+$ immunophenotype with a fairly normal γδ T-cell compartment (Morgan et al, 2010, Gil et al, 2011).
3. In rare cases, two T-cell populations are detected: one with impaired TCR complex expression and a second with normal TCR complex expression (Rieux-Laucat et al., 2006). Somatic mutations that reverted to wild type in certain T-cell clones were found to explain these findings (see the section on mutations analysis below).

Variable presentation of primary immune deficiency: Two cases with CD3γ deficiency presenting with only autoimmunity. *Pediatric Allergy and Immunology* 2013;24:257–262.

MOLECULAR BASIS

The lack of any invariant TCR complex chain has a profound impact on αβ TCR, pre-TCR, and γδ TCR expression and function. As these receptors are required for T-cell development, T lymphocytopenia ensues in patients, and adaptive immunity is impaired. Different invariant chains show different effects on T-cell selection, as shown in Figure 11.2, supporting the hierarchy indicated above (CD3ε ≥ CD3δ > CD3γ ≥ CD247). TCRα strictly associates to CD3δε dimers, whereas TCRβ has been shown to interact with γε as well as δε dimers before CD247 associates to the TCR complex (Call et al., 2002). This may explain the differential effect of the lack of CD3δ or ε, as compared to CD3γ (or CD247), on T-cell development, which is blocked in complete CD3δ or ε deficiency, but only impaired in human CD3γ or CD247 deficiency.

FUNCTIONAL ASPECTS

TCR complex function obviously cannot be studied in patients with TCR complex defects that block T-cell development. When some T cells are present, meaningful comparisons with normal individuals are difficult because T-cell subset representation and surface TCR complex expression are altered. Nonetheless, it is clear that normal TCR signaling is possible in vivo, since selection took place in those patients and in some cases (CD3γ, partial CD3ε) normal antibody responses indicate intact helper T-cell functions. T-cell lines from patients have been difficult to derive. Our studies in human CD3γ-deficient primary T cells, interleukin (IL)-2-dependent T-cell lines, and Herpesvirus saimiri- or HTLV-I-transformed T lymphocytes indicated that CD3γ contributes to but is not required for the regulation of TCR trafficking in resting and antigen-stimulated mature T lymphocytes (Torres et al., 2003). Despite its effects on TCR complex expression (likely due to impaired recycling), CD3γ is dispensable for several TCR-induced mature T-cell responses, such as calcium flux, cytotoxicity, up- or downregulation of several surface molecules, and proliferation and synthesis of certain cytokines (TNFα). In contrast, phorbol myristate acetate-induced TCR complex downregulation and TCR-induced synthesis of other cytokines (IL-2) as well as adhesion and polarization were severely impaired (Arnaiz-Villena et al., 1992; Pacheco-Castro et al., 1998; Perez-Aciego et al., 1991; Torres et al., 2002). The lack of CD3γ causes a stronger impairment of αβTCR expression in $CD8^+$ than in $CD4^+$ T cells in humans and in mice. We have shown that this is due to biochemical differences in the intracellular control of αβTCR complex assembly, maturation, or transport between the two lineages, which result in conformational lineage-specific differences regulated by activation or differentiation both in normal and in CD3γ-deficient primary T cells (Zapata et al., 1999, 2004). More recently, we have reported that the lack of CD3γ in humans caused a stronger impairment of CD3 expression in αβ than in γδ T cells (Siegers et al., 2007), whereas the opposite is true in partial CD3δ deficiency (Gil et al, 2011).

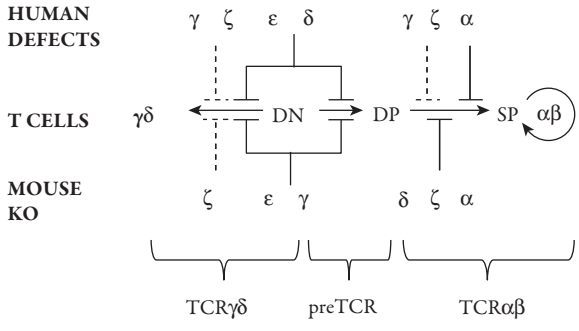

Figure 11.2 Leaky (dashed) or severe (solid) block of early T-cell differentiation caused by complete invariant TCR complex chain defects in humans or mice. αβ T-cell development is simplified in two steps: (1) pre-TCR-mediated double-negative (DN) $CD4^-CD8^-$ to double-positive (DP, $CD4^+CD8^+$) transition and (2) αβ TCR-mediated positive/negative selection and generation of single-positive (SP) $CD4^+$ and $CD8^+$ αβ T cells. γδ T cells develop from DN thymocytes. CD247 is depicted as ζ for brevity.

MUTATION ANALYSIS

Mutation analysis was started by probing T-cell RNA with *CD3*, *CD247*, or *TRAC*-specific sequences. For some CD3δ defects, microarray analysis of thymocyte RNA revealed low specific transcript levels. In all cases, cDNA was synthesized and used to amplify and sequence TCR complex genes. This revealed the presence of point mutations or small deletions (Fig. 11.3), which could be traced with mutation-specific oligonucleotides, restriction enzymes, or direct sequencing. Small deletions were due to splicing site mutations, which were identified on genomic DNA by sequencing relevant exon boundaries. As a consequence, no or very few specific proteins of the TCR complex could be detected biochemically.

In a partial CD247 deficiency, reversion of some T-cell clones to normal expression was observed in vivo as a consequence of additional mutations in T-cell precursors (Rieux-Laucat et al., 2006).

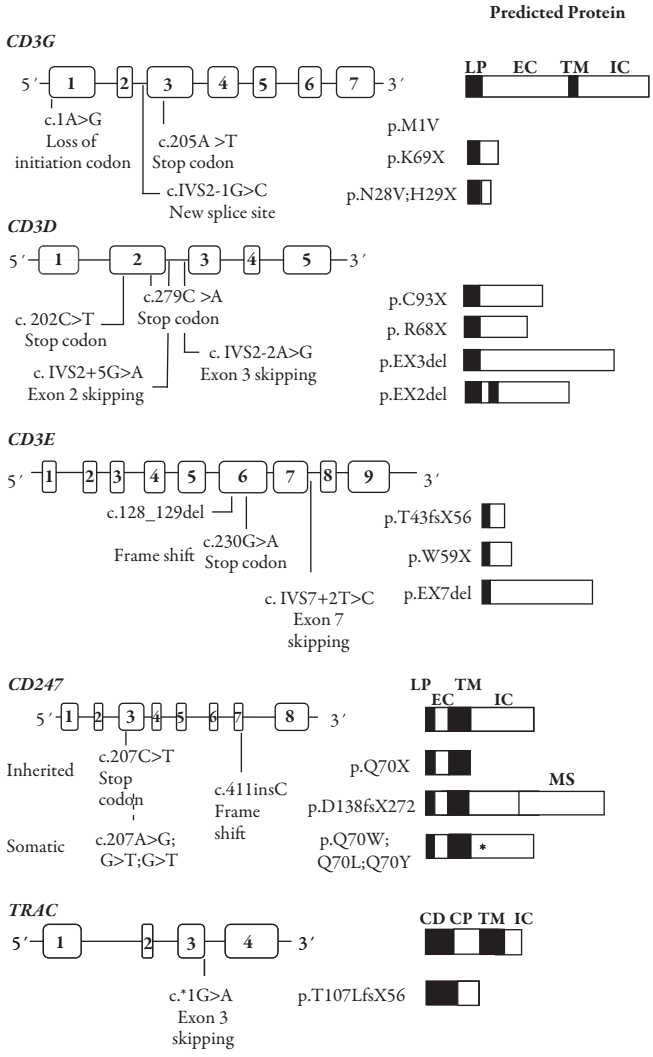

Figure 11.3 Mutations reported in genes encoding for TCR complex chains and predicted proteins. LP, leader peptide; EC, extracellular; TM, transmembrane; IC, intracellular; CD, constant domain; CP, connecting peptide; UT, untranslated.

STRATEGIES FOR DIAGNOSIS

Definitive: Male or female patient with surface TCR complex expression defect, selective peripheral blood T lymphocytopenia ($T^-B^+NK^+$ or $T^{+/-}B^+NK^+$ phenotype), and mutations in a TCR complex gene (such as *CD3G, CD3D, CD3E, CD247*, or *TRAC*).

Probable: Male or female patient with surface TCR complex expression defect and selective peripheral blood T lymphocytopenia ($T^-B^+NK^+$ or $T^{+/-}B^+NK^+$ phenotype)

Spectrum of disease: From SCID (common) to healthy (rare, overlooked?). Complete CD3ε or CD3δ defects show the $T^-B^+NK^+$ phenotype, whereas complete CD3γ or CD247 defects and partial defects tend to show the $T^{+/-}B^+NK^+$ phenotype. T-cell revertants with normal TCR complex expression due to somatic mutations may be present.

Differential diagnosis: With patients showing $T^-B^+NK^+$ or $T^{+/-}B^+NK^+$ phenotypes, such as those with defects in IL7Rα, FOXN1, Coronin-1A, Zap70, MHC class I or II, PNP, ADA, or DiGeorge syndrome

Testing for the percentage of $CD3^+$ lymphocytes may not be enough to detect TCR complex deficiencies, particularly when some T cells are present. Analyzing the mean fluorescence intensity is mandatory, as well as using a range of TCR-, CD3-, and CD247-specific monoclonals. The expression defect follows the CD3ε ≥ CD247 > CD3δ ≥ CD3γ hierarchy with a wide fold-difference range.

Biopsy specimens from lymphoid tissues should be thoroughly studied (Arnaiz-Villena et al., 1991; Dadi et al., 2003; Morgan et al., 2011) and T cells preserved if possible (Pacheco et al., 1998; Perez-Aciego et al., 1991) and analyzed by immunoprecipitation (Perez-Aciego et al., 1991; Thoenes et al., 1992) and molecular biology techniques (Arnaiz-Villena et al., 1992; Soudais et al., 1993).

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

TCR complex deficiencies are autosomal recessive disorders. Heterozygotes are healthy and cannot be easily distinguished from normals by standard laboratory tests, although half-normal CD3 expression levels have been reported by flow cytometry (Brooimans et al., 2000; Muñoz-Ruiz et al., 2013) or biochemistry (van Tol et al., 1997). Thus mutation analysis must be performed in each case, as explained above. Restriction fragment length polymorphism (RFLP) analysis using TaqI and a *CD3E* probe (50% heterozygosity) or polymorphic markers may help to define *CD3GDE* haplotype inheritance for carrier detection and/or prenatal diagnosis, since recombination within the *CD3* gene complex is rare.

TREATMENT AND PROGNOSIS

Unless the patient is transplanted, the prognosis is very poor for those with complete defects except CD3γ and for most partial defects (see Table 11.2). Matched related, haploidentical mismatched related (MMRD), matched unrelated (MUD), and mismatched unrelated donors have all been used for hematopoietic stem cell transplantation, with bone marrow, peripheral blood, or cord blood as sources. The recipients generally underwent myeloablative conditioning. The largest series consisted of patients with CD3δ defects; they showed a superior outcome using MUD as compared to MMRD (Marcus et al, 2011). Viral infections (herperviruses) are the most common cause of death among transplanted patients. Successfully transplanted patients have been shown to lead a normal life up to 18 years posttransplantation.

A few patients had no immunodeficiency symptoms and thus did not receive hematopoietic stem cell transplantation (CD3γ, partial CD3ε), reaching their third decade in good health. In those cases prophylactic intravenous immunoglobulin (IVIG) with (Le Deist et al., 1991) or without (van Tol et al., 1997) antibiotics were used, or antibiotics only when symptoms developed (Allende et al, 2000). The observation

that most antibody responses were normal in vivo in one case prompted a comprehensive vaccination program, excluding attenuated live viruses. No secondary effects were recorded. Thus, this approach may be helpful for other TCR complex-deficient patients on a preventive basis. Bronchial asthma in one case was treated with ketotifen and cromolyn sodium between 3.5 and 7 years of age (Sanal et al., 1996), followed by salbutamol sulfate and sodium chromoglycate to manage his nonatopic hyperreactive airway, including eformoterol with occasionally inhaled steroids. Gene therapy protocols were tested in vitro (Sun et al., 1997). However, transfer of CD3γ into mature T cells may disrupt their intrathymic fine tuning (Pacheco-Castro et al., 2003). Thus, lymphoid progenitors may be better targets in this case, although the selective advantage of transduced over untransduced T cells remains to be established.

ANIMAL MODELS

Single as well as multiple TCR complex deficiencies have been created in mice through gene targeting (Malissen et al., 1999; Mombaerts et al., 1992). Ablation of any invariant TCR complex protein essentially blocked T-cell development, although at different intrathymic checkpoints, and to a different extent (see Fig. 11.2). Indeed, all invariant TCR complex proteins, except CD3δ, are required for T-cell selection at the pre-TCR (TCRβ) checkpoint, with the following hierarchy: CD3ε > CD3γ > CD247. However, all invariant TCR complex chains, including CD3δ, are required for T-cell selection at the TCRαβ checkpoint and for αβTCR surface expression. Interestingly, CD3δ is also dispensable for γδ T-cell selection and for γδTCR surface expression in mice, but not in humans (Dadi et al., 2003). This is due to a differential stoichiometry of the γδTCR between the species (Siegers et al., 2007). The mouse surface γδTCR does not incorporate the CD3δ subunit; thus, its stoichiometry is TCRγδCD3εγεγζζ rather than TCRγδCD3εδεγζζ, as observed in humans (see Fig. 11.1). The murine models are similar to human CD3 deficiencies in some aspects (ε > γ in αβTCR expression, no peripheral T cells when CD3δ is lacking) but not in others (peripheral blood T-lymphocyte numbers are clearly higher in humans lacking CD3γ). Thus, peripheral lymphoid expansion mechanisms may differ between species. CD3 gene inactivation in mice, even when kept in pathogen-free facilities, may cause pathological manifestations, including enteropathy in ζ/η- or CD3δ-deficient mice, which resemble those observed in some CD3γ- or CD3δ-deficient humans.

CONCLUDING REMARKS

The TCR complex is first expressed and used by T cells early during their intrathymic development. Accordingly, complete TCR complex deficiencies strongly impair early T-cell differentiation events in humans, generally causing SCID. TCR complex deficiencies provide insights into the redundant and unique roles of these transmembrane molecules for TCR complex assembly and signal transduction and thus for T-cell selection and antigen recognition, which are not always recapitulated by murine models.

ACKNOWLEDGMENTS

Grants by Ministerio de Economía y Competitividad (SAF2011–24235), Comunidad Autónoma de Madrid (S2011/BMD-2316), Fundación Lair, Instituto de Salud Carlos III (RIER RD08-0075-0002, PI080921) and Fundación Mutua Madrileña have supported our work. We thank the following colleagues for updated/unpublished information in Table 11.2: Hidetoshi Takada (Department of Pediatrics, Graduate School of Medical Sciences, Kyushu University), Juana Gil (Inmunología, Hospital Gregorio Marañón, Madrid, Spain), Eduardo Lopez-Granados (Inmunología, Hospital La Paz, Madrid, Spain), Chaim M. Roifman (The Canadian Centre for Primary Immunodeficiency, Div. of Immunology and Allergy, The Hospital for Sick Children, Toronto, Ontario, Canada), and Françoise Le Deist (CHU Sainte-Justine, Montréal, Canada).

12.

SEVERE COMBINED IMMUNODEFICIENCY DUE TO MUTATIONS IN THE *CD45* GENE

Talala Chatila and Jennifer M. Puck

The protein tyrosine phosphatase CD45, also known as protein tyrosine phosphatase receptor type C (PTPRC) and leukocyte common antigen (LCA) (MIM 151460; disease #608971), is an abundant, high-molecular-weight type I transmembrane glycoprotein that is exclusively expressed on all nucleated hematopoietic cells (Thomas, 1989; Tonks et al., 1988; Trowbridge and Thomas, 1994). CD45 regulates the activity of receptor-associated Src-type tyrosine kinases (Alexander, 2000; Ashwell and D'Oro, 1999; Hermiston et al., 2002; Penninger et al., 2001; Thomas, 1999; Thomas and Brown, 1999). Its absence is associated with a block in signaling via antigen receptors (Desai et al., 1994; Koretzky et al., 1990; Pingel and Thomas, 1989). CD45 also downregulates the function of integrin-mediated adhesion and cytokine receptor signaling by dephosphorylating integrin-associated Src kinases (Roach et al., 1997) and cytokine receptor-associated Jak kinases, respectively (Irie-Sasaki et al., 2001).

CD45 deficiency in humans results from rare deleterious point mutations and deletions that are inherited in an autosomal recessive manner. Two patients have been described who presented in infancy with severe combined immunodeficiency (SCID) associated with T-cell depletion and failure of the residual T cells in the periphery to respond to mitogenic stimuli (Cale et al., 1997; Kung et al., 2000; Tchilian et al., 2001). The B cells, whose development was spared, failed to develop germinal centers or to sustain normal immunoglobulin production. The immunological abnormalities of these patients mirrored those of animal models of CD45 deficiency (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999), reflecting a requirement for CD45 in antigen receptor signaling during T-cell development and upon T- and B-cell activation in the periphery. A third, unrelated patient, has been reported who had a similar phenotype due to having inherited 2 maternal copies of a CD45-mutation-bearing chromosome 1, with no paternally derived chromosome 1; this situation is known as maternal uniparental isodisomy of chromosome 1 (Roberts et al., 2012).

REGULATORY FUNCTIONS OF CD45

The *CD45* gene, located on chromosome 1q31.3-q32.1, contains 34 exons encoding multiple splice variants (Hall et al., 1988). The extracellular portion of CD45 has a heavily *O*-glycosylated amino-terminal region and a cysteine-rich region containing fibronectin type III sequence motifs. Cell type-specific alternative splicing of exons 4/A, 5/B, and 6/C generates up to 8 CD45 isoforms, encoding extracellular regions ranging from 391 to 552 amino acids (Rogers et al., 1992). Differential interaction of these with other proteins either in *cis* or in *trans* may influence cell migration and alter biochemical signaling regulated by CD45.

In T cells, different CD45 isoforms are expressed in a manner specific to developmental stage and activation state (reviewed in Trowbridge and Thomas, 1994). Immature thymocytes express low-molecular-weight CD45 isoforms. Naïve T cells express high-molecular-weight, CD45RA-containing isoforms. Following activation, T cells switch to express a lower-molecular-weight isoform lacking all three alternatively spliced exons (CD45RO). The CD45RO phenotype found upon memory T cells is reversible in that CD45RO T cells can later resume expression of the high-molecular-weight isoforms. B cells express the largest CD45 isoform of 220 kD molecular weight (also known as B220) containing all 3 alternative exonic sequences (CD45RABC).

The CD45 cytoplasmic region contains two prototypic phosphatase domains in tandem. The proximal domain is catalytically active, whereas the distal pseudophosphatase domain is inactive but promotes recruitment of substrate proteins (Kashio et al., 1998). Reconstitution of the cytoplasmic domain of CD45 as part of chimeric molecules restores signaling via the T-cell antigen receptor in CD45-deficient cell lines, indicating that the lack of CD45 phosphatase activity is the fundamental abnormality underlying the failure of antigen receptor signaling in CD45 deficiency (Desai et al., 1994).

The role of CD45 in lymphocyte antigen receptor signaling centers on regulating the activity of antigen receptor-associated Src family kinases: p56Lck and p59Fyn in T cells, and Lyn in B cells (Thomas and Brown, 1999). A major function of CD45 is to maintain these kinases in a quiescent state, yet poised for activation upon engagement of antigen receptors. The activity of Src kinases is regulated by the phosphorylation status of 2 tyrosine residues: one at the carboxyl terminus, which serves a negative regulatory function; and the other within the kinase domain, which serves a positive regulatory function. In CD45-deficient cells, the C-terminal regulatory tyrosine residue is consistently found hyperphosphorylated, indicating that CD45 functions to maintain this site in a dephosphorylated form. Phosphorylation of the C-terminal regulatory tyrosine residue results in its intramolecular association with the SH2 domain of the same Src kinase, which locks the kinase in a closed conformation that renders it inactive. The deleterious impact of hyperphosphorylation Src kinase C-terminal inhibitory tyrosine in CD45 deficiency is highlighted by the observation that a constitutively active Lck mutant, in which the C-terminal tyrosine residue is changed into a phenylalanine, rescues the profound block in T-cell development in CD45-deficient mice (Pingel et al., 1999; Seavitt et al., 1999).

The positive regulatory tyrosine residue in the catalytic domain of Src kinases also serves as a substrate for CD45. This role is particularly important in regulating the function of Lck activity in thymocyte development and in downregulating the activity of the Src kinases Hck and Lyn during integrin-mediated adhesion in macrophages.

Given that the net effect of CD45 is to maintain Src kinases in a dephosphorylated, yet primed state, how are the positive effects of CD45 on antigen receptor signaling mediated? One answer to this question was provided by the finding that CD45 is excluded from the immunological synapse, the supramolecular structure formed at the interface of T cells with antigen-presenting cells that includes the T-cell receptor (TCR), CD4 and CD8 co-receptors, antigen-presenting major histocompatibility complex (MHC) molecules, and a variety of signaling molecules (Johnson et al., 2000). Lipid rafts containing the TCR, Lck, and the adapter protein LAT but excluding CD45 cluster at the immunological synapse, allowing effective src kinase activation.

A second mechanism by which CD45 activity is regulated involves receptor dimerization. On the basis of crystal structure of a related phosphatase, RPTPα, it was predicted that the juxtamembrane and proximal catalytic domains of CD45 form dimers in which the catalytic site of one catalytic domain is blocked by a wedge formed by the juxtamembrane region of its partner. Consistent with this model, mice carrying a mutation of the conserved glutamic amino acid to arginine at the tip of the CD45 wedge domain develop lymphoproliferation and autoimmune nephritis, as also associated with hyperactive src kinases (Majeti et al., 2000). The different CD45 isoforms may vary in their capacity to form dimers (Hermiston et al., 2002). According to this hypothesis, the extensive *O*-linked glycosylation and sialylation found on the alternatively spliced exons 4, 5, and 6 render the large CD45RA isoforms expressed on naïve T cells more resistant to dimerization because of electrostatic repulsion. In contrast, the absence of this electrostatic barrier in CD45RO memory T cells promotes dimerization. This may explain the more effective signaling in memory T cells.

While CD45 promotes signaling via antigen receptors, it can dampen signaling by other receptor complexes. For example, CD45 negatively regulates integrin-mediated adhesion, an effect related to its ability to dephosphorylate Src kinases at integrin focal adhesion sites (Roach et al., 1997). Consistent with this function is the observation that CD45-deficient T cells and macrophages are abnormally adherent, a phenotype that is reversed by reconstitution of CD45 expression. As in the case of lymphocyte antigen receptor, a topological explanation underlies the regulatory function of CD45 in integrin-mediated adhesion (Thomas and Brown, 1999). Unlike the case of signaling via antigen receptors, where CD45 is excluded from the immunological synapse, CD45 co-localizes with integrin-centered focal adhesion sites. This serves to maintain Src kinases clustered at these sites under negative dephosphorylation pressure.

CD45 also exerts negative regulation upon signaling via cytokine receptors, where it acts to dephosphorylate receptor-associated Jak kinases (Irie-Sasaki et al., 2001; Penninger et al., 2001). CD45-deficient mice exhibit increased cytokine-dependent myelopoiesis and erythropoiesis and are resistant to otherwise fatal cardiomyopathy associated with Coxsackie virus B3 infection. Given that other molecules, such as SOCS (suppressor of cytokine signaling) and nonreceptor phosphotyrosine phosphatases SHP1 and SHP2, also contribute to negative regulation of Jak kinase activation, the precise role of CD45 in negative regulation of Jak kinase activation remains to be fully mapped.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Of the two original cases of CD45-deficient SCID, one was a boy born to unrelated Finnish parents (Kung et al., 2000) and the other was a girl born to consanguineous Kurdish parents (Cale et al., 1997; Tchilian et al., 2001) (Table 12.1). The Finnish child suffered from recurrent infections starting at 6 weeks of age, including candida skin and oral infections, recurrent otitis media, bronchitis, conjunctivitis, impetigo, gluteal abcess, and chronic rotavirus diarrhea. He had leukopenia, lymphopenia, and severe anemia with marrow erythroplasia

Table 12.1 CLINICAL FINDINGS IN TWO CD45-DEFICIENT PATIENTS

FACTOR	FINNISH	KURDISH
Age at presentation	6 weeks	2 months
Failure to thrive	Yes	Yes
Recurrent bacterial or viral infections	Yes	Not reported
Chronic rotavirus diarrhea	Yes	NR
Opportunistic infections	BCG, oral candidiasis	CMV
Bone marrow transplant	No	Yes
Terminal event	B-cell lymphoma	Reactivated CMV infection

Data from Cale et al. (1997); Kung et al. (2000); Tchilian et al. (2001).

BCG, bacillus Calmette-Guérin; CMV, cytomegalovirus.

Table 12.2 LYMPHOCYTE SUBPOPULATIONS IN HUMAN AND MURINE CD45 DEFICIENCY

	CELL COUNT (% OF PERIPHERAL LYMPHOCYTES)*		
	CD45 KNOCKOUT MICE	FINNISH PATIENT	KURDISH PATIENT
CD3	Depleted	Depleted (8.9%)	Depleted (14.9%)
CD3/4	Depleted	Depleted (0.9%)	Depleted (4%)
CD3/8	Depleted	Depleted (4.9%)	Decreased (20%)**
TCRαβ	Depleted	Depleted (2.2%)	NR
TCRγδ	Preserved	Normal (6.7%)	NR
NK	Preserved	Decreased (3%)	NR
B cells	Preserved	Normal (84.5%)	Normal (68.9%)

*Mice were deficient in CD45 exons 6, 9, and 12 (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999). Patients are from Cale et al. (1997); Kung et al. (2000); Tchilian et al. (2001).

**Percentage refers to total $CD8^+$ cells in the periphery.

NR, not reported.

requiring transfusions. Reticulocytes appeared in the blood at the age of 3 months and his hemoglobin levels normalized thereafter, but lymphopenia persisted. Having been vaccinated with bacillus Calmette-Guérin (BCG) at birth, he developed BCG infection at age 4 months and isoniazid treatment was instituted. Despite supportive therapy, he suffered from severe malnutrition and failure to thrive. He had unrelenting chronic diarrhea associated with persistent *Clostridium difficile* and rotavirus infection. Respiratory syncytial virus antigen test was repeatedly positive in his nasopharyngeal aspirate. At the age 1 year and 5 months, weighing 5.5 kg, he was evaluated for bone marrow transplantation (BMT), but he died soon thereafter from an aggressive B-cell lymphoma.

The Kurdish child presented at the age of 2 months with disseminated, postnatally acquired cytomegalovirus (CMV) infection associated with fever, rash, pneumonitis, lymphadenopathy, hepatosplenomegaly, and pancytopenia. She underwent BMT at the age of 8 months. Despite T-cell engraftment she experienced fatal CMV reactivation. The third patient presented at 6 months of age with failure to thrive and gastroesophageal reflux and at age 10 months had *Pneumocystis jiroveci* pneumonia and adenovirus. He had T and B lymphopenia and absent proliferation to PHA. He was rescued with a maternal T cell depleted haploidentical hematopoietic cell transplant, as well as antiviral and antibiotic therapy, at Duke University Medical Center in the U.S.; he survived with excellent T cell engraftment and function, though he still requires immunoglobulin supplementation (Roberts et al., 2012).

LABORATORY FINDINGS

The laboratory findings of human CD45 deficiency were in accord with animal models (Table 12.2), with patients demonstrating lymphopenia, with particularly depleted CD4 T cells. B cells were normal in number, but immunoglobulin levels were low. The natural killer (NK) cell population was decreased in the Finnish infant (3 percent). CD45 expression as determined by flow cytometry was either totally absent (Finnish and U. S. infants) or minimally present (Kurdish infant). Parents of all children had normal CD45 expression. Proliferative responses to mitogenic lectins were totally absent in all patients.

MOLECULAR BASIS

All reported patients suffered from autosomal recessive defects in the CD45 gene (Fig. 12.1). The Finnish infant carried a large deletion of the 3' end of the gene on one allele, while the other had a G-to-A transition at the invariant (+1) position of the donor splice site of intron 13, resulting in no expression of normal mRNA (Kung et al., 2000). The Kurdish infant had a homozygous 6 bp deletion at nucleotide 1168 in exon 11 of the CD45 gene, resulting in deletion of glutamic acid 339 and tyrosine 340 in the first fibronectin type III module of the CD45 extracellular domain (Tchilian et al., 2001). When a mutant CD45 cDNA carrying this 6 bp deletion was transfected into Chinese Hamster Ovary and mouse EL-4 thymoma cells, no protein was found at the cell surface, although it was detected at reduced levels intracellularly. This finding indicated that the deleted amino acids may contribute to the proper folding, stability, and/or correct localization of the mutant protein. The U. S. Duke patient was homozygous for cDNA 1618 A tcT, causing a stop codon at amino acid position 540 (K540X).

STRATEGIES FOR DIAGNOSIS AND TREATMENT

CD45 deficiency has a characteristic picture of T^- B^+ SCID with profound but not total T-cell depletion, absent

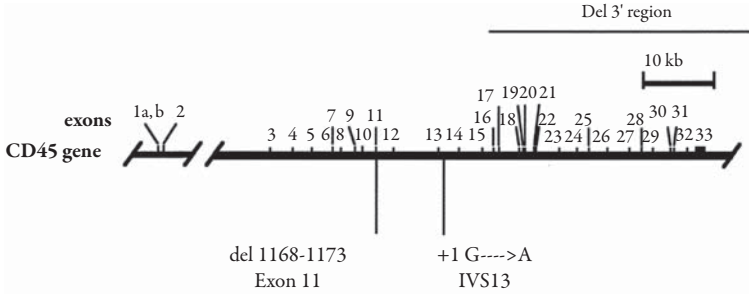

Figure 12.1 Genomic organization of CD45 gene organization. The mutations found in the affected infants are indicated. The Finnish infant suffered from a large deletion in the 3' region of the gene and a G → A substitution in the splice donor junction of intervening sequence (IVS) 13. The Kurdish homozygous 6bp deletion in exon 11, corresponding to nucleotides 1168–1173 of CD45 cDNA. The U. S. patient had a homozygous trunction mutation in exon 15 (not shaer).

proliferative responses to T-cell mitogens, and normal B-cell numbers. Little or no expression of CD45 was found on the surface of peripheral blood mononuclear cells in the cases discussed here. However, it is possible that loss-of-function CD45 mutations might retain expression of mutated protein; in such cases CD45 abnormalities can be excluded by evidence of normal signaling events triggered via TCR/CD3, including calcium mobilization and tyrosine phosphorylation. Alternatively, molecular lesions can be sought by DNA sequencing.

Definitive therapy for CD45 deficiency would be BMT. The fatal outcomes in the two patients reported point to the lethal nature of this immunodeficiency and the urgent need for timely immune reconstitution. As in other cases of SCID, the ideal transplant would be with bone marrow from a human leukocyte antigen (HLA)-matched sibling, followed by bone marrow from matched unrelated donors or HLA-haploidentical family members, as was successful in the Duke case.

ANIMAL MODELS

Studies of three different CD45 knockout mice, targeting exons 6, 9, and 12 respectively, have revealed a critical function for CD45 in thymocyte development (Byth et al., 1996; Kishihara et al., 1993; Mee et al., 1999). The most pronounced defect in the development in CD45-deficient thymocytes involves positive selection at the $CD4^+$ $CD8^+$ stage. This results in the exit into the periphery of only 5 to 10 percent of the expected number of mature T cells. Negative selection is also somewhat impaired. Both defects reflect reduced, though not totally absent, TCR signaling in CD45-deficient thymocytes, leading to a raised selection threshold. A constitutive active p56Lck mutant rescued thymocyte development in CD45-deficient animals, consistent with impaired activation of Lck as the principal underlying mechanism involved in ineffective selection of CD45-deficient thymocytes (Pingel et al., 1999; Seavitt et al., 1999). In the periphery, T-cell activation via the TCR, proliferation, and cytokine secretion in response to TCR ligation were abrogated.

As in humans, B-cell development was spared in CD45-deficient mice. However, B-cell proliferation in response to cross-linking of surface IgM was impaired (Benatar et al., 1996). A heightened signaling threshold also led to defects in positive and negative selection of maturing B cells, with impairment of the transition from IgM^{hi} IgD^{lo} to IgD^{hi} B cells. Negative selection at this stage was also impaired, also a reflection of attenuated BCR signaling (Cyster et al., 1996). T-cell independent B-cell responses were intact.

CONCLUSIONS AND FUTURE DIRECTIONS

The SCID phenotype associated with CD45 deficiency reflects the critical role played by this phosphatase in promoting antigen receptor signaling and in regulating the function of other signaling complexes, including cytokine receptors and integrins. CD45 deficiency expands the spectrum of immunodeficiency diseases associated with phosphotyrosine signaling pathways, including ZAP-70 and IL-7 receptor/common gamma chain/Jak3 kinase deficiency syndromes in T cells and Btk deficiency in B cells. It is plausible that CD45 deficiency represents the extreme end of a spectrum of CD45-related diseases associated with immunodeficiency, autoimmunity, and/or inflammation. Such disorders may result from selective defects in the expression of individual CD45 isoforms or abnormalities in CD45 function related to one or more receptor complexes. In mice, enhanced expression of particular CD45 isoforms in T-cell subsets has been associated with a number of autoimmune diseases (Penninger et al., 2001). In humans, a C/G polymorphism at nucleotide 77 in exon 4/A of CD45 that results in defective alternative splicing of exon 4/A has been associated with multiple sclerosis, although this association was not reproduced by other studies (Barcellos et al., 2001; Jacobsen et al., 2000; Vorechovsky et al., 2001). Future studies will further clarify mechanisms by which CD45 deficiency leads to SCID and the role of CD45 in other immunological diseases.

V(D)J RECOMBINATION DEFECTS

Jean-Pierre de Villartay, Mirjam van der Burg, Klaus Schwarz, and Anna Villa

The vertebrate cognate immune system recognizes and responds to a virtually infinite number of foreign antigens via antigen-specific immunoglobulin (Ig) or T-cell receptor (TCR) molecules expressed on the cell surface of B and T lymphocytes, respectively. While the Ig receptor of B cells binds to soluble antigens, the TCR receptor recognizes peptide antigens presented by human leukocyte antigen (HLA) molecules. In general, allelic exclusion prevents expression by a single lymphocyte of two different receptors encoded by homologous alleles. The expression of each distinct receptor is maintained in the clonal progeny of a lymphocyte.

V(D)J RECOMBINATION

Immunoglobulin and TCR chains each consist of two structural domains: their constant regions mediate effector functions, while the variable parts of the receptor chains form an antigen-binding pocket. Site-specific recombination events (VDJ recombination) in the receptor genes of each developing lymphocyte lead to generation and expression of a particular variable domain assembled from a set of subgenic segments classified as variable (V), diversity (D), and joining (J) elements (for review see Chapters 4 and 5, and Schlissel and Stanhope-Baker, 1997; Nemazee, 2000). In principle, each of the V elements can join to any of the D and J modules, thus allowing a finite number of subgenes to establish enormous antigen receptor diversity.

Seven gene loci encoding the Ig heavy (IgH) and light chains as well as the TCR α, β, γ, and δ chains can potentially undergo somatic DNA recombination during lymphocyte development. The loci share a similar conserved overall organization (Color Plate 13.IA); however, the precise number of subgenic segments and their organization vary between different loci and species (Litman et al., 1993).

The principle of V(D)J recombination is a simple cut-and-paste mechanism, fusing in each step two subgenic DNA segments (Plate 13.IB) (Lewis, 1994). This reaction is based on a universal tag for all V, (D), and J modules. These gene segments are flanked by recombination signal sequences (RSSs) (Plate 13.IA), which consist of a conserved heptamer and an AT-rich nonamer nucleotide motif, separated by a 12 ± 1 bp or 23 ± 1 bp spacer (Ramsden et al., 1994). Spacer length, therefore, defines two types of RSSs, termed 12-RSS and 23-RSS, and efficient recombination occurs only between a 12-RSS and a 23-RSS, a restriction called the *12/23 rule*. Additional regulatory effects of RSS sequence on recombination have been described (Bassing et al., 2000).

The V(D)J recombination reaction can be divided into two main steps involving several different subreactions (Table 13.1). The first part of the recombination process is lymphocyte-specific and comes about through an endonucleolytic cut in DNA leading to double-strand breaks (DSBs) at the border between the RSS heptamer and the flanking coding segment. In vivo, in a single V(D)J recombination reaction, four DNA ends are generated simultaneously through the synchronous cuts at two distinct gene segments: two blunt, phosphorylated signal ends and two hairpin-sealed coding ends. The second part of the V(D)J rearrangement involves the processing of the signal and coding ends, in which, ultimately, factors of a ubiquitous DNA double-strand repair pathway are recruited to link the signal and coding ends.

The standard products of V(D)J recombination result from ligation of the two coding elements (coding joints) and of the two heptamers of the RSS (signal joints). Depending on the orientation of the two RSSs to each other, the rearrangement process leads to a DNA deletion or inversion

(Plate 13.IC). Most rearrangement events stem from a deletion of the DNA connecting the recombined V(D)J elements and produce an extrachromosomal DNA circle with a signal joint (Fujimoto and Yamagishi, 1987; Okazaki et al., 1987). At the TCRβ, TCRδ, and Igα loci, inversions have been noticed (Feddersen and van Ness, 1985; Malissen et al., 1986; Korman et al., 1989), with a slight preference of deletions over inversions (Hesse et al., 1987). V(D)J recombination can result in alternative products such as "hybrid" or "open-and-shut" junctions (Plate 13.IC). *Hybrid joints* arise through the ligation of one coding end to the signal end of the other. In an *open-and-shut joint*, which is less common, the signal and coding ends created by site-specific cleavage are modified prior to their religation (Lewis, 1994). These alternative products are rare events, but they obey the rules of V(D)J recombination and are indicative of the notion that four open DNA ends are intermediates in the rearrangement process. The signal ends are usually ligated without modification of the DNA (Lieber et al., 1988). In contrast, joining of coding ends is generally imprecise, with base losses and/or additions (N and P nucleotides) of approximately 10 to 15 nucleotides. This process helps to diversify the receptor repertoire but introduces the risk of creating nonfunctional genes because of out-of-frame joining and/or introduction of premature stop codons. The enzyme terminal deoxynucleotidyl transferase (TdT) adds random, GC-enriched nucleotides (N nucleotides) to coding ends by a template-independent polymerization. P nucleotides represent short, palindromic repeats of coding end DNA. They are thought to be generated when the "hairpin," a coding end intermediate of the V(D)J recombination reaction (Color Plate 13.II), is resolved through an endonucleolytic attack, not at the tip of the covalently closed termini but within the coding element. Other mechanisms contributing to junctional diversity are erosion of a small and variable number of bases at coding ends by exo- or endonucleases, and homology joining through short-sequence homologies at free DNA ends (for review see Fugmann et al., 2000a).

The "recombinase" machinery, a multiprotein complex, is responsible for the V(D)J recombination. Nine proteins have been identified thus far as participating in the various steps of the V(D)J recombination reaction (Table 13.1), and the proteins the mediate recombination are listed in Table 13.2. The recombination activating genes 1 and 2 (*RAG1* and *RAG2*) encode proteins necessary and sufficient to initiate V(D)J recombination at an accessible antigen receptor gene locus (McBlane et al., 1996). The second step of this reaction requires the Artemis protein encoded by the gene *DCLRE1C* in addition to RAG1/RAG2 processing of the coding end intermediates. The template-independent DNA polymerase TdT adds N nucleotides and contributes substantially to receptor diversity. The DNA-dependent protein kinase (DNA-PK), with its DNA binding constituents KU70 and KU80 and its catalytic subunit DNA-PKcs, recognizes open DNA ends. XRCC4 (the gene product responsible for the defect of cells of group 4 of X-ray cross-complementing cell lines) seems to interact with Ligase IV in the ligation step of DNA DSB repair. *Cernunnos/XLF*, a recently identified NHEJ gene structurally related to XRCC4, participates in the same complex together with Ligase IV. Despite this recent progress, many different factors of the recombinase machinery (*trans-acting* factors for locus accessibility and exo- and endonucleases) are still unknown. Of the identified factors, the *RAG1*, *RAG2*, *LIG4*, *DCLRE1C (Artemis*), *NHEJ1 (Cernunnos/XLF)*, and *PRKDC (DNA-PKcs)* genes have been implicated in inborn immunodeficiencies (Table 13.2) (Buck et al., 2006; Corneo et al., 2000; Moshous et al., 2001; O'Driscoll et al., 2001; Schwarz et al., 1996; van der Burg et al., 2009; Villa et al., 1998).

Table 13.1 **MECHANISTIC STEPS IN V(D)J RECOMBINATION AND PROTEINS INVOLVED***

STEPS	PROTEINS
Lymphocytes-Specific Steps	
1. Locus accessibility	?
2. RSS recognition and nicking	RAG1 + RAG2
3. Synapsis of RSS	RAG1 + RAG2+?
4. Hairpin formation	RAG 1 + RAG2
General DNA Double-Strand Break Repair Steps	
5. Hairpin opening	Artemis and RAG1 + RAG2
6. Modification of coding ends	TdT + exonuclease(s)?
7. Recognition of DNA double strand. Disassembly of synaptic complex	DNA-PKcs + Artemis
8. Ligation	XRCC4 + Ligase IV+ Cernunnos

RSS, recombination signal sequence; TdT, terminal deoxynucleotidyl transferase.
*Alternative models suggest that steps 2 and 3 are interchangeable and that step 7 may precede steps 5 and 6.

COMPLETE *RAG1* AND *RAG2* | DEFICIENCY (B^- T^- SCID)

HISTORY

Siblings with diarrhea, candidiasis, lymphopenia, and diminished lymphoid tissue were first described by Glanzman and Riniker (1950). Thymic dysplasia and hypogammaglobulinemia were subsequently analyzed in new cases (Cottier, 1958; Hitzig et al., 1958). Knowledge of the antigen receptor gene structures and their processing allowed the definition of recombinase defective patients (Abe et al., 1994; Schwarz et al., 1991). A subgroup of patients with defective V(D)J recombination exhibited *RAG1/2* mutations (Schwarz et al., 1996).

DEFINITION

The functional failure of one of the constituents of the V(D) J recombinase machinery, such as RAG1 or RAG2, MIM (Mendelian Inheritance in Man) numbers 179615 and 179616, respectively, results in a SCID without B or T cells (B^- T^- SCID).

Table 13.2 CONSTITUENTS OF THE RECOMBINASE MACHINERY

	HUMAN GENE LOCUS	HUMAN DISEASE	CELL LINES
RAG1	11p13	SCID	AMuLV-transformed pre-B cells
RAG2	11p13	SCID	AMuLV-transformed pre-B cells
TdT	10q23–24	–	–
Ku80	2q33–35	–	XRCC5 cells (xrs5, 6, XR-V9B, XR-V15B, sxi-1, -2, -3, etc.)
Ku70	22q13	–	XRCC6
DNA-PKcs	8qll	RS-SCID	XRCC7
XRCC4	5q13	–	XRCC4
Ligase IV	13q33–34	Leaky SCID	Human fibroblast
Artemis	10p13	RS-SCID	Human fibroblast
Cernunnos	2q35	RS-SCID	Human fibroblast

AMuLV, Abelson murine leukemia virus; DNA-PKcs, DNA-protein kinase–dependent catalytic subunit; KO, artemis legend accordingly.

CLINICAL MANIFESTATION

Severe combined immunodeficiency (SCID) has an estimated incidence of approximately 1 per 100,000 live births (Stephan et al., 1993). In the original report, 6 of 30 SCID cases analyzed exhibited a RAG1 or RAG2 defect; thus the RAG deficiencies may account for a substantial proportion of human SCID cases (Schwarz et al., 1996). In a larger series, about 20 percent of SCID cases were RAG deficient (Villa et al., 2001; reviewed in Sobacchi et al., 2006). The clinical presentation is relatively uniform. As a rule, no symptoms are detected during pregnancy, at birth, or within the first few weeks of life. In most cases, the symptoms start within the second or third month after birth. Infectious complications are the hallmark of the disease, with a high preponderance of opportunistic infections (e.g., *Pneumocystis jiroveci* infection). The clinical presentation is characterized by chronic, persistent disease of the airways, recurrent acute pneumonia, therapy-resistant mucocutaneous candidiasis, eczematous dermatitis, and local as well as systemic bacterial infections (otitis, mastoiditis, purulent rhinitis and conjunctivitis, systemic sepsis, meningitis, arthritis, and localized abscesses). The recurrent infections as well as chronic enteritis lead to growth failure. Furthermore, intracellular pathogens (*Listeria*, *Legionella*) as well as viruses (Epstein-Barr virus [EBV] and cytomegalovirus [CMV]) may cause lethal complications.

Noninfectious clinical manifestations may result from graft-versus-host disease (GVHD). Because of the immunodeficiency, patients cannot reject allogeneic cells. Allogeneic cells can be introduced into patients either through maternofetal transfusion at the time of birth or by supportive transfusion therapy with nonirradiated blood products. While GVHD due to maternal lymphocytes is usually relatively mild with erythroderma, eosinophilia, enteritis, and hepatitis, GVHD following unirradiated transfusion is frequently lethal. Vaccination with living organisms such as application of the bacillus Calmette-Guérin (BCG) strain may cause disseminated disease with fatal consequences. All SCID children die within a few months if they are not provided with hematopoietic stem cells to restore functional T-cell immunity. Physical examination of completely RAG-deficient patients reveals unusual infections and a characteristic absence of lymphatic organs. In most cases cervical lymph nodes and tonsils are undetectable.

LABORATORY FINDINGS

Patients lacking RAG1 or RAG2 exhibit no B or T cells of their own in the peripheral blood ($B^- T^-$ SCID) (Table 13.3). Maternal T lymphocytes can be detectable in some cases and functional natural killer (NK) cells are present. After loss of the initially present maternal transplacentally transfused IgG, no antibodies circulate in the peripheral blood of RAG-deficient patients. In vivo and in vitro functional lymphocyte tests are abnormal because of the lack of the respective cells.

The RAG1 and RAG2 deficiencies are autosomal recessive diseases. Both genes are located on chromosome 11p 13 (Oettinger et al., 1992; Schwarz et al., 1994). Carriers of the mutant genes are healthy without any immunological disturbances and are therefore detected only through molecular identification of a mutation identified in the affected patient. A $B^- T^-$ SCID phenotype in umbilical cord blood may suggest, among other gene defects, a *RAG* mutatnt genotype that must be confirmed by molecular analysis.

RAG GENE STRUCTURE AND FUNCTION

The murine *Rag1* and *Rag2* genes were initially identified and cloned on the basis of their ability to rearrange an integrated artificial recombination substrate in a cell line (Oettinger et al., 1990; Schatz et al., 1989). The two complementing genes show a unique organization. Their 3' ends face each other and are

separated in human DNA by 15–18 kb. The coding sequences and the 3' untranslated region (UTR) of each gene is located in a single exon (Ichihara et al., 1992). *RAG1* possesses one extra 5' UTR exon, whereas in the *RAG2* locus at least two 5' UTR exons have been identified (Lauring and Schlissel, 1999). The amino acid sequence of both RAG genes and the overall genomic organization are highly conserved throughout evolution from sea urchins to humans (Bernstein et al., 1994; Fugmann et al., 2006; Wienholds et al., 2002). The human *RAG1* gene encodes 1403 amino acids; the *RAG2* gene, 527 amino acids.

RAG1 and RAG2 protein sequences are not related to each other. A sequence comparison of RAG1 with other proteins shows that RAG1 possesses five basic regions that are necessary for nuclear localization (binding sites for nuclear protein SRP1 and RCH1), a region with homology to bacterial invertases and homeodomain proteins, zinc finger domains, and a zinc binding dimerization motif (Plate 13.III) (Rodgers et al., 1996; Silver et al., 1993; Spanopoulou et al., 1996). Extensive mutagenesis of acidic amino acids in RAG1 identified three catalytic residues (D600, D708, and E962, the so-called DDE motif) critical for both nicking and hairpin formation (Landree et al., 1999); two of these (D600 and D708) coordinate catalytic divalent metal ions (Fugmann et al., 2000b; Kim et al., 1999; Landree et al., 1999). These residues are located in a region that displays marked conservation in predicted secondary structure with the catalytic cores of other transposases (Fugmann et al., 2000b). Further insight into RAG1 activities has been derived from mutants blocking the hairpin formation, which are all in the vicinity of D600 (Kale et al., 2001). Two regions of RAG1, the nonamer binding domain and the carboxyterminal domain, contact DNA containing the coding flank at the cleavage site (Mo et al., 2001). Recently, a RAG1 nonamer binding domain (NBD) has been demonstrated to form a tightly interwoven dimer that binds and synapses two nonamer elements, with each NBD making contact with both DNA molecules. Biochemical and biophysical experiments have confirmed that the two nonamers are in close proximity in the RAG1/2-DNA synaptic complex (Yin et al., 2009).

The molecular roles of RAG2 in V(D)J recombination are less known. The presence of RAG2 is required for all catalytic steps and helps to form the RAGRSS complex. Secondary structure prediction and mutagenesis studies have suggested that RAG2 adopts a six-bladed β-propeller fold (Fig. 13.1) (Callebaut and Mornon, 1998; Corneo et al., 2000; Gomez et al., 2000), a structural motif found in many proteins of

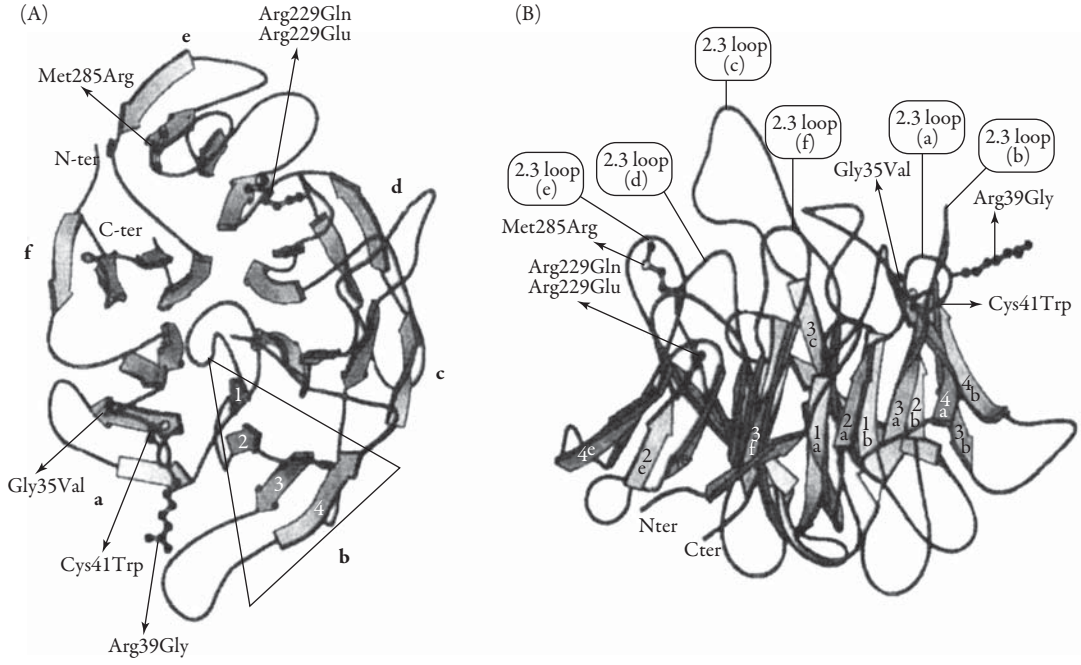

Figure 13.1 (A) Beta-propeller structure of RAG2. Each blade of the propeller consists of a four-stranded beta sheet. (B) Beta-propeller structure viewed along the perpendicular axis. Mutated amino acids are indicated.

diverse function (Adams et al., 2000). The core region of RAG2 (aa 1–382 out of 527) assists RAG1 interaction with the RSS and is essential for DNA distortion. The C terminus of RAG2 includes a hinge domain with a high percentage of acidic residues that connects the core region to a noncanonical plant homeo domain (PHD) finger (Callebaut and Mornon, 1998; Corneo et al., 2002; Elkin et al., 2005), which overlaps a phosphorylation site at residue T490 implicated in the cell-cycle-regulated degradation of RAG2 (Li et al., 1996; Lee and Desiderio, 1999; Lin and Desiderio, 1993; Ross et al., 2003). Furthermore, this region has been implicated in binding to the core histone proteins (West et al., 2005). Importantly, in B cells the C-terminal region of RAG2 is important for IgH V to DJ rearrangement (Kirch et al., 1998).

Another role of RAG proteins is their ability to catalyze in vitro transpositional insertion, which suggests that this process could be a source of genomic instability in vivo (Agrawal et al., 1998; Hiom et al., 1998). Indeed, RAG transposase forms productive complexes with target DNA both before and after RSS cleavage, and these show a preference for transposition into nearby targets, such as Ig and TCR loci. This could bias transposition toward relatively safe regions in the genome (Neiditch et al., 2001). In addition, the transposition events are stimulated and targeted by the presence of distorted DNA structures such as hairpins. Because there is no evidence that RAG-mediated transposition occurs in vivo, it is likely that regulatory mechanisms limit the frequency of transposition events in lymphocytes. During lymphocyte development in adults, the *RAG* genes are convergently transcribed in thymic and bone marrow cells with a capability for V(D)J recombination (Oettinger et al., 1990; Schatz et al., 1989). Mature RAG proteins are localized to the nucleus in developing thymocytes. RAG expression is first detected in committed double-negative (DN) thymic T-cell precursors, whereas the first B cells expressing RAG1 and RAG2, at very low levels, are AA 4.1^+ HAS^- $B220^+$ $CD4^+$ $CD43^+$. RAG expression increases as B cells mature. Following the proliferative expansion of pre-B and pre-T cells, a second wave of RAG expression is initiated in $CD25^+$ pre-BII B lineage cells and $CD4^+$ and $CD8^+$ double-positive (DP) early T cells. This second expression has been shown to be regulated by elements at the 5' end of RAG2 promoter (Yu et al., 1999). RAGs are not expressed in mature T cells. Immunohistochemical analysis detected RAG expression in germinal centers in the mouse (Han et al., 1996; Hikida et al., 1996); however, transgenic indicator and gene-targeted indicator lines proved that the small number of cells expressing RAG are immature B cells (reviewed in Nagaoka et al., 2000).

It has been suggested that a RAG1/RAG2 complex nucleates a specialized subnuclear compartment named the V(D)J recombination factory (Matthews and Oettinger, 2009). This molecular machine does more than merely catalyze the phosphoryl-transfer reactions during DNA DSB generation. In addition to cutting DNA, the RAG1/RAG2 complex interacts with methylated histones (H3K4me3), stimulating the complex to perform both nicking and hairpinning in *trans* in addition to tethering in *cis* (Shimazaki et al. 2009). The complex is involved in immunoglobulin allelic pairing and helps determine whether the V(D)J recombination DNA breaks will be repaired by classical NHEJ (cNHEJ), altenative NHEJ (aNHEJ), or homologous recombination.

MUTATION ANALYSIS

Mutagenesis experiments have defined core regions for RAG1 and RAG2 that are necessary and sufficient to recombine extrachromosomal V(D)J recombination substrates. The RAG1 core includes amino acids 392–1011, whereas the RAG2 core extends from amino acids 1–382 (Cuomo and Oettinger, 1994; Sadofsky et al., 1993, 1994; Silver et al., 1993). After the first description of T^- B^- SCID cases with RAG defects, many additional mutations have been detected in RAG1 and RAG2 (Corneo et al., 2000, 2001; Gomez et al., 2000; Sobacchi et al., 2006; Villa et al., 2001). Mutation analysis of RAG1 and RAG2 (http://bioinf.uta.fi/RAG1base and http://bioinf.uta.fi/RAG2base) indicates that most are null mutations (nonsense or frameshift). In addition, although some patients with classical T^- B^- SCID bear missense mutations, biochemical studies have shown that these amino acid changes completely abrogate recombination and therefore represent functionally null alleles (Corneo et al., 2000; Gomez et al., 2000; Schwarz et al., 1996). In transient transfection assays with artificial extrachromosomal rearrangement substrates, the mutants derived from completely RAG-deficient SCID patients show only residual recombination values that are typically 0.1 to 1 percent of wild type for both coding and signal joint formation. Pre-B and pre-T cells do not survive during lymphocyte development if they do not obtain a survival signal from their respective pre-B and pre-T cell receptors. The heavy chain of the IgM molecule and the TCR chain are necessary constituents of the respective receptors. In complete RAG deficiency, V(D)J recombination cannot be initiated; thus IgM and TCR chains are not synthesized and pre-B or pre-T cell receptors are not expressed. Such precursor lymphocytes receive no survival signals and consequently are eliminated, hence the alymphocytosis in patients with complete RAG1 and RAG2 deficiency.

DIAGNOSIS

At present, no simple functional test exists to reveal a V(D)J recombinase defect in general or a specific RAG defect. Protein analysis is not a practical alternative because the recombining cells are a minority within the bone marrow or require a thymic biopsy. Thus, direct sequencing of *RAG* gene DNA is essential, with functional assessment of effect on recombination by in vitro analysis if necessary.

TREATMENT

Treatment of RAG-defective children consists of a combination of supportive measures (see Chapter 59) and curative therapy by hematopoietic stem cell transplantation (HSCT) (see Chapter 60). An HLA-identical donor is no longer a prerequisite for reconstitutive HSCT, since depletion of T cells

from a nonidentical graft omits or greatly reduces the risk of GVHD. When indicated, patients may be transplanted prior to conditioning because their immunodeficiency makes graft rejection unlikely. Survival after transplantation in RAG-deficient SCID is historically around 65 percent. In utero bone marrow transplantation (BMT) has been performed in selected patients (Pirovano et al., 2004). An alternative therapeutic approach could be gene therapy (Cavazzano-Calvo et al., 2000; Fischer et al., 2002; Lagresle-Peyrou et al., 2008). Although there have been no studies of *RAG2* gene therapy in humans, experiments of retrovirally mediated *Rag2* gene transfer in hematopoietic stem cells of *Rag2* knockout mice showed good results (Yates et al., 2002). Recently, Wagemaker et al. developed new third-generation lentivital vectors carrying a *Rag2* gene able to overcome the T- and B-cell block in the *Rag2* knockout mouse, thus opening the door to clinical application (N. van-Til, personal communication).

ANIMAL MODELS OF RAG1/2 DEFICIENCY

Mice with homozygous deletions of *Rag1* or *Rag2* have been created by gene targeting (Mombaerts et al., 1992; Shinkai et al., 1992). Both exhibit an identical phenotype to that of each other and of human RAG-deficient patients. The animals cannot initiate V(D)J recombination, and thus lack B and T cells. B-cell development is halted at the pre-B cell stage (Diamond et al., 1997; Mombaerts et al., 1992; Shinkai et al., 1992). Functional defects in Rag-deficient mice appear limited to the immune system. One report stated that Rag1 knockout mice had increased locomotor activity and reduced levels of fearfulness (Cushman et al., 2003).

Rag2 mice generated by replacing the endogenous Rag2 locus with core Rag2 lacking the "dispensable" C-terminal domain had reduced B- and T-cell numbers (Akamatsu et al., 2003; Liang et al., 2002). This finding demonstrated that the C-terminal domain, which is dispensable for V(D)J recombination in vitro, nonetheless has relevant functions in vivo.

PARTIAL *RAG1* AND *RAG2* DEFICIENCY (OMENN SYNDROME)

Omenn syndrome (OS) (MIM 267700) is a rare disorder that was long an enigma for pediatricians and immunologists (Omenn, 1965). OS is a rare autosomal recessive disease characterized by symptoms of SCID plus erythroderma, eosinophilia, hepatosplenomegaly, lymphadenopathy, and elevated serum IgE levels, suggesting a defect in the activation and/or regulation of T-cell proliferation. The identification of specific mutations of *RAG* genes in OS patients made it clear that the underlying defect affects the maturation of both T and B lymphocytes and that T cells are activated secondary to a partially defective V(D)J recombination process (Villa et al., 1998). However, the occurrence of the same RAG gene mutations in patients with T^- B^- SCID as with OS raises the possibility that additional factors such as epigenetic factors influence development of the Omenn phenotype (Corneo et al., 2001; Villa et al., 2001).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Patients with OS have early-onset generalized erythroderma, lymphoadenopathy, hepatosplenomegaly, fever, protracted diarrhea, and failure to thrive (Plate 13.IV, Table 13.4). Protein loss due to diarrhea and exudative erythroderma often leads to generalized edema. The presence of a massive inflammatory infiltrate gives the skin a unique appearance and consistency (pachydermia). Alopecia is frequent (Aleman et al., 2001). Despite the presence of lymph nodes and variable, often elevated, numbers of circulating T lymphocytes, OS patients are highly susceptible to bacterial, viral, and fungal infections. Unless treated by HSCT the disease is invariably fatal. Infections and malnutrition are the main causes of death (Gomez et al., 1995). Septicemia, often arising from skin infections, is common. The clinical hallmarks of the disease are reminiscent of GVHD. Indeed, in some cases the occurrence of maternal T-cell engraftment or unirradiated blood-product transfusion in infants with SCID may result in clinically overt GVHD and mimic OS (Anderson and Weinstein, 1990; Le Deist et al., 1987; Pollack et al., 1982). For a diagnosis of OS, it is therefore essential that, in addition to typical clinical and laboratory findings, allogeneic T-cell engraftment be excluded. The similarity of OS to GVHD is further reinforced by the pathological features of OS. Skin biopsies reveal lymphocytic infiltrates in the upper dermis, with occasional histiocytes and eosinophils (Dyke et al., 1991). Immunohistochemical analysis shows that the lymphocytic infiltrate is composed of activated ($CD45RO$, DR^+) T cells, many of which co-express CD30, a surface molecule associated with Th2-type cytokine secretion (Chilosi et al., 1996b). The differential diagnosis of OS includes severe atopic dermatitis, GVHD, and histiocytosis X, known as Letterer Siwe syndrome (Aleman et al., 2001). Lymph node enlargement, typically observed in OS, is in contrast to the paucity of peripheral lymphoid tissue usually detected in patients with combined immune deficiencies. However, the lymph node architecture is severely altered in OS, with lack of follicles, depletion of the normal lymphocytic population, and increased proportion of interdigitating reticulum cells and eosinophils (Barth et al., 1972; Dyke et al., 1991; Martin et al., 1995; Omenn, 1965). On the basis of these findings, the disease was originally also named *familial reticuloendotheliosis with eosinophilia* (Omenn, 1965) or *combined immunodeficiency and reticuloendotheliosis with eosinophilia* (Ochs et al., 1974). Immunohistochemistry indicates that the lymphocytic component in the lymph nodes is similar to that in skin infiltrates (Brugnoni et al., 1997; Chilosi et al., 1996a, 1996b). Interestingly, staining with BlimpI and CD138 reveals the presence of positive immunoglobulin secreting cells (ISCs) in the lymph nodes of the patients (Cassani et al., 2010). The splenic white pulp, Peyer's patches, and lamina propria of the gut are also markedly depleted of lymphocytes. The thymus, which is profoundly hypoplastic, has a noticeable depletion of lymphoid components and often lacks Hassall's bodies (Barth et al., 1972; Businco et al., 1987). Indeed thymic biopsies obtained from OS patients have allowed the evaluation of the thymic architecture and cellular distribution, with particular

attention to the presence of dendritic cells (DCs) and natural regulatory T cells (nTreg). Analysis of medullary thymic epithelial cells showed in the OS thymus absence of Aire expression, a transcription factor driving the expression of tissue restricted antigens that are presenting to autoreactive T cells, inducing deletional central tolerance (Cavadini et al., 2005). Furthermore, immunohistochemical analysis with S100, CD11c, and Foxp3, staining DCs and nTreg respectively, showed virtual absence of thymic DCs and lack of Foxp3+ cells (Poliani et al., 2009). All these findings, the lack of Aire expression, the severe depletion of thymic Foxp3+ cells may provide a mechanism to explain the pathophysiology of autoimmune manifestations in Omenn syndrome.

LABORATORY FINDINGS

As summarized in Table 13.4, the main laboratory findings in OS consist of eosinophilia, hypogammaglobulinemia with increased serum IgE, presence of activated circulating T lymphocytes, in contrast to the usual lack of peripheral blood B cells, and a poor in vitro proliferative response of T lymphocytes to specific antigens (with variable responses to mitogens). Additional laboratory findings include anemia (and sometimes thrombocytopenia) and hypoproteinemia due to protein loss through the stools and the skin. In contrast to most forms of combined immunodeficiency, the total number of circulating T cells is variable but often elevated (Table 13.3). Distribution of the main T-cell subsets (i.e., CD4 vs. CD8) is frequently imbalanced (Brugnoni et al., 1997; Businco et al., 1987; Karol et al., 1983; Le Deist et al., 1985). An extreme example of the variability in T-cell number in OS (which offered a crucial clue to the molecular basis of the disease) is represented by a pedigree in which one patient had typical OS with increased circulating T cells, whereas one of his younger brothers died with T^- B^- SCID (de Saint Basile et al., 1991).

Table 13.4 **DIAGNOSIS OF OMENN SYNDROME: CLINICAL AND LABORATORY HALLMARKS**

Clinical Features
Early-onset, generalized erythroderma
Failure to thrive
Protracted diarrhea
Edema
Lymphadenopathy
Hepatosplenomegaly
Severe infections (pneumonia, sepsis)
Laboratory Features
Hypoproteinemia
Frequent anemia, thrombocytopenia
Remarkable eosinophilia (usually >1,000/μL)
Very low IgG, IgA, and IgM, but usually increased IgE
Very low or absent circulating B cells
Variable (often elevated) number of activated ($CD45R0^+$, DR^+) circulating T cells
Very low in vitro proliferative responses to antigens, variable response to PHA
Low, IgM-restricted, antibody responses

Many of the immunological hallmarks of OS reflect the presence of activated T cells skewed to a Th2 phenotype. Similar to skin and lymph nodes, circulating T cells express activation markers (CD45R0, DR, CD25, CD95, CD30) and secrete Th2-type cytokines (IL-4, IL-5) upon in vitro activation. Accordingly, serum levels of IL-4 and IL-5 are increased. In contrast, serum levels and in vitro production of IL-2 and IFN-γ are reduced (Brugnoni et al., 1997; Chilosi et al., 1996a; Schandene et al., 1993). The IL-4 and IL-5 may drive increased production of IgE and eosinophilia, respectively. Finally, invariant natural killer T (iNKT) cells, important immunoregulatory cells, are absent in OS patients (Matangkasombut et al., 2008).

Although serum IgG, IgA, and IgM are markedly reduced in OS, specific antibody production is not completely impaired (Le Deist et al., 1985), indicated by a measurable although low and IgM-restricted response to immunization with bacteriophage x174 (Ochs et al., 1974). Hypogammaglobulinemia is partially due to protein loss but also reflects defective B-cell differentiation, with a very low or absent number of circulating B cells. Because B lymphocytes are usually undetectable in the lymph nodes and the gut, it remains unknown where the IgE secretion occurs. Although T lymphocytes are consistently present and show an activated phenotype, they are functionally defective, with reduced proliferative responses to antigens and occasionally to mitogens as well (Brugnoni et al., 1997; Businco et al., 1987; Harville et al., 1997; Le Deist et al., 1985). Oligoclonality of circulating T cells has been consistently described in OS (de Saint Basile et al., 1991; Harville et al., 1997; Rieux-Laucat et al., 1998; Villa et al., 1998; Wirt et al., 1989). Although the use of distinct variable (V) gene segments is not particularly biased, few clones are expanded within each population of T cells that express specific V genes, as demonstrated by sequence analysis showing sets of identical V(D)J sequences (Harville et al., 1997; Villa et al., 1998). It has been hypothesized that restriction of the TCR repertoire could arise in the periphery or in the thymus. Analysis of T cells from both thymus and peripheral blood from a deceased OS patient demonstrated that the TCRβ repertoire was already restricted in the thymus, although further selection occurred in the periphery (Pirovano et al., 2003; Signorini et al., 1999). Defects in regulatory T cells leading to a breakdown of peripheral tolerance have been described, along with a defect in central tolerance explaining the occurrence of autoimmune manifestations (Cassani et al., 2010a; Somech et al., 2009).

MUTATION ANALYSIS IN PATIENTS WITH OMENN SYNDROME

The rarity of OS made positional cloning of a responsible gene impossible, and as mentioned above, the unique clinical picture of OS gave few reasons to suspect that *RAG* mutations could be the cause. However, one hint came from descriptions

of the occurrence of OS and SCID within members of the same family (de Saint Basile et al., 1991). Gene identification was also complicated by the similarities between OS and SCID with GVHD. Nevertheless, the analysis of *RAG* genes showed mutations in OS patients (Corneo et al., 2001; Villa et al., 1998). To explain why a defect in the same genes can give rise to such different phenotypes, factors such as genetic background, modifier genes, and epigenetic events were evoked. However, it is now clear that mutations in different domains of the *RAG* genes can affect the protein structure to various extents, leading either to null alleles or to hypomorphic alleles retaining variable degrees of function. Careful analysis supports the hypothesis that while SCID represents "null" RAG alleles, the OS phenotype is caused by RAG alleles that retain partial V(D)J recombination activity. According to this view, OS is a "leaky" SCID, allowing some degree of maturation along the T-cell lineage to occur. In contrast to the mutations noted in T^- B^- SCID patients, OS patients show predominantly missense mutations, with at least one missense mutation present in every patient. This finding, together with the presence of oligoclonal cells in the periphery, led us to suggest that limited V(D)J recombination events occur in these patients. Biochemical assays analyzing the capacity to mediate full V(D)J recombination events, *SCC* formation, and the introduction of DSBs revealed that the proteins containing missense mutations had reduced but still detectable activity. Hence, in general, SCID patients have two entirely defective alleles, whereas OS patients have at least one allele that is partially functional and capable of establishing the restricted receptor repertoire seen in OS (Corneo et al., 2001; Kumaki et al., 2001; Noordzij et al., 2002; Villa et al., 1998, 2001; Wada et al., 2000).

Particularly interesting is the description of OS cases with alleles carrying nucleotide deletions in the N-terminal domain. In fact, an N-terminus-truncated active RAG1 protein is generated from these alleles by reinitiation from internal in-frame methionine residues downstream of the deletion (Noordzij et al., 2000; Santagata et al., 2000). The biochemical analysis of both null and hypomorphic mutations in *RAG1* and *RAG2* have provided valuable insights into the biology of the RAG1/RAG2 recombinase. The importance of the NBD has been reinforced by the finding that over 30 percent of *RAG1* mutations in OS patients result in amino acid substitutions in the NBD, a region spanning only 4 percent of the molecule.

The structural model of Rag2 as a six-bladed β-propeller with a C-terminal PHD finger has been supported by functional data from a number of identified OS and SCID mutations. Amino acid substitutions in three SCID patients were localized to the second β strand of the first, second, and fourth kelch repeats of RAG2 and were shown to abrogate the V(D)J recombination activity of the altered proteins (Corneo et al., 2000; Gomez et al., 2000). Moreover, many of the null and hypomorphic RAG2 active core mutations have a spatial clustering on one face of the predicted β-propeller, thereby defining a potentially critical surface for interaction with RAG1 (Corneo et al., 2000). Further support of the structural model of RAG2 has been provided by the identification of four mutations leading to amino acid substitutions in the C-terminal PHD finger (C423Y, W453R, N474S, and C478Y). The W453R substitution was identified in an OS patient and has residual levels of recombination activity (Gomez et al., 2000), while the other three substitutions were found in T^- B^- SCID patients and are likely inactive for recombination. Two of the altered amino acids, C423 and C478 (Schwarz et al., 1996, A. Villa et al., unpublished results), are predicted to coordinate zinc ion and are therefore entirely conserved in all known PHD fingers.

Finally, the importance of hypomorphic RAG mutations in sustaining the OS phenotype is also demonstrated by the case of an infant who presented with T^- B^- SCID because of homozygosity for a null RAG1 mutation and then developed a typical OS phenotype because of somatic mosaicism with multiple second-site mutations that restored RAG1 expression (Wada et al., 2005).

MUTATION ANALYSIS IN PATIENTS WITH ATYPICAL AND LEAKY SCID

The analysis of a large series of immunodeficient cases with RAG defects has permitted the identification of a new group of patients with some, but not all, of the clinical and immunological features of OS, a condition we call "atypical SCID/OS." In molecular terms this category appears more like OS than classic SCID because all of patients carry at least one missense mutation, some of which are also found in OS patients. This finding supports the idea that in these atypical patients, partial RAG activity is responsible for the development of a low number of T and possibly B lymphocytes. A third phenotype, characterized by mutations in RAG1, CMV infection, and oligoclonal expansion of TCRγδ T cells, has been described by two independent groups (de Villartay et al., 2005; Ehl et al., 2005), demonstrating that environmental factors can add to the complexity of the clinical and immunological phenotype.

An additional phenotype of hypomorphic RAG combined immunodeficiency (CID) was characterized by granulomas in the skin, mucous membranes, and internal organs. All patients had severe complications after viral infections, including B-cell lymphoma associated with EBV. Other findings were hypogammaglobulinemia, a diminished number of T and B cells, and sparse thymic tissue on ultrasonography. Moreover, the patients were diagnosed as children (3 to 11 years), demonstrating that "classical" SCID genes must be considered in the diagnostic workup of childhood presentation of CID (Schuetz et al., 2008).

Overall, these findings indicate that partial RAG activity may be a prerequisite for OS or CID, but other epigenetic factors are needed to understand the disease (Corneo et al., 2001; Villa et al., 2001). Alternatively, it is possible that individual differences such as early or delayed medical treatment could contribute to clinical and immunological heterogeneity, particularly because some patients undergo HSCT very early in the course of the disease and this treatment could prevent the development of typical OS findings.

However, not all cases of OS are due to defects in RAG genes. OS was also identified in one patient with mutations in the DLCRE1C gene, encoding Artemis, a factor mediating hairpin coding end opening during the V(D)J recombination process (Ege et al., 2005). The patient was a compound heterozygote; 1 allele carried a hypomorphic mutation (M1T) that preserved residual V(D)J activity (2.1 to 2.7 percent). Moreover, mutations in DNA-ligase IV were reported to cause features of OS (Grunebaum et al., 2008). Interestingly mutations in this gene have been previously found in a variety of clinical settings, including leukemia, lymphoma, and bone marrow failure, and in a subset of patients with absent T and B cells (Enders et al., 2006, van der Burg et al., 2006).

Beyond the involvement of VDJ recombination factors in the pathogenesis of OS, other gene defects have been described to cause OS. Indeed, mutations in *RMRP*, associated with cartilage-hair hypoplasia (CHH) (see Chapter 37), have been reported in two patients presenting with clinical features consistent with OS (Roifman et al., 2006). Two unrelated cases of adenosine deaminase deficiency had clinical features of OS (Roifman et al., 2008). Finally, OS with hypomorphic defects in the common γ-chain, the IL-7 receptor α chain, and the chromodomain helicase DNA binding protein 7 (CHD7) have been reported, supporting the concept that OS represents an aberrant inflammatory condition brought about by different genetic defects (Marrella et al., 2011; Villa et al., 2008).

TREATMENT

Unless treated by HSCT, OS is invariably fatal because of infections and/or malnutrition. The clinical presentation is usually so severe that supportive treatment is warranted even before a diagnosis is formally established.

Despite this broad supportive treatment, the clinical status of OS patients waiting for HSCT often remains critical, mainly because of cutaneous and intestinal problems directly related to deranged T-cell activation. In an attempt to overcome the activation of Th2 cells and to achieve better control of disease activity, different strategies have been used. The daily use of IFNγ (the rationale being to restore the balance between Th1- and Th2-type cytokines) succeeded in ameliorating clinical conditions in one infant, concurrently with a decrease in eosinophil count and an increase in lymphocyte proliferation to mitogens (Schandene et al., 1993). Other groups have tried to block T-cell activation using immunosuppressive drugs. Steroids have proven ineffective or only partially effective (Barth et al., 1972; Le Deist et al., 1985; Ochs et al., 1974; Omenn, 1965). Somewhat better results have been obtained with cyclosporine A (Brugnoni et al., 1997; Wirt et al., 1989). However, the potential beneficial effect of immunosuppressive drugs and IFNγ is of limited duration.

Because of the specific features of OS, the overall results of HSCT in these children are less satisfactory than in other forms of combined immunodeficiency. The first attempts reported were disappointing, as only 7 of 26 patients were cured (Barth et al., 1972; Bruckmann et al., 1991; Fischer et al., 1990, 1994; Heyderman et al., 1991; Junker et al., 1988; Loechelt et al., 1995; Schofer et al., 1991). A high frequency of graft failure was observed. Aggressive conditioning with myeloablative and immune-suppressive drugs is needed to circumvent this problem. More recently, the use of appropriate supportive treatment and prophylaxis of infection, together with tailored conditioning regimens, has resulted in better outcomes. Taking advantage of these advances, Gomez et al. (1995) reported the cure of OS by HSCT in six of nine patients; similarly, another group achieved successful treatment in four of five OS patients (Brugnoni et al., 1997; Chilosi et al., 1996a). The successful engraftment of donor-derived hematopoietic stem cells is associated with the development of normal numbers and functions of both T and B lymphocytes, with full clinical and immunological recovery.

ANIMAL MODELS OF RAG DEFECTS

Although the molecular bases of OS have been extensively analyzed, several aspects of the disease have not yet been clarified. Selective expansion of certain TCR clones may be a consequence of either intrathymic selection of specific rearrangements or peripheral expansion in response to infections or perhaps autoantigens. It has been suggested that given the extreme disorganization of the thymic microenvironment in OS, negative selection of autoreactive clones may be inoperative, and a few residual T-cell clones may expand in the periphery because of their autoreactive character (Fischer and Malissen, 1998; Marrella et al. 2007, 2008). Another unexplained phenomenon is the fact that RAG proteins direct recombination in both B and T cells, yet B cells are absent in the peripheral blood of OS patients. In view of the elevated IgE levels in OS patients, it is clear that somewhere, B cells that perform Ig rearrangements and switch to IgE production do exist. It is noteworthy that V(D)J recombination deficiencies that lead to low to normal numbers of T cells in the absence of mature B cells is a recurring theme. Another point that must be clarified is the role of environmental factors in the pathogenesis of the Th2 expansion and the resulting clinical features. As observed in other cases, immunodeficient individuals have by definition a more intense antigen exposure and a defect in antigen clearance that results in a persistent high antigen load. If, as in OS, the genetic defect is permissive and allows the development of limited clones of mature T cells, the antigen overload favors prolonged T-cell activation that has been associated with increased IL-4 secretion and polarization toward a Th2 phenotype (Hosken et al., 1995; Hsieh et al., 1993). The availability of murine models carrying the same mutations found in OS and leaky SCID patients helps to clarify the cellular and molecular mechanisms underlying these enigmatic aspects. To this aim, three independent groups have investigated the effects of three hypomorphic mutations of OS patients (Rag2 R229Q, Rag1 R972Q, and Rag1 S723C).

Mice with R229Q in Rag2, *rag2*$^{R229Q/\ R229Q}$, showed a peculiar phenotype, with 60 percent developing alopecia, skin erythroderma, wasting syndrome, and colitis (Marrella et al., 2007). Importantly, the skin and gut of the affected

animals had autoreactive T-cell infiltration with eosinophils. Hematopoietic organs showed severe alterations. The thymus had a reduced number of single-positive (SP) T cells in spite of the absence of DP thymocytes and a severe block at the DN3 stage ($CD44^{-}$ $CD25^{+}$) at which the TCRβ locus rearranges. Notably, few DP thymocytes showed upregulation of TCRα or β or of CD69, suggesting that positive selection was intact. Positively selected SP cells reaching the periphery displayed an oligoclonal repertoire and effector or memory-like phenotype $CD44^{+}$ $CD62L^{low}$ and were unresponsive to anti-CD3 mAb in vitro. As in OS patients, T cells showed an oligoclonal repertoire and circulating B cells were reduced.

There was profound hypogammaglobulinema in spite of high levels of IgE. B-cell differentiation in the bone marrow was arrested at the pre-B cell stage, lymph nodes lacked germinal centers, and no marginal-zone B cells were detected in the spleen. Despite the severe pre-B cell arrest, a few IgM^{+} B cells expressed activation markers and generated ISCs. In a scenario of severe lymphopenia, a compensatory homeostatic regulation and an increased transcriptional program led to the maturation of a few autoreactive B cells that expanded in the periphery, causing organ infiltration and damage (Cassani et al., 2010b). Importantly, *rag2*$^{R229Q/\ R229Q}$ mice had autoimmune manifestations attributed to defects in both central and peripheral tolerance. Indeed, analysis of Aire expression, a key factor controlling the negative selection process, was severely abrogated in the thymus, similarly to that observed in patients (Cavadini et al., 2005). Moreover, nTreg cells ($CD4^{+}$ $CD25^{high}$ $Foxp3^{+}$) were markedly reduced in all hematopoietic organs. Furthermore, as in OS patients, invariant natural killer (iNKT) cells, a population having a role in regulating adaptive and innate immune response, were completely absent.

In parallel to this model, an independent group described a spontaneous mutant mouse carrying a point mutation in Rag1 corresponding to the human amino acid R975 and showing a high percentage of memory phenotype T cells (Khiong et al., 2007). In these mice, named MM (memory mouse), T-cell development in the thymus was partially blocked at the DN3 stage, while spleens and lymph nodes showed elevated numbers of activated memory T cells ($CD69^{+}$, $CD44^{hi}$) and biased usage of TCRVβ and α, although less profound than the extremely severe oligoclonality in OS patients. In contrast to OS features but similar to the atypical form of SCID, MM mice displayed a bone marrow B-cell developmental arrest at the pro-B cell stage ($CD43^{+}$ $B220^{med}$), while splenic B cells arrested at the pre-B stage. B cells had a restricted spectratype suggesting an oligoclonal repertoire. In contrast with what was observed in patients, MM mice had higher serum immunoglobulins and no T-cell infiltration in tissues or autoimmunity in spite of T-cell activation marker expression and high production of Th2 cytokines IL-4 and IL-6. To explain abnormal cytokine production from $CD4^{+}$ T cells including Th2 subset, the authors demonstrated involvement of homeostatic proliferation of $CD4^{+}$ T cells, known as a trigger of autoimmune manifestations (King et al., 2004; Sawa et al., 2006). Thus, MM mice had some OS manifestations but more closely recapitulated the atypical forms of SCID.

Finally, a third mouse mutant, carrying an hypomorphic mutation S723C in Rag1, had few mature CD4 and CD8 SP αβ T cells in the peripheral lymphoid organs (Giblin et al., 2009). B cells were arrested at the pro-B stage. Furthermore, heterozygous mice developed age-associated immune dysfunction in T and B cells compared with age-matched controls. And interestingly, when backcrossed into a p53 mutant background, they developed thymic lymphomas associated with chromosomal translocations. The occurrence of cancer in *rag1*$^{S723C/7S723}$ mice in a $p53^{-/-}$ background revealed a possible implication of Rag hypomorphic mutations in the pathogenesis of tumors and premature immunosenescence.

In conclusion, the observations derived from these mouse models, showing alteration in homeostatic proliferation, failure in central and peripheral tolerance, allow us to better understand some of the clinical features shown in OS and atypical and leaky SCID.

RADIOSENSITIVE $T^{-}B^{-}$ SCID

DEFINITION

Some $T^{-}B^{-}$SCID patients lack mutation in either *RAG1* or *RAG2*, despite having the same clinical presentation (Table 13.3). The alymphocytosis in these patients is accompanied by an increased cellular sensitivity to ionizing radiation, or radiosensitivity (RS-SCID, MIM 602450 and 605988), a situation reminiscent of the well-known *scid* mouse, leading to the hypothesis of a general defect in the DNA repair machinery. The RS-SCID phenotype is also found with high incidence among Athabascan-speaking Native American Indians (1 in 2,000 live births among Navajo Indians) (Hu et al., 1988).

LABORATORY FINDINGS

Bone marrow cells (colony forming units-granulo-monocytes [CFU-GM]) and primary skin fibroblasts of patients with RS-SCID have increased sensitivity to ionizing radiation (Cavazzana-Calvo et al., 1993), as well as a defect in V(D)J recombination in fibroblasts in vitro (Nicolas et al., 1998). V(D)J recombination analysis in fibroblasts from Athabascan SCID patients suggested a common molecular defect (Moshous et al., 2000) and, therefore, the existence of a new V(D)J recombination factor. The disease-related locus was assigned to the short arm of human chromosome 10 by linkage analysis (Li et al., 1998; Moshous et al., 2000).

THE ARTEMIS FACTOR

Given the location of the RS-SCID gene on human chromosome 10, genomic DNA sequences released were systematically analyzed using two computer programs, FGENESH and GENESCAN, aimed at identifying putative genes. On the basis of a putative peptide proposed by these programs, a full-length cDNA coding for a new factor called *Artemis* was isolated (Moshous et al., 2001). Functional complementation and

mutation analyses certified that Artemis was indeed defective in RS-SCID. As expected, because of the ubiquitous increase of cellular radiosensitivity in RS-SCIDs, Artemis was expressed in every tissue tested. Although Artemis does not have any global homologs in the databases, BLAST search analyses revealed significant similarities of the first 150 amino acids to members of the metallo-β-lactamase superfamily. The metallo-β-lactamase fold, first described for the *Bacillus cereus* β-lactamase (Carfi et al., 1995), is adopted by various metallo-enzymes (Aravind, 1997). It consists of a four-layered β sandwich with two mixed β sheets flanked by α helices, with the metal-binding sites located at one edge of the β sandwich (Color Plate 13.V). Sequence analysis and secondary structure prediction for Artemis indicated conservation of motifs typical of the metallo-β-lactamase fold, participating in the metal-binding pocket and representing the catalytic site of the metallo-β-lactamases. Altogether, this analysis indicated that Artemis not only probably adopted the β-lactamase fold, but may also have conserved an associated catalytic activity (Aravind, 1997).

MUTATION ANALYSIS

Eight different alterations of Artemis were found in 11 families (Plate 13.VI); although some of the mutations were recurrent, it was not possible to draw any clear correlation with the geographical origins of the patients. One, the C279T modification, created a nonsense mutation. Other mutations, including amino acid substitutions, were subsequently described (Kobayashi et al., 2003; Li et al., 2002; Noordzij et al., 2003). The other nucleotide changes affected splice donor sequences leading to either frameshifts in three cases or to in-frame deletion of part of the protein in one case. The Artemis gene may represent a hot spot for deletion. Three mutations were deletions spanning several exons, leading to frameshifts and premature terminations in two cases and in-frame deletion of 216 amino acids in one case. In three patients a deletion comprised exons 1 to 4, resulting in a complete absence of Artemis mRNA. This null allele demonstrated that Artemis is not an essential protein for viability, in contrast to XRCC4 or DNA-ligase IV, for example (Barnes et al., 1998; Frank et al., 1998; Gao et al., 1998a).

Hypomorphic Artemis mutations were found in a patient affected by OS with clinical presentation as well as immunophenotype indistinguishable from those caused by hypomorphic mutations RAG mutations (Ege et al., 2005). Furthermore, hypomorphic mutations of Artemis that allow the emergence of a few B and T lymphocytes were accompanied by the development of EBV-associated B-cell lymphomas in a general context of genomic instability (Moshous et al., 2003). This is reminiscent of the pro-B cell lymphomas that emerge in NHEJ-deficient mice when crossed onto a cell-cycle checkpoint defect such as $p53^{-/-}$ (Ferguson et al., 2001).

Artemis knockout mice are viable and recapitulate the phenotype seen in human RS-SCID patients (Li et al., 2005; Rivera-Munoz et al., 2009; Rooney et al., 2002). In the model developed by Rooney et al., a significant numbers of bona-fide mature T lymphocytes, mostly $CD4^+$, are detected in the periphery of certain mice. This may be a consequence of the genetic background (Xiao et al., 2009). Artemis deficiency in mice results in chromosomal fragments, fusion, and detached centromeres in both embryonic stem cells and murine embryonic fibroblasts (Rooney et al., 2002, 2003). These findings strongly suggest that Artemis has an important role in genome stability and may be considered a genomic caretaker.

STRUCTURE AND FUNCTION

With no ortholog of human and murine Artemis in other species, we are left with the similarity of Artemis to various members of the metallo-β-lactamase family, including murine SNM1 and yeast PSO2. However, despite their SNM1 similarity regions, the three proteins differ in their associated domains. While murine and yeast SNM1/PSO2 mutants demonstrate a strong defect in the repair of DNA damage caused by DNA interstrand cross-linking agents (Dronkert et al., 2000; Henriques and Moustacchi, 1980), they do not display elevated sensitivity to ionizing radiation, indicating that these two proteins are probably not directly involved in the repair of DNA DSB. This is in sharp contrast to the phenotype of RS-SCID patients, whose primary molecular defect is indeed the absence of DNA DSB repair, illustrated by the lack of coding joint formation in the course of V(D)J recombination and the increased sensitivity of bone marrow and fibroblast cells to γ rays (Cavazzana-Calvo et al., 1993; Nicolas et al., 1998). Interestingly, Artemis, murine SNM1, and yeast PSO2 share a domain adopting a metallo-β-lactamase fold. Sequence analysis revealed the existence of a conserved region that accompanies the metallo-β-lactamase domain in members of the Artemis/SNM1/PSO2 subfamily, including various other sequences related to nucleic acid metabolism such as two subunits of the cleavage and polyadenylation specificity factor (CPSF). We named this domain βCASP, for metallo-β-lactamase-associated CPSF Artemis SNM1/PSO2 domain (Callebaut et al., 2002). It is tempting to speculate that this domain could contribute to substrate binding, in a way similar to the α-helical domain of glyoxalase, another member of the β-lactamase family (Cameron et al., 1999).

DNA DSBs can be repaired either by homologous recombination (HR) or by the NHEJ (reviewed in Haber, 2000). Whereas HR is the predominant repair pathway in yeast, NHEJ is mostly used in higher eukaryotes and represents the DNA repair pathway followed during V(D)J recombination. At least two protein complexes are thought to act in concert or sequentially at the site of the RAG1/2-derived DSBs. The Ku70–80 complex is probably recruited first at the site of the lesion, followed by the addition of the DNA-PKcs subunit. This initial complex is considered the primary DNA damage sensor that will activate the DNA repair machinery. The XRCC4/DNA-ligase IV complex represents the best candidate to actually repair the gap.

Careful analysis of the various phenotypes among the different V(D)J recombination deficient models, including RS-SCID, has provided some hypotheses regarding the possible role of Artemis during V(D)J recombination. Two major differences exist between the RS-SCID condition and that of XRCC4 and DNA-ligase IV knockout mice. First, a

complete null allele of Artemis does not lead to embryonic lethality in humans. This observation, therefore, does not support an implication of Artemis in this phase of NHEJ. Second, the rejoining of linearized DNA constructs introduced in RS-SCID fibroblasts is not altered (J. P. de Villartay, unpublished observations), whereas this assay, when defective, is highly diagnostic of abnormal NHEJ in yeast (Teo and Jackson, 1997; Wilson et al., 1997). Perhaps the most evident link between Artemis and NHEJ is found in regard to the Ku/DNA-PK complex. Indeed, human RS-SCID patients and *scid* mice, which harbor a mutation in DNA-PKcs, are the only conditions in which a V(D)J recombination-associated DNA repair defect uniquely affects coding joints, leaving signal joint formation unaltered. This is in striking contrast to all the other known V(D)J recombination/DNA repair deficiency settings. Hairpin-sealed coding ends represent the unprocessed V(D)J recombination intermediates that accumulate in murine *scid* lymphoid cells. Although recent data have indicated that RAG1 and RAG2 are capable of opening these hairpin structures in vitro, repair factors such as DNA-PK may be required for this process in vivo. Artemis, through its putative hydrolase activity, may participate in opening the hairpin at the coding ends in vivo. Artemis does indeed possess an intrinsic exonuclease activity in vitro that can be redirected to an endonuclease activity capable of resolving Rag1/2-generated hairpins in vitro when Artemis is complexed to and phosphorylated by DNA-PKcs (Ma et al., 2002). The catalytic core of Artemis is carried by the metallo-β-lactamase/βCASP domain (J. P. de Villartay, unpublished observations). The accumulation of hairpin-sealed coding ends in thymocytes from Artemis and scid/DNA-PKcs knockout mice strongly supports this function (Rooney et al., 2002).

Although it is clear that factors of the NHEJ are required to complete V(D)J recombination, the question of their role during another essential recombination phase of immunoglobulin genes, the class switch recombination (CSR), has been a matter of debate. Recently it was demonstrated that in the absence of a bona-fide NHEJ pathway (occurring in the lack of XRCC4 and DNA-ligase IV), CSR is only moderately affected (Soulas-Sprauel et al., 2007). Likewise, although Artemis was first thought dispensable for CSR (Rooney et al., 2005), the identification of unresolved CSR-generated DNA breaks in B cells from Artemis-deficient mice suggests a possible role for Artemis during CSR (Franco et al., 2008).

DNA-LIGASE IV DEFECTS

As previously described, DNA-ligase IV forms a complex with XRCC4, which is essential for NHEJ and V(D)J recombination (Critchlow et al., 1997; Grawunder et al., 1997). The inactivation of both alleles of DNA-ligase IV in a human pre-B cell line produced radiosensitivity and abrogated V(D)J recombination activity (Grawunder et al., 1998a). Riballo et al. (1999) identified a patient with a defect in NHEJ bearing a missense mutation in the gene encoding DNA-ligase IV. This patient did not show any immunodeficiency; however, he developed leukemia at age 14 and overresponded to radiotherapy (Riballo et al., 2001). More recently, the finding of *LIG4* mutations in four patients thought to have Nijmegen breakage syndrome (NBS) at clinical presentation led to the identification of a new syndrome, designated *LIG4 syndrome*. This disorder is characterized by developmental delay, chromosomal instability, and immunodeficiency (O'Driscoll et al., 2001).

The clinical features of these patients resemble those of NBS, but the cellular phenotype is distinct. Although cells from both syndromes show radiosensitivity, LIG4-deficient cell lines have normal checkpoint function and are defective in DSB repair. The analysis of chromosome breakage in peripheral blood lymphocytes obtained from LIG4 patients did not show any translocations or inversions involving chromosomes 7 and 14, which are typical of ataxia-telangiectasia and NBS.

Many of the features of patients with LIG4 syndrome resemble a particular form of dwarfism named *Seckel syndrome*, recently found to be due to AT and Rad3-related protein defects (O'Driscoll et al., 2003). Patients had microcephaly and one of them had a bird-like face. Pancytopenia is a common feature in these patients, but they do not develop a SCID phenotype, consistent with the hypothesis that the mutations impair but do not abolish the VDJ activity. Skin disease is common and includes plantar warts, psoriasis, and photosensitivity. None of these patients developed cancer, although two of four patients showed hypothyroidism and hypogonadism.

MUTATIONS

The first patient described by Riballo et al. (1999) who developed leukemia had a missense R278H mutation mapping to the LIG4 active site. The same mutation was also present in another patient whose clinical features were completely different, suggesting that epigenetic factors may influence the onset of the disease. Mutations Q280R, H282L, and M249E, also in the vicinity of the active site, resulted in impaired activity of the enzyme to a level of 5 to 10 percent. Two mutations in other patients were stop mutations (R580X, R814X) leading to protein truncation in the BRCT region, which is supposed to interact with XRCC4 (Grawunder et al., 1998b). It is noteworthy that LIG4-null mutations in mice result in embryonic lethality. This finding suggests that the mutations in these patients could be hypomorphic, thus explaining the mild phenotype of the immunodeficiency. However, the R580X stop mutation is not easily reconciled with this hypothesis. Deletion of 5 bp at nt position 1270–1274, causing a premature stop codon 20aa downstream K424, has been found in three patients exhibiting a SCID phenotype (Buck et al., 2006; Toita et al., 2007).

CERNUNNOS DEFECTS

Buck et al. (2006) reported patients with SCID, growth delay, and microcephaly who also had increased radiosensitivity,

defective V(D)J recombination, and impaired in vitro NHEJ activity reminiscent of LIG4 syndrome. However, neither LIG IV nor the other known NHEJ factors were found to be mutated (Revy et al., 2005). A new NHEJ factor named *Cernunnos* was identified through cDNA functional complementation of patients' fibroblasts. The same NHEJ factor, named XLF (for XRCC4-like factor), was independently identified through a yeast two hybrid screen using XRCC4 as bait (Ahnesorg et al., 2006). Deleterious mutations of the *Cernunnos* gene were found in all patients, and the ectopic expression of a wild-type *Cernunnos* complemented the DNA repair defect (Ahnesorg et al., 2006; Buck et al., 2006). *Cernunnos*-deficient murine ES cells had a phenotype similar to that of human deficient cells (increased radiosensitivity, genomic instability, defective DNA repair) but retained V(D)J recombination, although with decreased efficiency (Buck et al., 2006; Dai et al., 2003; Zha et al., 2007). In striking contrast with both XRCC4 and LIG4 knockout mice, *Cernunnos/XLF* deficiency does not result in embryonic lethality (Li et al., 2008, and J. P. de Villartay, unpublished observations). The immunological phenotype also appears less severe in these mice than in the human condition, with only a mild diminution of B and T lymphocytes in the periphery.

CERNUNNOS STRUCTURE

The human *Cernunno/XLFs* gene, composed of eight exons, is located on chromosome 2q35 and encodes a 2063 nucleotide transcript (Ahnesorg et al., 2006; Buck et al., 2006). The Cernunnos/XLF protein is 299 amino acids with an apparent weight of about 33 kDa. Although divergent, Cernunnos is the genuine ortholog of Nej1p/Lif2 (Callebaut et al., 2006), a NHEJ factor described in yeast (Frank-Vaillant and Marcand, 2001; Kegel et al., 2001; Valencia et al., 2001). XLF orthologs have been found in many eukaryotes (Callebaut et al., 2006; Cavero et al., 2007; Hentges et al., 2006). Nej1p in yeast interacts with the XRCC4 ortholog Lif1p, suggesting that Nej1p and Cernunnos have conserved an analogous function throughout evolution.

Cernunnos is ubiquitously expressed and localized predominantly in the nucleus. It shares structural features with *XRCC4*, revealing the existence of a new protein family (Ahnesorg et al., 2006, Callebaut et al., 2006; Hentges et al., 2006; Junop et al., 2000; Sibanda et al., 2001). The predicted conformation for Cernunnos (i.e., a globular head domain followed by a coil-coiled tail) has been confirmed (Andres et al., 2007; Li et al., 2008). Cernunnos, like XRCC4, can bind DNA in a sequence-independent manner (Hentges et al., 2006; Lu et al., 2007) and homodimerize or participate in the same complex together with LIG4 (Ahnesorg et al., 2006; Callebaut et al., 2006; Deshpande et al., 2007, Hentges et al., 2006). The exact nature of the complex(es) formed between XRCC4, DNA-ligase IV, and Cernunnos remains to be established. Despite their close relationship, Cernunnos and XRCC4 have distinct specific roles during NHEJ (Malivert et al., 2009).

CERNUNNOS FUNCTION

Like XRCC4 and several other factors that participate in the DNA damage response (DDR), Cernunnos and its yeast ortholog Nej1p are phosphorylated upon DNA damage (Ahnesorg et al., 2007; Wu et al., 2007). However, the recruitment of Cernunnos to the site of DNA breaks does not require this DNA-PK-dependent phosphorylation event (Wu et al., 2007). Although XRCC4 and Cernunnos share structural characteristics and are part of the same complex, overexpression of XRCC4 cannot functionally complement Cernunnos-deficient cells (Callebaut et al., 2006), suggesting that these two factors act in a cooperative manner. Moreover, defects of XRCC4 or Cernunnos have different impact on the LIG4, which is destabilized in the absence of XRCC4 (Grawunder et al., 1998; Teo et al., 2000) but not in Cernunnos-deficient cells (Ahnesorg et al., 2006; Callebaut et al., 2006). Although the XRCC4/LIG4 complex exerts DNA-end ligation in vitro (Grawunder et al., 1997), Cernunnos further potentiates this activity (Hentges et al., 2006; Lu et al., 2007). Cernunnos seems particularly important for the ligation of mismatched or noncohesive DNA ends, but not of compatible DNA ends, in vitro (Akopiant et al., 2009), suggesting that it may potentiate the ligation activity of the XRCC4/LIG4 complex on specific DNA end structures. Cernunnos is also involved in the response to replicative stress (Schwartz et al., 2009).

DNA-PKCS DEFICIENCY

Thus far, only one case of human DNA-PKcs deficiency has been reported. The patient presented with classical SCID with recurrent oral candidiasis and lower respiratory tract infections from the third month of life with progressive respiratory distress (van der Burg et al., 2009). She had minimal tonsillary tissue. She was successfully transplanted from a healthy HLA-identical male cousin without pretransplant conditioning.

MUTATION ANALYSIS

The above patient had two homozygous variations: a three-nucleotide deletion (c.6338_6340delGAG) resulting in the deletion of a Glycine (p.delG2113) and a missense mutation (c.9185T>G), resulting in replacement of one leucine with arginine (p.L3062R) (van der Burg et al., 2009). The missense mutation p.L3062R was the disease-causing mutation, as demonstrated with complementation assays (Fig. 13.2). The DNA-PKcs missense mutation did not result in an absence of protein and the mutated DNA-PKcs protein had retained autophosphorylation and kinase activity. The composition of the coding joints was suggestive of insufficient or inefficient Artemis activity, as Artemis activity depends on DNA-PKcs for phosphorylation. Similar to the *scid* mouse, the junctions showed an increased number of palindromic nucleotides, indicative of defective hairpin opening, as observed previously in Artemis-deficient patients (van der Burg et al.,

2007), although the number of P-nucleotides was lower in the DNA-PKcs-deficient patient. Accumulation of mutated DNA-PKcs protein to laser-induced DSB sites in living cells and subsequent recruitment of Artemis was normal. The DNA-PKcs mutation probably affects Artemis activation or Artemis positioning relative to the hairpin.

DNA-PKCS GENE STRUCTURE AND FUNCTION

DNA-PKcs is the catalytic subunit of the DNA-PK complex. It is a large protein of more than 4,000 amino acids and is a member of the PIKKs (phosphatidylinositol-3-kinase [PI3K]-like kinases) protein family (Abraham, 2004). Other members of this family that are involved in DNA damage response are ataxia-telangiectasia mutated (ATM) and AT-related (ATR) and RAD3 (see Chapters 47, 48). The N-terminal region consists of two HEAT (huntingtin, elongation factor 3, A subunit of protein phosphatase 2A, TOR1) repeats (Brewerton et al., 2004) and a leucine-rich region (LRR), which has DNA-binding capacity (Fig. 13.2) (Gupta et al., 2005). The C-terminal region of DNA-PKcs is also conserved across the protein family. It is composed of a FAT (FRAP, ATM, and TRAP) domain, a PI3K kinase domain, and a C-terminal FATC domain. Ku80 has been shown to interact with the C-terminal region of DNA-PKcs. The C-terminus seems to mediate DNA-PKcs autophosphorylation, which in turn may influence DNA processing by Artemis (Weterings et al., 2009). Ku70/Ku80 can interact with DNA-PKcs only in the presence of DNA. The Ku70/Ku80 heterodimer binds specifically to double-stranded DNA ends in a ring shape and subsequently DNA-PKcs is recruited to form a DNA end synapsis, ensuring protection from exonuclease activities and juxtaposition of DNA ends (van Gent and van der Burg, 2007). The assembled DNA-PK complex then acquires the ability to phosphorylate a number of target proteins, including itself. This autophosphorylation is very important for the NHEJ reaction (Chan et al., 2002; Ding et al., 2003). DNA-PKcs has several autophosphorylation clusters, including the ABCDE cluster (T2609, S2612, T2620, S2624, T2638, and T2647) (Meek et al., 2004) and the PQR cluster (S2023, S2029, S2041, S2051, S2053, and S2056) (Cui et al., 2005; Meek et al., 2007). In addition, DNA-PKcs has an autophosphorylation site within the activation (T) loop of the kinase (T3950) (Douglas et al., 2007). The ABCDE cluster has a major role in remodeling the DNA-PK complex to make the DNA ends accessible for ligation (Block et al., 2004; Ding et al., 2003; Reddy et al., 2004), whereas phosphorylation in the PQR region appears to be involved in reducing access of nuclease activities to the DNA ends (Chen et al., 2005; Cui et al., 2005); phosphorylation of residue T3950 also influences the joining efficiency (Douglas et al., 2007). Although Ku70/80 binds DNA ends quite tightly, Ku70/80 as well as DNA-PKCS exchange from DSBs within a few minutes in living cells (Mari et al., 2006; Uematsu et al., 2007). The dynamics of NHEJ complexes is influenced dramatically by DNA-PK autophosphorylation: a DNA-PKCS mutant protein without kinase activity or with mutations in the autophosphorylation sites exchanged much more slowly than the wild-type protein (Uematsu et al., 2007).

DNA-PKCS ANIMAL MODELS

Spontaneous mutations in DNA-PKcs have been found in Arabian horses (McGuire et al., 1973), the classical *scid* mouse (Bosma et al., 1983), and Jack Russell terriers (Meek et al., 2001). All three species harbor mutations that result in absence of DNA-PKcs protein due to a C-terminal deletion (Fig. 13.2). In SCID horses, a 5bp deletion resulted in a frameshift and premature stop codon that prevented the translation of the 967 C-terminal codons (Shin et al., 1997; Wiler et al., 1995) (Fig. 13.2). C.B-17 BALB/c SCID mice have a nonsense mutation at codon 4045, predicting deletion of the 83 C-terminal amino acids (Blunt et al., 1996b). Jack Russell terriers also have a nonsense mutation that deletes the 517 C-terminal codons (Bell et al., 2002; Meek et al., 2001).

The phenotypes of horses, dogs, and the human SCID patient were similar. The phenotype in the mouse seems to be less severe than in the other species and is regarded as a "leaky" SCID. *Scid* mice are susceptible to bacterial, viral, fungal, and protozoal infections but can live beyond 1 year under germ-free conditions. This longer lifespan was explained by the presence of immunoglobulins and some T cells that apparently give some protection. DNA-PKcs is an evolutionarily conserved protein, which is highly homologous between these three species and human (≥80 percent homology at the protein level). However, the human L3062R mutation, which retained some kinase activity, differs substantially from the truncating mutations in SCID horses, mice, and dogs. In these three species,

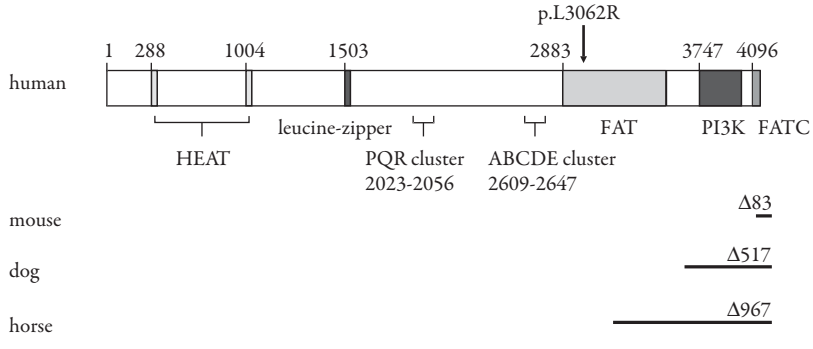

Figure 13.2 Schematic representation of the DNA-PKcs protein with the mutations as identified in human, mouse, dog, and horse. For details, see text.

the DNA-PKcs defects resulted in absence of protein and consequently in absence of kinase activity (Blunt et al., 1996a; Meek et al., 2001; Wiler et al., 1995). Low levels of mutated DNA-PKcs protein isolated from the *scid* mouse were shown to be catalytically inactive (Beamish et al., 2000).

14.

IMMUNODEFICIENCY DUE TO DEFECTS OF PURINE METABOLISM

Rochelle Hirschhorn, Eyal Grunebaum, Chaim Roifman, and Fabio Candotti

INTRODUCTION

Genetic deficiency of the purine salvage enzyme adenosine deaminase (ADA) causes approximately 30–40 percent of autosomal recessive cases of severe combined immunodeficiency (SCID) and therefore approximately 15–20 percent of all cases of SCID (Bertrand et al., 1999; Buckley, 2000; Hirschhorn, 1979b). The identification of deficiency of adenosine deaminase as the basis for immunodeficiency (MIM 102700) was serendipitous and unexpected (Giblett et al., 1972). By contrast, immunodeficiency due to genetic deficiency of purine nucleoside phosphorylase (PNP, MIM 164050), the next enzyme in the purine salvage pathway, was then identified by specific screening for deficiency of enzymes in this pathway in immunodeficient patients (Giblett et al., 1975). PNP deficiency is significantly less common than ADA deficiency. Study of patients with these two disorders has shed light on the significance of the purine salvage pathway for lymphoid and nonlymphoid cells and led to the development of new antileukemic and immune-modulating agents (Dillman, 2004; Hershfield and Mitchell, 2001; Hirschhorn, 1993; Markert, 1994; Suetsugu et al., 1999).

Both ADA and PNP are ubiquitous, "housekeeping" enzymes whose deficiency essentially results in metabolic poisoning, with the most immediate effects manifested in lymphoid cells. As a result, both are diseases characterized by increasing attrition in immune function over time, as well as by blocks at specific steps of differentiation of lymphoid cells. Since the toxic metabolites that accumulate because of the enzyme defect primarily derive from dying cells, it is not surprising that clinical histories, particularly of patients with later onset, are consistent with the hypothesis that each infection results in additional attrition of immune cells and function. ADA and PNP deficiency share many clinical characteristics; however, several features distinguish the two diseases, reflecting varying expression and function of ADA and PNP enzymes (Table 14.1).

Since the previous edition of this book, several advances in both clinical and basic-science aspects of ADA and PNP deficiency have been made. Although the proportion of SCID cases due to ADA deficiency has not changed, only a few novel mutations were reported in recent years (Artac et al., 2009; Honig et al., 2007; Liu et al., 2009), suggesting either that this disease may be inherited from a restricted number of founders or that specific locations of the ADA gene are preferentially susceptible to mutagenesis. Following the initial report in 1996 of somatic reversion of an inherited ADA mutation to wild type (Hirschhorn et al., 1996), additional cases have been described (Liu et al., 2009), reflecting the recent increased awareness of somatic mosaicism due to in vivo reversion to normal of inherited mutations in several different immunological and nonimmunological disorders, including Wiskott-Aldrich syndrome (see Chapter 43) (Hirschhorn, 2003; Wada and Candotti, 2008). On the clinical side, studies have provided new insights into the molecular mechanisms causing T- and B-cell dysfunction and skeletal abnormalities in ADA-deficient patients. New phenotypic presentations, including non-infectious lung diseases with pulmonary alveolar proteinosis, Omenn syndrome, hematological findings of myeloid dysplasia, and susceptibility to dermatofibrosarcoma protuberans, have come into focus (Cassani et al., 2008; Roifman et al., 2008; Sauer et al., 2009; Sauer et al., 2012a; Sauer et al., 2012b, Booth et al., 2012, Grunebaum et al., 2012; Sokolic et al., 2011; Kesserwan et al., 2012). From the prospective of therapy and long-term outcome, it has been confirmed that hematopoietic cell transplantation (HCT) is often unable to improve or prevent the neurological abnormalities in long-term survivors (Honig et al., 2007) and that

Table 14.1 COMPARISON BETWEEN TYPICAL CASES OF ADA AND PNP DEFICIENCY

	ADA DEFICIENCY	PNP DEFICIENCY
Age of presentation	0.2–1 y	>1–2 y
Clinical manifestations at presentation	Infections Failure to thrive	Infections Neurological abnormalities Failure to thrive
Lymphopenia affecting	T and B cells (low NK cells)	T cells
Additional immune abnormalities	Autoimmunity Malignancy	Autoimmunity Malignancy
Organs affected	Bone marrow Liver Brain Skeleton Lung	Bone marrow Brain
Splenomegaly	Rare	Common
Reduced uric acid	No	Yes

HCT using mismatched donors is burdened by high mortality in this genetic form of SCID (Gaspar et al., 2009; Hassan et al., 2012). These findings have coincided with reports of efficacy of autologous hematopoietic cell gene therapy for ADA deficiency (Aiuti et al., 2009b; Gaspar et al, 2011, Sauer et al., 2012b, Candotti et al., 2012). Finally, the available *Ada* knockout mice have continued to prove as useful models for modeling and testing of cell and gene therapy approaches (Carbonaro et al., 2006, 2008, 2012), as well as contribute additional knowledge on nonimmunological consequences of ADA deficiency pointing to adenosine as an important profibrotic signal in the dermal skin and lungs (Chunn et al., 2005, 2006; Fernandez et al., 2008).

In PNP research, recognition of the importance of PNP substrates for T-cell development and function (Cohen et al., 1978) and determination of the human PNP protein structure (Ealick et al., 1990) have led to the development of several PNP inhibitors (Ravandi and Gandhi, 2006), some of which are being assessed for the treatment of T-cell lymphoma and autoimmunity (Gandhi et al., 2005; Morris and Omura, 2000). At the clinical level, several novel mutations in the *PNP* gene have been identified (Alangari et al., 2009; Al-Saud et al., 2009; Madkaikar et al., 2011; Walker et al., 2011; Somech et al., 2012) and early clinical observations that the nervous system is affected by PNP deficiency (Simmonds et al., 1987) have been complemented by demonstration of the important role of purine receptors in the brain (Liu and Salter, 2005). Finally, the availability of a mouse model of PNP deficiency that recapitulates most of the features observed in PNP-deficient humans (Arpaia et al., 2000) has provided a crucial tool for studying the pathogenesis of the immune and nonimmune abnormalities in PNP deficiency and facilitated the recent development of novel gene and protein replacement therapies (Liao et al., 2008; Toro and Grunebaum, 2006; Papinazath et al., 2011; Mansouri et al., 2012).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

ADA DEFICIENCY—CLINICAL SPECTRUM OF IMMUNODEFICIENCY

Early-Onset Disease

The early descriptions of clinical and pathological manifestations in ADA-deficient SCID patients were based upon retrospective studies of children diagnosed as having classical SCID with marked developmental delay and failure to thrive (Hirschhorn, 1979a; Meuwissen et al., 1975). Because of the original means of identifying patients to be tested for ADA deficiency, over 95 percent of the initial cases described were clinically and immunologically virtually indistinguishable from patients with other forms of classical SCID. These ADA-deficient patients had neonatal-onset disease with lymphopenia, absence of both cellular and humoral immune function, failure to thrive, and a rapidly fatal course due to infections with fungal, viral, and opportunistic agents (Hirschhorn, 1979a; Meuwissen et al., 1975). Many of these early-onset cases lacked B cells as well as T cells and would now be classified as having T cell-negative and B cell-negative (T^- B^-) SCID.

In some cases, ADA-deficient patients have presented with lymphadenopathy, hepatosplenomegaly, and erythroderma, thus mimicking the presentation of Omenn syndrome (Roifman et al., 2008). However, in addition to immunological defects, a distinguishing feature in approximately 50 percent of this group is a skeletal abnormality of the costochondral junctions, best visualized by X-ray on a lateral exposure of the chest as cupping and flaring, with a unique histology on biopsy (Cederbaum et al., 1976; Manson et al., 2013). A small percentage of cases, including the first two cases described, exhibit a somewhat delayed onset of disease, with diagnosis as late as the second year of life. Such patients may transiently retain the capability to produce autologous immunoglobulins, although both originally described patients produced essentially no specific antibodies (Table 14.2).

Delayed/Late-Onset Disease

It is now apparent that the clinical spectrum resulting from ADA deficiency is much broader than classical SCID. Testing for ADA deficiency in a wide range of individuals with abnormal immune function has broadened the spectrum considerably, not only as to age of onset but also as to immunological abnormality. Following the early identification of severely affected infants with ADA-deficient SCID and then the appreciation that onset could be somewhat delayed in the first two years of life and be associated with retention of immunoglobulin production, an increasing number of patients are now being found with late-onset ADA deficiency diagnosed between 3 to 15 years of age and even in adulthood (Table 14.2) (Antony et al., 2002; Artac et al., 2010; Geffner et al., 1986; Hershfield, 1998; Hirschhorn et al., 1993b, 1996; Levy et al., 1988; Morgan et al., 1987; Ozsahin et al., 1997; Shovlin et al., 1993). These later-onset patients present with significant

Table 14.2 CLINICAL PHENOTYPES IN ADA DEFICIENCY

1. Neonatal/infantile onset—Severe combined immunodeficiency	Clinically indistinguishable from other forms of SCID, except for bony abnormality in 50% of patients. May present as Omenn syndrome.
2. Delayed/late onset in childhood or adulthood—Combined immunodeficiency	Progressive attrition of immunity. May present with recurrent bacterial sinopulmonary infections, persistent viral warts or recurrent or severe varicella or herpes zoster; immune-mediated thrombocytopenic purpura (ITP). May have lymphopenia, elevated serum IgE, eosinophilia, autoantibodies.
3. ADA deficiency without immunodeficiency (partial)	Identification by population screening or analysis of relatives of affected individuals. No confirmed immunodeficiency to date.
4. ADA deficiency ameriolated by somatic revertant mutations or other function-restoring mutations resulting in lymphocyte mosaicism	Clinical improvement over time without therapy, lower-than-expected levels of toxic metabolites. and newly detected residual ADA enzyme activity

immunodeficiency but may have any of a variety of clinical histories, including recurrent sinopulmonary bacterial infections, episodes of pneumonia frequently due to *S. pneumoniae* with or without septicemia, and HPV disease. After infection or immunization these patients typically fail to produce antibody to some antigens, such as *S. pneumoniae* polysaccharides. They may lack IgG_2 antibodies but have markedly elevated IgE and/or eosinophilia. Immune dysregulation may be present, manifested by autoimmunity including autoimmune hypothyroidism, diabetes mellitus, hemolytic anemia, and idiopathic thrombocytopenia. All have had lymphopenia.

ADA Deficiency with Immunodeficiency Diagnosed in Adulthood

Similar to the ADA-deficient patients with late onset, the small number of adults who have been diagnosed with ADA deficiency have had variety of clinical presentations, including recurrent sinopulmonary bacterial infections, septicemia, and pulmonary infections. Persistent viral warts, recurrent herpes zoster attacks, and asthma have been noted, as well as autoimmune hypothyroidism, hemolytic anemia, and idiopathic thrombocytopenia. Initial immunological investigations have revealed absence of IgG_2, failure to produce antibody to pneumococcal antigens, elevated IgE, eosinophilia, and autoantibodies. Diagnosis of ADA-deficient immunodeficiency in adulthood can be complicated by effects of administration of immunosuppressive medications for autoimmune disorders. The autoimmune phenomena probably reflect abnormal regulation of immune responses, which has been related to loss of regulatory T cell function (Sauer et al., 2012a), as well as new defective B cell tolerance (Sauer et al., 2012b).

In the three initial published cases of ADA deficiency diagnosed in adulthood, lymphopenia was present prior to the diagnosis of immunodeficiency (Ozsahin et al., 1997; Shovlin et al., 1993). The first cases were two siblings with recalcitrant warts as a major manifestation, who in retrospect had the onset of immunological abnormalities during late adolescence (Antony et al., 2002; Shovlin et al., 1993). One of the sibs with severe lung disease died in her late 30s, despite enzyme replacement therapy (PEG-ADA, see "Treatment and Prognosis"). The surviving sib improved substantially with PEG-ADA but then developed a neutralizing antibody response to the enzyme sufficient to preclude continued therapy. At that time, treatment with ADA enzyme encapsulated into autologous erythrocytes, which represents the first therapeutic approach of this kind for ADA deficiency, was used (Bax et al., 2007). One additional patient was diagnosed at the age of 39 after a long history of multiple infections and leukopenia in childhood. In adult life she was well until septicemia followed a cesarean section. She also exhibited hepatic granulomas of unknown etiology and pulmonary tuberculosis as well as asthma and elevated IgE (Ozsahin et al., 1997).

It is likely that these adult patients with ADA defects constitute one subset of patients currently classified as having common variable immunodeficiency (CVID, see Chapter 23), although a screening of 44 unselected CVID patients failed to identify any individuals with ADA or PNP deficiency (Fleischman et al., 1998), suggesting that ADA-deficient subjects do not represent a large subset of CVID. Perhaps selection for such markers as early lymphopenia, hyper-IgE, eosinophilia, asthma, and persistent warts might be informative.

ADA Deficiency with Normal Clinical Phenotype ("partial" ADA deficiency)

An additional group of individuals with absence of ADA activity in erythrocytes has been identified by screening of normal populations or in healthy relatives of affected patients. Most of these individuals were identified as newborns through a screening program directed at early detection of ADA-deficient SCID patients. These patients were initially termed "partially deficient" because while they showed absent ADA activity in red cells, they retained 5 to 80 percent of normal ADA enzyme activity in nonerythroid cells (Borkowsky et al., 1980; Hirschhorn et al., 1979a, 1983, 1989, 1990, 1997; Hirschhorn and Ellenbogen, 1986). These children had dATP levels that were only marginally elevated and in amounts that are insignificant relative to values observed in immunodeficient patients. Although these children were healthy in early childhood, and one subject (homozygous for Ala215Thr mutations) was healthy as late as 18 years of age, their eventual outcomes are unknown. One of these children, lost to follow-up, carried a partial mutation

heterozygous with a "null" similar to adult-onset patients (Shovlin et al., 1993).

A number of healthy relatives in families with a proband with SCID were found to carry additional ADA mutations and to exhibit very low levels of ADA activity in blood cells (Ariga et al., 2001a; Ozsahin et al., 1997).

ADA DEFICIENCY—NONIMMUNOLOGICAL ABNORMALITIES

Several abnormalities have been described in only a few patients and therefore could reflect effects of infectious agents rather than primary defects due to ADA deficiency. These include renal and adrenal abnormalities, neurological abnormalities similar to those seen in PNP deficiency (see below), pyloric stenosis, and hepatic disease (Bollinger et al., 1996; Hershfield and Mitchell, 2001; Hirschhorn, 1979a; Ratech et al., 1985, 1989; Somech et al., 2009; and Hirschhorn, unpublished). In a series of 14 cases, morphological abnormalities of the myeloid lineages have been observed in the peripheral blood from 12 patients (>85 percent) and in the bone marrow of 5 out of 5 cases evaluated. These findings were associated with neutropenia in 7 patients (Sokolic et al., 2011) and suggest that ADA deficiency may have significant hematological consequences beyond affecting the generation of lymphoid lineages. Neutropenia and myeloid dysplasia have also been observed in a delayed-onset patient (Nomura et al., 2013). Abnormal platelet aggregation has also been described (Schwartz et al., 1978). Although it is difficult to prove that neurological abnormalities are not secondary to viral encephalitis, we have suggested that these abnormalities might reflect the interaction of high concentrations of adenosine with known adenosine A1 receptors in nervous tissue. This hypothesis is based upon our finding of amelioration of neurological manifestations concomitant with therapeutic measures that resulted in lowering of metabolites that otherwise accumulate in ADA deficiency (Hirschhorn et al., 1980a). Lymphoma, often associated with cells bearing Epstein-Barr virus (EBV) genomes, has occurred in several patients. In addition, a striking association between ADA deficiency and the occurrence of dermatofibrosarcoma protuberans has been recently demonstrated, with 8 of 12 patients evaluated in one series presenting with a previously unrecognized multicentric variant of this rare skin sarcoma (Kesserwan et al., 2012).

Several observations have demonstrated that ADA deficiency is frequently accompanied by cognitive and behavioral abnormalities, as well as neurosensorial deafness, that appear not to be shared by patients with other forms of SCID (Albuquerque and Gaspar, 2004; Rogers et al., 2001; Tanaka et al., 1996). Also at difference with other forms of SCID, ADA-deficient patients often present with pulmonary alveolar proteinosis (PAP) and severe respiratory symptoms and radiological findings in the absence of positive microbiological isolates (Booth et al., 2012; Grunebaum et al., 2012). These findings suggest a metabolic pathogenesis of the lung disease in ADA-defieincy that is reminiscent of the pulmonary abnormalities observed in *Ada* knockout mice (Blackburn et al., 2000) and deserves further investigation.

PNP DEFICIENCY—CLINICAL SPECTRUM OF IMMUNODEFICIENCY

Previously, it has been estimated that approximately 4 percent of patients presenting with symptoms of SCID have PNP deficiency (Markert, 1991). However, the variable clinical spectrum of PNP deficiency and the difficulties in diagnosing PNP-deficient patients prevent accurate determination of the true incidence and prevalence of this disease. To date, patients with PNP immunodeficiency from approximately 60 families have been reported worldwide (Al-Saud et al., 2009; Alangari et al., 2009; Andrews and Markert, 1992; Aust et al., 1992; Aytekin et al., 2010; Baguette et al., 2002; Banzhoff et al., 1997; Broome et al., 1996; Carpenter et al., 1996; Classen et al., 2001; Dalal et al., 2001; Dror et al., 2004; Madkaikar et al, 2011; Markert, 1991; Markert et al., 1997; Moallem et al., 2002; Pannicke et al., 1996; Sasaki et al., 1998; Somech et al., 2012; Tam and Leshner, 1995; Tsuda et al., 2002; Yamamoto et al., 1999). Additional patients have been identified but not reported (Roifman, unpublished).

The most characteristic immune abnormality observed in PNP-deficient patients is a profound T-cell defect resulting in SCID. Patients typically present in the first or second year of life with recurrent upper and lower respiratory tract infections due to bacterial, viral, or opportunistic pathogens. PNP-deficient patients also often fail to thrive. Debilitating meningitis infections were reported among some patients (Chantin et al., 1996). Urinary tract infections are frequent among PNP-deficient patients (Sasaki et al., 1998; Watson et al., 1981) but uncommon in other forms of SCID. Additional patients have been described who did not present with infections until later in childhood (Fox et al., 1977). Physical examinations often reveal small lymph nodes and tonsils (Rich et al., 1979), while diagnostic imaging studies, such as chest X-rays and computed tomography or dedicated ultrasound exams of the neck, show a small or absent thymus (Staal et al., 1980b).

The profound T-cell abnormality also predisposes PNP-deficient patients to contract disseminated and persistent varicella zoster infections that are particularly difficult to treat (Baguette et al., 2002; Banzhoff et al., 1997; Classen et al., 2001; Dror et al., 2004; Hallett et al., 1994; Sakiyama et al., 1989; Simmonds et al., 1987). One patient died at 9 years of age from demyelinating progressive multifocal leukoencephalopathy caused by JC virus (Parvaneh et al., 2007). Although the hallmark of PNP immunodeficiency is a profound susceptibility to pathogens controlled by T cells, only a single case of fatal pneumonia due to *Pneumocystis carinii* and Legionella infection has been observed (McGinniss et al., 1985), and only one patient has been reported to die from measles infection (Baguette et al., 2002). Moreover, many PNP-deficient patients tolerated bacillus Calmette-Guérin (BCG) immunizations, as well as live attenuated polio and MMR vaccinations (Markert, 1991), although measles virus was detected in the lungs, liver, and spleen of one patient after MMR immunization (Grunebaum and Roifman, 2002). Thus, while PNP deficiency causes a severe T-cell immunodeficiency, patients seem to be less susceptible, at least early in life, to opportunistic infections than in other forms of SCID.

Reduced B-cell numbers and abnormal humoral functions have been reported in a few PNP-deficient patients (Markert et al., 1987) and lack of B cells containing signal joint circles and abnormal BCR repertoires have also been reported, pointing to direct negative effects of PNP deficiency on B lymphocytes (Somech et al., 2012). In addition, defective production of antibodies has been documented in many PNP-deficient patients (Giblett et al., 1975; Hershfield and Mitchell, 2001; Markert, 1991; Somech et al., 2012). One patient developed chronic meningoencephalitis due to echovirus infection (Markert, 1991), a complication more often seen among patients with X-linked agammaglobulinemia.

Autoimmunity is common among PNP-deficient patients. In a large review, 13 of 34 PNP-deficient patients had one or more autoimmune disorders (Markert, 1991). Autoimmune manifestations included noninfectious arthritis, pericarditis, autoimmune thyroiditis, lupus-like symptoms, central nervous vasculitis, and massive splenomegaly (Carpenter et al., 1996; Parvaneh et al., 2007; Rich et al., 1979; Tam and Leshner, 1995). Severe immune-mediated hematopoietic cytopenias can be extremely difficult to treat in PNP-deficient patients (Carapella De Luca et al., 1986; Delicou et al., 2007; Markert et al., 1987; Rich et al., 1979). It is also important to distinguish between cytopenias caused by autoimmunity and those caused by primary bone marrow abnormalities (see below).

Abnormal immune surveillance in PNP deficiency likely contributes to the increased incidence of uncontrolled cell proliferations observed in these patients. One patient had monoclonal gammopathy (Rich et al., 1979), another died of hemophagocytic lymphohistiocytosis (Grunebaum and Roifman, 2002), and several have developed lymphoma (Banzhoff et al., 1997; Blatt, 1990; Soutar and Day, 1991). One PNP-deficient patient had a malignant pharyngeal tumor.

PNP DEFICIENCY—NONIMMUNOLOGICAL ABNORMALITIES

PNP is a ubiquitous enzyme required for purine metabolism in all cells; thus, it is not surprising that many PNP-deficient patients also suffer from nonimmunological abnormalities. Neurological dysfunction, which precedes and cannot be explained by the immune abnormalities, is found in more than half of the patients (Markert, 1991). The majority of neurological manifestations are related to motor development and function, including nonprogressive cerebral palsy, spastic paresis, hypotonia or hypertonia, difficulties maintaining posture, tremor, and ataxia (Al-Saud et al., 2009; Alangari et al., 2009; Aytekin et al., 2008; Baguette et al., 2002; Broome et al., 1996; Carpenter et al., 1996; Dror et al., 2004; Gelfand et al., 1978; Madkaikar et al., 2011; Rich et al., 1979; Simmonds et al., 1987; Staal et al., 1980b; Stoop et al., 1977; Watson et al., 1981). Some patients also suffer from varying degrees of hyperactivity, behavioral problems, deafness, blindness, and mental retardation (Sakiyama et al., 1989). Systematic evaluations of the neurological abnormalities have not been reported, and the few reports of cranial magnetic resonance imaging (MRI) performed in PNP-deficient patients provide conflicting data. A 26-month-old girl with retarded cognitive and motor development was found to have mild cerebral atrophy and bilateral hypomyelinization in the globus pallidus and periaqueductal area (Ozkinay et al., 2007). An MRI performed in a 3-year-old child who suffered from spastic paraplegia from the first year of life showed abnormal hypersignals in the white matter located behind the occipital horns and in the centrum semiovale (Tabarki et al., 2003). Interestingly, her sister, who suffered from similar neurological abnormalities, had normal MRI studies at 8 and 20 months of age. Abnormal motor nerve conduction velocity was also reported in one patient (Tabarki et al., 2003). Importantly, in contrast to the neurological defects that occur in other inherited immune deficiency diseases, the neurological abnormalities in PNP deficiency often precede infections or autoimmunity. Thus, association of severe T-cell immune deficiency with noninfectious nervous system abnormalities should suggest the diagnosis of PNP deficiency.

A few PNP-deficient patients develop bone marrow abnormalities, possibly related to an increased sensitivity of the bone marrow cells to oxidative damage (Carpenter et al., 1996; Delicou et al., 2007; Dror et al., 2004; Soutar and Day, 1991; Staal et al., 1980b; Stoop et al., 1977; Watson et al., 1981). Decreased proliferation of skin fibroblasts from PNP-deficient patients has also been reported, although the clinical significance of this finding is still not clear (Burke et al., 1977).

PATHOLOGY

ADA Deficiency. Examination of tissues at autopsy has been reported only in ADA-deficient patients with early-onset "classical" SCID. Abnormalities in the spleen, lymph nodes, gut, and thymus primarily reflect an absence of cells of the lymphoid system (Hirschhorn, 1979b; Ratech et al., 1985, 1989). Thymic pathology, examined by biopsy as well as autopsy, demonstrates an absent or small dysplastic organ with sparse, if any, lymphocytes; this is seen in most SCID cases and is not specific for ADA deficiency. Although florid pathology in this group of patients is predominantly limited to the immune system, some nonlymphoid organs also show unusual features (Hirschhorn et al., 1982; Mills et al., 1982; Simmonds et al., 1978). Thus, approximately 50 percent of early-onset ADA-deficient SCID patients exhibit a radiologically detectable bony lesion accompanied by a histological appearance unique to ADA deficiency (Cederbaum et al., 1976; Manson et al., 2012). While the lesion may be pathognomonic histologically, we have shown that the radiological abnormality is not specific for ADA-deficient SCID and can be seen in other disorders (Hirschhorn et al., 1979b). Nonetheless, the correct diagnosis of ADA-deficient SCID has not infrequently been suggested by the characteristic appearance of flared costochondral junctions on routine chest X-ray, best appreciated on a lateral view, as well as by the physical finding of a "rachitic rosary." Abnormalities of renal function have been noted in some patients, and we have described an unusual mesangial sclerosis in autopsy material from six of eight patients (Ratech et al., 1985). Renal abnormalities have also been described

in the murine model for ADA deficiency, suggesting that his abnormality is due to the primary metabolic defect itself. Additionally, we have described in these same patients an unusual form of adrenal cortical fibrosis. However, in view of the overwhelming and multiple infections in these children, the significance of the renal and adrenal lesions remains to be evaluated by comparison with autopsy material from SCID patients who were not deficient in ADA. In a patient with neonatal onset of disease, hepatic pathology was reported, with early giant-cell transformation, enlarged foamy hepatocytes, and portal and lobular eosinophilic infiltrates (Bollinger et al., 1996). In another early-onset case, elevated liver transaminases were noted at 6 weeks of life and the patient progressed to hepato-renal failure in the next 4 weeks with extensive microbiology investigations failing to identify infectious causes of hepatitis (Kühl et al., 2011). Although liver abnormalities were not appreciated in autopsies of the above eight patients with similar disease onset, the exclusion of known pathogens in these reported cases makes it possible that liver hepatitis may be a primary result of ADA deficiency.

Both histological and clinical evidence for graft-versus-host disease have been commonly reported at the time of diagnosis because of maternal T-cell engraftment or the administration of unirradiated blood products containing HLA-incompatible lymphocytes that attack the patient's tissues. Graft-versus-host reactions are fortunately now a rare complication of transfusions, but they can still be observed after transplantation therapy.

PNP Deficiency. Pathological reports are available from few PNP-deficient patients. An autopsy of a 23-month-old girl who suffered from familial disequilibrium-diplegia and T-lymphocyte deficiency showed atrophic lymph nodes with scant lymphocytes in the paracortical zone (Graham-Pole et al., 1975). Germinal centers could not be detected, although plasma cells were present in normal numbers. In addition, lymphocyte depletion was noted in the periarteriolar zones of her spleen. The status of the thymus was not recorded. The cerebellum was of normal size, but histological examination of the cerebellum was not performed. Appendectomy and hemicolectomy of her 7-year-old PNP-deficient brother also showed a paucity of submucosal lymphoid tissue and a marked reduction of lymphocytes, lack of germinal centers, but preserved plasma cells.

An atrophic thymus was found at autopsy of a 2.5-year-old PNP-deficient boy who died of malignant histiocytic lymphoma after treatment with prednisone and vincristine. Histological assessment showed dysplastic changes, lymphocyte depletion, epithelial immaturity, an absence of well-formed Hassall's corpuscles and lack of corticomedullary differentiation (Watson et al., 1981). An autopsy of another PNP-deficient patient who died of disseminated viral infection, presumably varicella, after 9 months of bovine thymosin F5 infusions and an additional 9 months of uridine treatment, showed similar findings (Ammann, 1978). Microscopic study of the thymus, which was difficult to locate, revealed fatty infiltration, vague corticomedullary distinction, a reduced number of lymphocytes, increased numbers of spindle cells, and numerous poorly formed Hassall's corpuscles of variable size. The tonsils and lymph nodes were small, with poor organization and no well-formed germinal centers. Plasma cells were abundant. Many macrophages showed erythrophagocytosis. The appendix contained only a few round cells in the lamina propria. The spleen showed a marked decrease in white pulp mass, as well as congestion and focal necrosis. The autopsy of another 2-year-old PNP-deficient patient who developed neurological deficits at 3 months of age and suffered from profound tonus abnormalities did not reveal any structural brain lesion; however, histological examinations were not reported (Simmonds et al., 1987).

LABORATORY FINDINGS

IMMUNOLOGICAL FINDINGS

ADA Deficiency. Lymphopenia and attrition of immune function over time are the two findings common to all presentations of immunodeficiency due to ADA deficiency (Table 14.3). Lymphopenia, as well as elevation of toxic metabolites, such as deoxy ATP (dATP) in red blood cells, are already present prenatally and at birth, as has been demonstrated in affected pregnancies of families with prior children with early-onset ADA deficiency (Hirschhorn et al., 1980b; Linch et al., 1984). In early-onset patients, there is essentially complete absence of lymphocytes and of both cellular and humoral immune function. Isoagglutinins are generally absent; immunoglobulins, particularly IgA and IgM, are low to absent, although absence of IgG, and occasionally other isotypes, is not easily evaluated because of maternally derived IgG and variable amounts of immunoglobulins transiently produced by infants. Antibody responses to T-dependent antigens are severely depressed. In ADA-deficient patients with delayed presentation, B cells and antibodies may be found, but eventually all functional antibodies are lost, and a mono-oligoclonal distribution of immunoglobulin may be detected. Abnormal laboratory results seen in autoimmune states are another feature of later-onset patients.

PNP Deficiency. PNP deficiency has a profound effect on T-cell maturation and function. Most patients are lymphopenic, with markedly depressed T-lymphocyte numbers. T-cell receptor excision circles (TRECs), which represent new thymic emigrants, are also reduced (Somech et al., 2012 and Roifman, unpublished). Kappa-deleting recombination excision circles (KRECs), that are present solely in newly derived bone marrow B-cells have been also found to be decreased (Somech et al., 2012).

The function of lymphocytes from PNP-deficient patients, assessed by the ability to proliferate in response to mitogens, antigens, or foreign cells in vitro, is markedly reduced (Gelfand et al., 1978; Somech et al., 2012). Similarly, in vivo determinations of T-cell function, such as reactivity to Candida or PPD skin tests, are depressed. Importantly, T-lymphocyte numbers and function may be normal early in life and deteriorate as toxic purine metabolites accumulate and infections become more frequent (Gelfand et al., 1978; Markert, 1991). In addition, fluctuations in T-cell immunity have been reported (Markert et al., 1987). Therefore, repeated immune evaluations should

be performed when PNP deficiency is suspected. Humoral immunity, assessed by immunoglobulin levels and the formation of specific antibodies to proteins and polysaccharide antigens, is normal in many, but not all patients (Ammann, 1978; Gelfand et al., 1978; Rich et al., 1979; Stoop et al., 1977). In some PNP-deficient patients, B-cell numbers and isohemagglutinins are reduced and the production of specific antibodies is poor (Somech et al., 2012). Two patients immunized with the T-cell-dependent bacteriophage ΦX174 responded with markedly depressed antibody titers, poor amplification, and a complete inability to switch from IgM to IgG. Abnormal antibody responses may represent defective interaction between T and B cells, or indicate a direct toxic effect of purine metabolites on B lymphocytes. Elevated IgE concentrations have also been reported (Ammann, 1978). One patient was found to have significantly increased serum concentrations of IL-18, possibly secondary to abnormal regulation of macrophages and NK cells (Yamamoto et al., 1999). Neutropenia, secondary to either autoimmune cytopenia or abnormal bone marrow function, is also common among PNP-deficient patients (Delicou et al., 2007; Dror et al., 2004; Soutar and Day, 1991).

BIOCHEMICAL FINDINGS

Protein Expression and Enzymatic Activity

ADA enzyme activity in cells from patients with classic ADA-deficient SCID is essentially undetectable (Table 14.3).

The reported activity must take into account the minor activity of a nonrelevant isozyme that exhibits ADA activity but is encoded by another genetic locus not affected in ADA-deficient SCID (Hirschhorn and Ratech, 1980; see "Biochemistry of ADA" below). Late-onset patients may retain 2 to 5 percent of normal activity, with the highest residual activity reported in subjects with adult-onset disease (Shovlin et al., 1993). In most patients examined for protein with anti-ADA-specific antibodies, ADA protein has been undetectable, suggesting that most ADA mutations result in unstable proteins (Arredondo-Vega et al., 2001; Otsu et al., 2002; Wiginton and Hutton, 1982). However, it is possible that the antibodies used did not recognize some mutant proteins.

Our own unpublished experiments using quantitative immunoprecipitation with a polyclonal antibody and a series of mutants did detect protein in quantities proportional to the relative enzyme activity. One patient originally reported to have normal protein for the amount of enzyme activity seen was demonstrated to be a somatic mosaic, with some cells expressing normal ADA (Hirschhorn et al., 1994b; see "Molecular Biology of ADA" below).

As mentioned, partially ADA-deficient individuals lack ADA activity in erythrocytes but express 5 to 80 percent normal activity in nonerythroid cells, such as cultured EBV-transformed B cells. These individuals were ascertained as a result of population screening undertaken in both normal adults and newborns (Hirschhorn, 1979a; Hirschhorn et al., 1990; 1997). They have been designated "partial ADA deficients" and to date have not presented with immunodeficiency. However, one of the same mutations that permits approximately 5 percent of normal activity has recently been identified in patients with adult-onset immunodeficiency, suggesting that some of the mutations present in partially ADA deficients may not be benign when hetero-allelic with a mutation that totally abolishes activity (see "Genotype–Phenotype Correlations" below).

The biochemical hallmark of PNP deficiency is markedly reduced or absent PNP enzymatic activity in cells. PNP enzyme activity is commonly measured in erythrocyte lysates by the conversion of radiolabeled inosine to hypoxanthine. The two metabolites are separated by thin-layer chromatography and quantified by a scintillation counter. Results are expressed in relation to time and the number of cells analyzed, the amount of protein in the sample, or the patient's hemoglobin. Thus, the PNP activity in erythrocyte lysates of normal individuals had been reported as 1,336 ± 441 nmol/hour/mg protein (Myers et al., 2004), 2,499 to 3,735 nmol/minute/10^6 cells (Dalal et al., 2001), or 2,700 to 3,300 nmol/hour/mg hemoglobin (Parvaneh et al., 2008). PNP activity can also be measured by a nonradiochemical HPLC-linked method, which has the advantage of allowing screening of PNP activity in dried blood spots (Jacomelli et al., 2002). PNP activity can also be quantified by spectrophotometery using coupled conversion of inosine to uric acid in the presence of xanthine oxidase (Chu et al., 1989; Hershfield and Mitchell, 2001; Osborne, 1980). By this assay, the mean normal erythrocyte PNP activity has been determined to be 18.6 U/mL of packed erythrocytes. PNP itself can be detected by Western blot analysis, as the protein typically migrates to the 32 kDa weight in denaturing conditions (Sasaki et al., 1998; Toro and Grunebaum, 2006); however, antibodies to human PNP are available only through a few research labs. Moreover, even if the protein is present, it may not function appropriately. Similarly, while indirect immune fluorescence is a rapid method for visualizing PNP in single cells (Pruslin and Reem, 1980), it may falsely detect nonfunctional enzyme.

Measurement of PNP activity using erythrocytes is affected by recent blood transfusions. As an alternative, PNP activity can be tested in isolated mononuclear cells or peripheral T cells, although the low number of lymphocytes and small blood volume obtainable from young patients often limits the number of cells that can be obtained.

PNP activity varies in different human cells and tissue extracts (Carson et al., 1977). Highest PNP levels are found in peripheral blood granulocytes and lymphocytes (121 and 115 nmol/minute/mg, respectively) followed by cells isolated from the kidneys, small intestine (100 and 64 nmol/minute/mg, respectively), and spleen (54 nmol/minute/mg). PNP activity in the liver, lung, and heart is practically identical and ranges between 32 and 38 nmol/minute/mg, while activity in the brain is the lowest, at 10 nmol/minute/mg. The activity in the thymus is 23 nmol/minute/mg, with higher activity in medullary thymocytes than cortical thymocytes. Another study demonstrated that PNP activity in skin fibroblasts was only 12 ± 2 nmol/minute/mg protein (Burgio et al., 1993). It should be noted that different laboratories have found different PNP activities in similar cells, emphasizing the importance of establishing a range in each lab and choosing appropriate controls.

Metabolic Consequences of ADA Deficiency

ADA is an enzyme of the purine salvage pathway that catalyzes the deamination of adenosine and 2-deoxyadenosine, as well as several naturally occurring methylated adenosine compounds (Hirschhorn and Ratech, 1980; Ratech et al., 1981, 1982). The deamination of adenosine and deoxyadenosine gives rise, respectively, to inosine and to deoxyinosine (Fig. 14.1). In humans these compounds can be further converted into hypoxanthine and then either enter a nonreversible pathway to uric acid or, by the initial action of hypoxanthine phosphoribosyl transferase (HPRT), be salvaged back from hypoxanthine into other purines. The absence of ADA would be expected to result in diminution of the products of the reaction, inosine and 2-deoxyinosine. However, the presence of alternative "bypass" pathways apparently results in normal concentrations of these two products in patients with ADA deficiency and, in contrast to PNP deficiency, also normal concentrations of uric acid, the final product of the pathway. Conversely, the absence of the ADA would be expected to result in accumulation of the substrates adenosine and 2-deoxyadenosine. Not only are these substrates found in increased amounts in plasma and excreted in urine, but they also spill over into additional pathways that are normally only minimally utilized (Cohen et al., 1978; Coleman et al., 1978; Fairbanks et al., 1994; Hirschhorn et al., 1981; 1982;

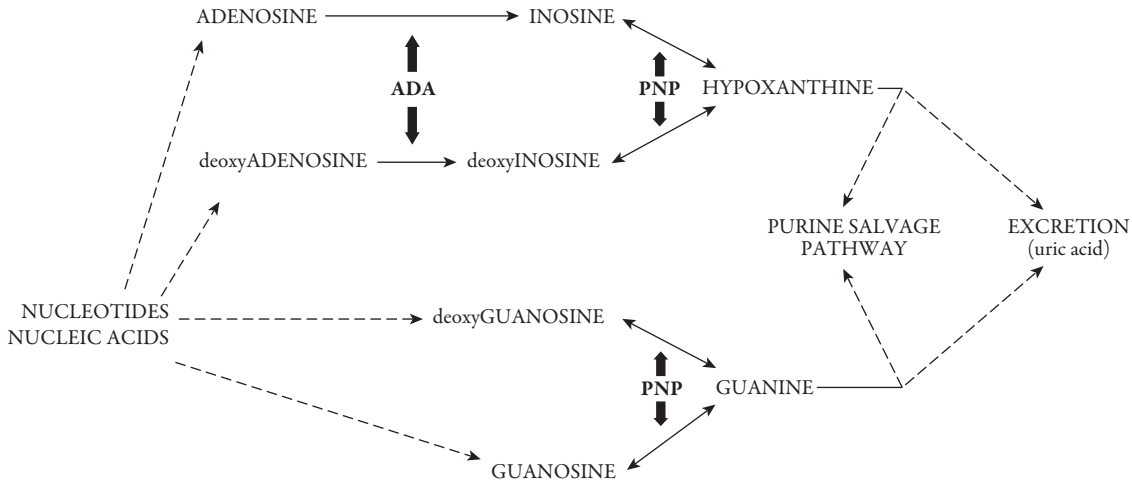

Figure 14.1 Schematic representation of ADA and PNP metabolic pathways.

Kuttesch et al., 1978; Mills et al., 1982; Morgan et al., 1987; Simmonds et al., 1978, 1982).

Deoxyadenosine is a component of DNA and primarily derives from the breakdown of DNA (Figs. 14.1 and 14.2). Therefore, 2-deoxyadenosine would be expected to be in highest concentrations at sites of frequent cell death such as the thymus, where lymphocytes undergo apoptotic death during the course of differentiation and repertoire selection. Adenosine is a component of adenine nucleotides, including ATP and RNA, and can be made both from the normal intracellular breakdown of ATP and from degradation of RNA following cell death. Both adenosine and deoxyadenosine are normally present in plasma, with normal concentrations of approximately 1 μM for adenosine and 0.5 μM for deoxyadenosine.

Patients with ADA-deficient SCID have elevated concentrations of adenosine and 2-deoxyadenosine in plasma (1 to 6 μM for adenosine, 1 μM for deoxyadenosine). The actual concentrations in plasma are difficult to determine by ordinary procedures, as both compounds are almost instantaneously taken up by erythrocytes during drawing of a blood sample and trapped intracellularly by phosphorylation. The most striking alteration in ADA deficiency is the accumulation of massive amounts of dATP in erythrocytes and lymphocytes (Hirschhorn et al., 1992). This results from uptake of the increased deoxyadenosine present in surrounding body fluids, with subsequent intracellular phosphorylation and trapping. In cases with the most marked accumulation of dATP, ATP concentrations fall. The accumulation of dATP in a particular cell type or tissue depends on the rate of phosphorylation versus the rate of dephosphorylation. There has been only one published study of dATP in nonlymphoid tissues (in a patient dying of lymphoma and previously treated with partial exchange transfusions). This study of the heart, brain, liver, and spleen reported only modest elevations in dATP, recalculated as 2 to 20 versus the 500 to 2,000 found in red blood cells (Coleman et al., 1985). Surprisingly, among several

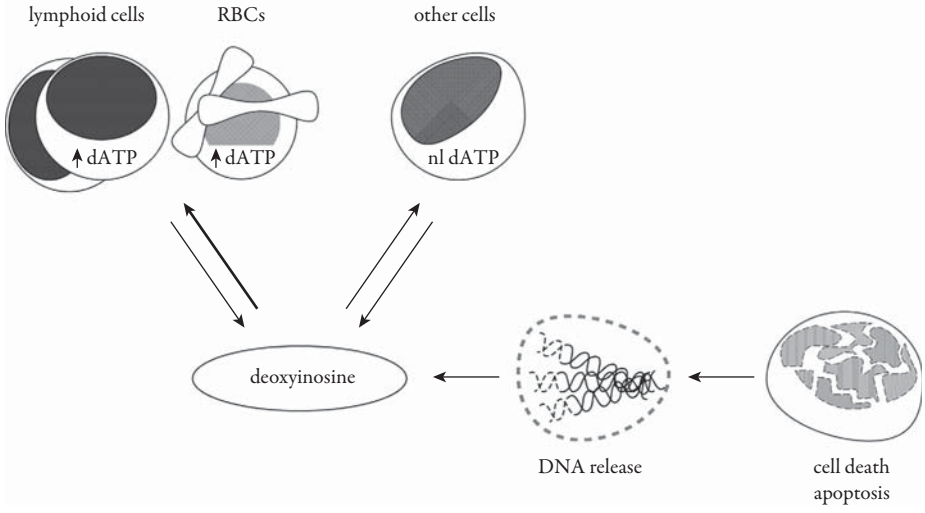

Figure 14.2 ADA deficiency: cellular and metabolic interactions.

tissues examined, massive accumulation of phosphorylated deoxyadenosine was found only in the kidney (R. Hirschhorn, unpublished studies).

Patients with ADA deficiency additionally show a massive increase in excretion of deoxyadenosine in urine, where it is normally undetectable. By comparison, excretion of adenosine is only minimally elevated over that found in normals. Several naturally occurring methylated adenosine compounds that are substrates for ADA are also excreted in urine in increased amounts in ADA-deficient individuals (Hirschhorn et al., 1982).

The increased concentrations of deoxyadenosine also inactivate the enzyme S-adenosylhomocysteine hydrolase (SAH hydrolase), resulting in a secondary deficiency of that enzyme activity in erythrocytes (Hershfield et al., 1979; Hershfield and Mitchell, 2001). Normalization of SAH hydrolase activity appears to be the most sensitive indicator of normalization of metabolite concentrations (see "Treatment and Prognosis" section below). Although several other alterations in metabolites have been proposed, based upon in vitro investigations of proposed pathophysiological mechanisms, none of these additional alterations has been demonstrated in vivo.

In general, adenosine metabolite concentrations correlate with severity of disease. In partially ADA-deficient individuals who are healthy, metabolite concentrations are on average greater than normal but still markedly lower than those found in immunodeficient patients. Red blood cell dATP in partially deficient subjects ranges from a normal of 5 to 40 nmol/ml, compared to 25-fold increased in adult-onset patients and over 1,000 fold-increased concentrations in infantile-onset patients (Table 14.3) (Hirschhorn et al., 1982, 1997). Deoxyadenosine excretion parallels concentrations of dATP, while adenosine concentration in urine is a poor discriminator between different types of individuals (Hirschhorn, unpublished).

Different therapeutic maneuvers lower the concentrations of metabolites to differing degrees. Following bone marrow transplantation, metabolites in red cells, plasma, and urine are dramatically decreased. However, sensitive measurements indicate that metabolites are still elevated, and in particular that plasma adenosine remains very high. Whether or not this is influenced by the bone marrow donor being a carrier or homozygous normal for the disorder is unknown. Metabolite concentrations following polyethylene glycol (PEG)-ADA therapy (see "Treatment and Prognosis") are lower with respect to dATP in red cells than seen following bone marrow transplantation or vigorous partial exchange transfusion (Hirschhorn et al., 1980a, 1981). It is not surprising that adenosine concentrations are less diminished, since the affinity of ADA is greater for deoxyadenosine than for adenosine.

Metabolic Consequences of PNP Deficiency

PNP (EC 2.4.2.1) catalyzes the reversible phosphorolysis of four purine nucleosides, guanosine, deoxyguanosine, inosine, and deoxyinosine, to yield guanine or hypoxanthine and ribose-1-phosphate or 2′-deoxy ribose-1-phosphate (Fig. 14.1). The purine bases, hypoxanthine and guanine, may then be recycled by the action of HPRT to inosine monophosphate (IMP) and guanosine monophosphate (GMP), which can undergo further phosphorylation to GTP. Alternatively, purine bases may be excreted as uric acid by the action of xanthine oxidase. The reverse reaction is not likely to occur in vivo because of the low levels of deoxyribose-1-phosphate and the rapid metabolism of hypoxanthine and guanine by HPRT.

PNP deficiency results in an accumulation of its substrates, guanosine, deoxyguanosine, inosine, and deoxyinosine, in all cells and body compartments, including cerebrospinal fluid (Hershfield and Mitchell, 2001). These metabolites can be accurately assessed by HPLC of cells, serum, urine, and even dried blood spots (Chantin et al., 1996). Deoxyguanosine may undergo phosphorylation by deoxyguanosine kinase (dGK) to dGMP and subsequently to dGTP; hence, PNP deficiency is accompanied by markedly elevated dGTP levels in cells (Cohen et al., 1978). Because dGTP concentrations are relatively low, they are best quantified by the DNA polymerase method (Sherman and Fyfe, 1989).

The impaired production of purine bases results in low serum and urine uric acid levels, an important clue in the diagnosis of PNP deficiency. Calculation of the uric acid/creatinine ratio can further enhance the sensitivity of uric acid measurement (Wortmann et al., 1979). In addition, concentrations of GTP are reduced in the erythrocytes of PNP-deficient patients to the range seen in patients with HPRT deficiency (Cohen et al., 1976; Simmonds et al., 1986).

BIOCHEMICAL BASIS AND PATHOPHYSIOLOGY

BIOCHEMISTRY OF ADA

ADA (EC 3.5.4.4) is an enzyme of the purine salvage pathway that catalyzes the irreversible deamination of adenosine and, perhaps more significantly, deoxyadenosine to inosine and deoxyinosine, respectively. The enzyme is an ubiquitous "housekeeping" enzyme that exists as a 40-kDa monomer predominantly in the cytoplasm (Daddona and Kelley, 1977; Schrader and Stacy, 1977). A small proportion of the enzyme is present on the cell surface of fibroblasts, T lymphocytes, and probably most cells, as a dimer complexed to two molecules of a combining protein, now identified as CD26 in T lymphocytes (Hirschhorn, 1975; Kameoka et al., 1993; Nishihara et al., 1973). It is hypothesized that ADA on the cell surface serves to regulate local concentrations of adenosine and thus engagement of the various cellular stimulatory and inhibitory adenosine receptors. ADA is also genetically polymorphic, with two common biochemical variants, or allozymes, segregating in the normal population (Spencer et al., 1968).

Although ADA is present in all cells, enzyme activity differs considerably in different tissues. The highest amounts are found in humans in lymphoid tissues, particularly intrathymic immature T cells, as well as brain and gastrointestinal tract, while the lowest activity is seen in erythrocytes (Hirschhorn et al., 1978). In lymphoid cells, enzyme activity declines with maturation of T cells but is higher in peripheral blood T cells

than in B cells (Tung et al., 1976). In addition to the ADA coded for on chromosome 20 and deficient in ADA deficiency (ADA1), an additional isozyme of ADA, ADA2, accounts for 1 to 2 percent of total ADA activity but deaminates adenosine only at higher-than-physiological concentrations and is not inhibited by EHNA, an inhibitor of the major ADA isozyme (Daddona, 1981). ADA2 is the product of the CECR1 (cat eye syndrome chromosome region, candidate 1) gene on chromosome 22 and belongs to novel family of ADA-related growth factors with unclear function. It has been speculated that ADA2 may be active in sites of inflammation during hypoxia and in areas where adenosine is elevated (e.g., tumor sites) (Zavialov and Engstrom, 2005).

The murine ADA enzyme has been crystallized and areas of evolutionary conservation from *E. coli* to man have been identified (Chang et al., 1991; Sharff et al., 1992; Wilson and Quiocho, 1993; Wilson et al., 1991). The enzyme is composed of a motif of eight β pleated sheets alternating with eight α helices. There are also five clearly defined additional α helices, three following the first β sheet and the fourth and fifth following the last β sheet. The β sheets form a barrel shape surrounding the catalytic site that lies at the carboxyl end of the barrel. There is a zinc ion coordinately bound at the bottom of the β barrel, under the substrate-binding site. The unexpected presence of zinc within the catalytic pocket of ADA and in other enzymes of the purine and pyrimidine salvage pathways could potentially illuminate the immunodeficiency associated with zinc deficiency. Several amino acids have been identified that are significant for binding of zinc and for catalysis. The precise mechanism of catalysis is under investigation by analysis of effect of mutations as measured by various parameters, including crystallography (Bhaumik et al., 1993; Ibrahim et al., 1995; Mohamedali et al., 1996; Sideraki et al., 1996).

Proposed Mechanisms for ADA Deficiency

Although much is known about the biochemistry of adenosine deaminase, the mechanism(s) whereby deficiency of a ubiquitous enzyme results in predominantly lymphospecific pathology remain an area of investigation (reviewed in Benveniste and Cohen, 1995; Hershfield and Mitchell, 2001; Hirschhorn, 1993; Sekhsaria et al., 1996). Based on the metabolic consequences of ADA deficiency (Fig. 14.3), several pathophysiological mechanisms have been proposed, supported by in vivo and/or in vitro findings. As listed in Table 14.4, dATP is known to be a feedback inhibitor of ribonucleotide reductase, an enzyme required for normal DNA synthesis. The observed marked elevation of dATP could thereby explain the lack of lymphocyte proliferation required for further differentiation to mature cells. The lymphospecific toxicity has been explained by in vitro studies showing that in lymphocytes, and particularly immature T cells, the pathway for phosphorylation of deoxyadenosine is more active than the reverse pathway leading to dephosphorylation; this results in intracellular trapping of the phosphorylated compound. However, while this simplistic explanation is easily remembered and therefore attractive, more recent observations suggest that preferential trapping of dATP is more closely correlated with maturity of lymphoid cells than subtype, which is further supported by the greater sensitivity of chronic lymphocytic leukemia cells and hairy-cell leukemia cells (both usually derived from B cells) to ADA inhibitors or toxic adenosine analogs (Dillman, 2004).

An additional mechanism is suggested by the finding of marked diminution of S-adenosylhomocysteine hydrolase (SAH) activity. Deoxyadenosine irreversibly inactivates the enzyme SAH hydrolase, with markedly reduced activity of this enzyme found in untreated ADA-deficient children. In vitro, this has been shown to result in accumulation of the substrate S-adenosylhomocysteine. Elevated concentrations of SAH result in feedback inhibition of the conversion of S-adenosylmethionine to S-adenosylhomocysteine and therefore prevent the transfer of methyl groups required for virtually all essential methylation reactions. The role of SAH hydrolase inactivation in the pathogenesis of the clinical findings in ADA deficiency remains to be determined. Interestingly, genetic deficiency of SAH hydrolase is not associated with

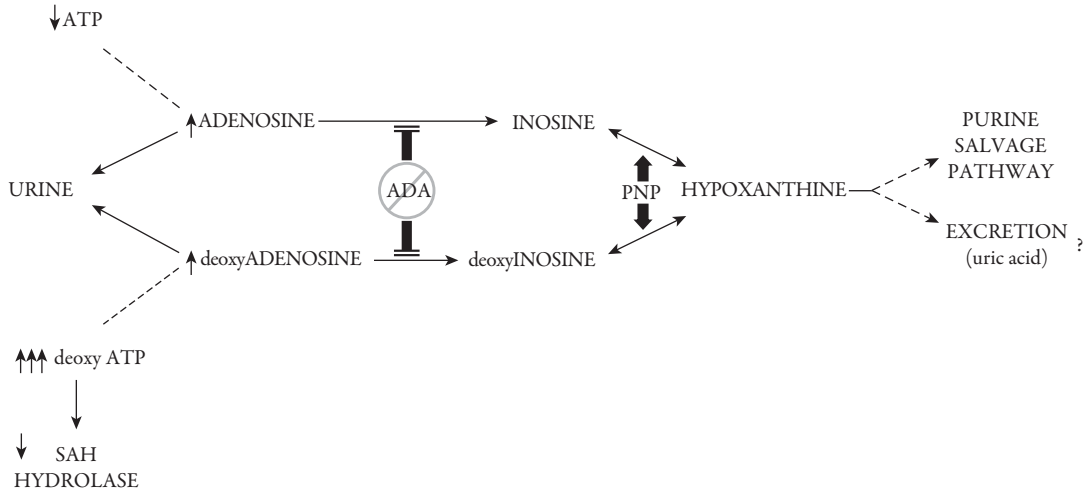

Figure 14.3 Metabolic consequences of enzyme deficiency found in ADA-deficient patients.

Table 14.4 **PROPOSED PATHOPHYSIOLOGICAL MECHANISMS IN ADA DEFICIENCY**

Elevated deoxy-ATP	**Inhibition of ribonucleotide reductase (required for DNA synthesis) and block of DNA replication**
Elevated deoxyadenosine	**Inhibition of DNA repair leading to higher number of chromosome breaks and induction of apoptosis**
Elevated adenosine	**Adenosine receptor interactions contributing to neurological/cognitive changes, sensorineural deafness, sleep abnormalities (based on pharmacology)**
Inhibition of SAH hydrolase	**Inhibition of methylation reactions (potentially contributing to neurological changes rather than immunodeficiency, based on phenotype of SAH hydrolase-deficient humans)**

immune abnormalities but does demonstrate profound psychomotor delay, hypotonia, and defects of myelination (Baric et al., 2004).

Elevation of SAH has not been demonstrated in vivo in ADA-deficient patients, and inhibition of SAH hydrolase is still found in bone-marrow-transplanted children who have normal immune function. However, administration of deoxycoformycin, a known inhibitor of ADA, to patients with leukemia was accompanied by elevations of SAH in vivo. The significance of this observation for patients with ADA deficiency is difficult to evaluate for several reasons. Deoxycoformycin also inhibits at least one other relevant enzyme, AMP deaminase, and the elevations of deoxyadenosine resulting from the death of malignant cells in the presence of ADA inhibition (and of uric acid) far exceeded that observed in any SCID patients. No explanation for why this mechanism would lead to lymphospecific toxicity has been advanced.

Elevation of cyclic AMP in lymphocytes, known to inhibit lymphocyte function, has also been demonstrated in vitro but not in vivo. A proposed mechanism, inhibition of pyrimidine biosynthesis by elevation of ATP, can no longer be supported because in fact, decreased rather than increased ATP is found in SCID patients with the most marked elevations of dATP (the original report of elevated ATP used an assay that measured dATP as well as ATP). Additional pathophysiological mechanisms have been proposed based on in vitro observations (e.g., activation of ATP catabolism by deoxyadenosine and interference with terminal transferase by dATP); however, they have not yet found confirmation from in vivo data. In summary, while the bulk of in vivo and in vitro data support dATP as an important toxic metabolite, this does not explain several in vitro observations. It is likely that additional mechanisms are operative.

It is also clear that all pathophysiological mechanisms in ADA deficiency result from the presence of increased concentrations of substrates of ADA. These may be particularly elevated in the thymus, within which lymphoid cells differentiate and normally undergo apoptosis, and in infected or inflamed tissues, where mature lymphoid cells are engaged in an immune response. Deoxyadenosine has been reported to result in chromosome breakage and to induce apoptosis in relatively immature thymic lymphocytes by a pathway found after DNA breakage, requiring expression of p53 and reversible by overexpression of Bcl-1. These studies correlate with the high expression of p53 and low expression of Bcl-1 in immature intrathymic lymphocytes and suggest that a major block in lymphocyte differentiation resulting from ADA deficiency is intrathymic (Benveniste and Cohen, 1995). However, GM-CSF-stimulated recovery of $CD34^+$ hematopoietic progenitors is lower in ADA-deficient patients than in normals, suggesting that there is also a block at an earlier stage (Sekhsaria et al., 1996).

In addition to affecting development of T lymphocytes, ADA deficiency results in T-cell dysfunction. Primary CD4 T-cell lines from ADA-SCID patients have defective proliferative responses to TcR stimulation, associated with impaired downstream signaling (ZAP-70 phosphorylation, ERK activation, and calcium flux), that may contribute to the immunodeficiency in affected patients (Cassani et al., 2008). In addition, high adenosine concentrations interfere with regulatory T cell function (Sauer et al., 2012a), which may contribute to the susceptibility to autoimmune complications that are not uncommon in ADA-deficient patients.

Molecular Biology of PNP

Native human PNP is a trimer of 3 identical 32,153-Da subunits, each with a substrate-binding site. PNP has been isolated from a wide variety of species, including bacteria (e.g., *E. coli, Haemophilus influenzae*), protozoa (e.g., *Plasmodium falciparum*), rodents (e.g., mice and rats), and mammals, including cows and chimpanzees. A high degree of homology exists between these PNP enzymes, with human and bovine and the human and murine PNPs demonstrating 87 percent and >84 percent homology, respectively (Li et al., 2008; Nelson et al., 1992). PNP from *E. coli*, Schistosoma, bovine, human, and other species has been crystallized with various compounds and analogs in the search for specific PNP inhibitors (Bennett et al., 2003; Canduri et al., 2005; Caceres et al., 2010). Studies that revealed the active site of the PNP enzymes enabled designing of selective PNP inhibitors (Ealick et al., 1991, 1993). Notably, Immucillin H, commercially known as Forodesine, which abrogates PNP function in human T cells, is being used in clinical trials for T-cell lymphomas and leukemia (Alonso et al., 2009; Gandhi et al., 2005). Similarly, specific PNP inhibitors might be beneficial for treatment of T-cell-mediated autoimmune diseases and allograft rejection.

PNP from all species tested can metabolize guanosine; however, the enzymes differ in their action on other purine analogs. This led several groups to investigate the possibility of delivering *E. coli* PNP into human tumor cells to selectively induce susceptibility of these cells to purine metabolites. A phase I study is investigating the expression of *E. coli* PNP in prostate cancer cells followed by treatment with a pro-drug, fludarabine, that is converted by the *E. coli* PNP, but not by the human PNP, into highly cytotoxic 2-fluoroadenine (Hebrard et al., 2009).

PNP is a member of the nucleoside phosphorylase-I (NP-I) family. The NP-I family includes enzymes that share a common single-domain subunit, with either a trimeric or a hexameric quaternary structure that accepts both purine and pyrimidine nucleoside substrates. Despite species-dependent differences in the quaternary structures of members of the NP-I family, the subunit fold is highly conserved with a central β sheet that forms a distorted β barrel, surrounded by several α helices. The active site in members of the NP-I family consists of adjacent phosphate- and nucleoside-binding pockets. Residues from the central β sheet, interconnecting loops, and an adjacent subunit form the binding site. The central β-sheet structural motif, where the nucleoside and phosphate bind at the C-terminal end of the strands, is completely conserved. This suggests that the β-sheet structural motif is important for nucleoside and phosphate binding and catalyzing phosphorolysis (Pugmire and Ealick, 2002).

PNP has been identified in the cytoplasm of cells (Rubio and Berne, 1980; Toro and Grunebaum, 2006) and also found associated with centrioles and basal bodies (Oliver et al., 1981). Recent studies also suggest that the enzymes involved in purine synthesis are co-localized in a cytoplasmic complex named the purinosome (An et al., 2008). However, it is still unclear whether purine degradation enzymes, such as PNP, are organized in a similar manner. In contrast to ADA, PNP has not been detected on the surface of cells.

PNP is considered a ubiquitous "housekeeping" enzyme, but its expression and activity differ considerably in different cells. The highest activity of PNP is in peripheral blood granulocyte and lymphoid cells. Among human T-lineage cells, PNP activity in peripheral T lymphocytes (63 + 4 nmol/minute/10^8 cells) is significantly higher than in thymocytes (18 + 2 nmol/minute/10^8 cells) or leukemic T-ALL cells (37 + 3 nmol/minute/10^8 cells) (van de Griend et al., 1983). In human gastrointestinal tissue, PNP was detected in the duodenum but not in the tongue or esophagus (Witte et al., 1991). In mice, the highest PNP activity was found in the small intestine, followed by the tongue and esophagus. Northern blot analysis in these mice also demonstrated PNP mRNA in the liver, lungs, and kidney (Mohamedali et al., 1993). In adult neuronal tissue, PNP is expressed in white and gray brain astrocytes and microglia but not in neurons (Castellano et al., 1990).

Proposed Mechanisms for PNP Deficiency

Several mechanisms have been proposed to explain the effects of PNP deficiency on cells in general and on T-lineage cells in particular. Most researchers have focused on the intracellular accumulation of PNP nucleoside substrates and their metabolic products (Hershfield and Mitchell, 2001). Among the four PNP purine substrates that accumulate in PNP deficiency, only deoxyguanosine has an alternative metabolic fate, as it can be phosphorylated by the mitochondrial deoxyguanosine kinase (dGK) or the nuclear deoxycytidine kinase (dCK) to deoxyguanosine monophosphate (dGMP), as described in Figure 14.4. dGMP can undergo further phosphorylation to deoxyguanosine diphosphate (dGDP) and subsequently to deoxyguanosine triphosphate (dGTP), which are trapped inside the cells.

Evidence for the central role of deoxyguanosine in mediating the effects of PNP deficiency includes the unique ability of deoxyguanosine, but not other PNP substrates, to inhibit the growth of T cells. This inhibition was associated with an increased intracellular concentration of dGTP (Gudas et al., 1978; Ullman et al., 1979), supporting the hypothesis that the toxicity was caused by phosphorylation of deoxyguanosine to dGTP. Moreover, the inhibitory effect of deoxyguanosine was abolished by disruption of its delivery into cells or by inactivation of dGK or dCK, which prevents the formation of dGTP (Ullman et al., 1979). Indeed, dGTP concentrations

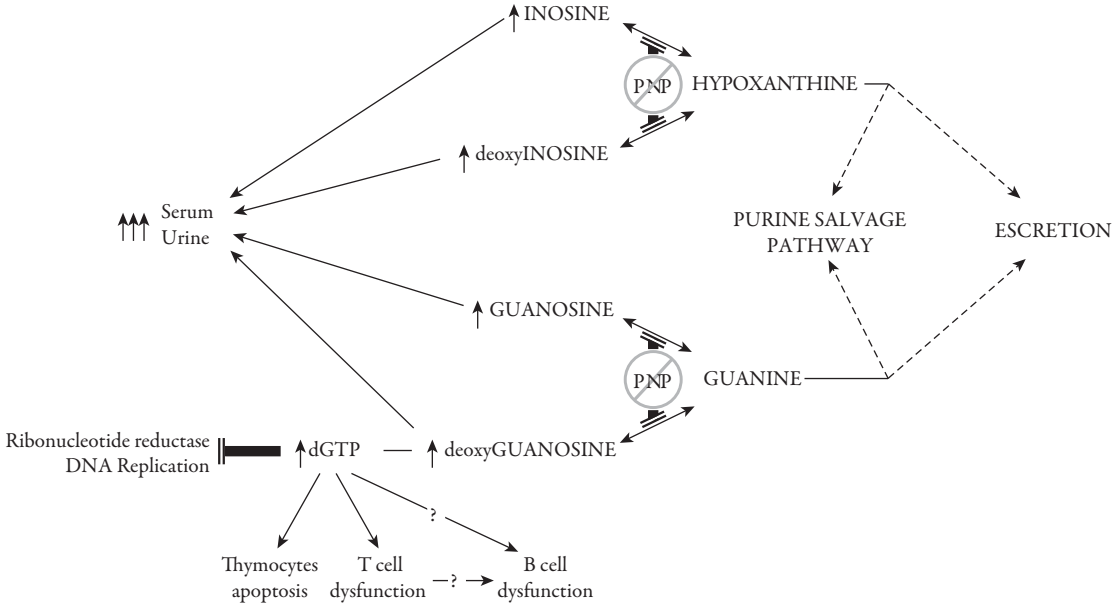

Figure 14.4 Metabolic and proposed cellular consequences of PNP deficiency.

are markedly increased in the cells of PNP-deficient patients (Cohen et al., 1978), in cells with chemically inhibited PNP activity (Bantia et al., 2003; Gandhi et al., 2005), and in cells from PNP-deficient mice (Arpaia et al., 2000).

Maintenance of low and balanced concentrations of intracellular deoxynucleoside triphosphates, including dGTP, is essential for the integrity of DNA synthesis and repair. dGTP binds and inhibits the function of ribonucleoside reductase, an enzyme responsible for the de novo synthesis of deoxyribonucleotides from ADP, GDP, UDP, and CDP. Inactivation of ribonucleoside reductase was also found to prevent the inhibitory effects of deoxyguanosine (Ullman et al., 1979), which led to the model that increased dGTP, secondary to accumulation of deoxyguanosine, may also affect cells by interfering with the synthesis of other deoxyribonucleotides.

Both an enhanced ability to accumulate dGTP and increased sensitivity to dGTP have been suggested as causes for the preferential T-lineage abnormalities in PNP deficiency. Human thymocytes were found to have increased dGK activity and increased dGTP concentrations compared to peripheral T and B lymphocytes (Cohen et al., 1980). Moreover, the mitochondrial localization of dGK and the increased dGTP concentrations in the mitochondria of thymocytes from PNP-deficient mice suggested that mitochondrial DNA maintenance might be particularly affected by PNP deficiency (Arpaia et al., 2000).

Support for this hypothesis was provided by accumulation of dGTP in the mitochondria of PNP-expressing thymocytes incubated with deoxyguanosine in the presence of a PNP inhibitor (Arpaia et al., 2000). Moreover, dissipation of mitochondrial membrane potential in these cells was resistant to caspase inhibition, indicating that the apoptotic signals initiated by deoxyguanosine originated within the mitochondria. Interestingly, Northern blotting demonstrated increased mRNA for dCK, but not dGK, in normal human thymus (Johansson and Karlsson, 1996), suggesting that dCK expression may also have a significant role in the increased sensitivity of human thymocytes to PNP deficiency.

A second explanation for the preferential damage to thymocytes in PNP deficiency stems from the increased propensity for apoptosis of immature thymocytes, which normally downregulate anti-apoptotic molecules such as Bcl-2, during selection in the thymus. Studies in the murine models of PNP deficiency demonstrated that thymocyte differentiation is severely affected at the $CD4^+$ $CD8^+$ double-positive stage, with increased apoptosis of double-positive thymocytes (Arpaia et al., 2000; Snyder et al., 1997). Furthermore, deoxyguanosine was found to induce apoptosis of double-positive thymocytes isolated from either normal mice treated with a PNP inhibitor or PNP-deficient mice (Arpaia et al., 2000; Papinazath et al., 2011). In addition, Bcl-2 overexpression completely protects against deoxyguanosine-induced apoptosis in murine thymocytes treated with a PNP inhibitor (Arpaia et al., 2000). Further exacerbation of thymocyte damage may result from locally increased toxic purine metabolites released from dying thymocytes.

Alterations in intracellular purine dNTP pools might affect V(D)J recombination in ADA- and PNP-deficient thymocytes. Cell lines representing various T-lineage stages, treated with deoxyguanosine, demonstrated that an increase in dGTP concentration was associated with a two-fold reduction of signal-joint recombination in immature T cells, although the ratio of G + C/A + T *N*-region composition was not significantly altered (Gangi-Peterson et al., 1999). Thus, the abnormal accumulation of dGTP in maturing thymocytes may affect V(D)J recombination efficacy or interfere with DNA integrity and result in enhanced cell death in these cells that are already prone to undergo apoptosis.

The reduced response of T cells from PNP-deficient patients to mitogens and the increased sensitivity of such cells to ionizing irradiation (Dror et al., 2004) suggests that in addition to causing abnormal thymocyte development, PNP deficiency may directly affect peripheral T cells. Incubation of PNP-proficient cells with deoxyguanosine and PNP inhibitor, to simulate PNP deficiency conditions, causes increased apoptosis of T-cell lines and stimulated T cells but has practically no effect on unstimulated T cells (Carson et al., 1982; Wilson et al., 1979). Lymphocytes from patients with T-cell malignancies treated in vitro or in vivo with chemical PNP inhibitors demonstrate increased dGTP accumulation and reduced proliferation (Bantia et al., 2003; Conry et al., 1998; Gandhi et al., 2005). The differences in susceptibility of thymocytes, activated lymphocytes, and nonstimulated lymphocytes to abnormal purine metabolism could be attributed to the lack of dCK expression and markedly reduced dGK expression in nonstimulated T lymphocytes (Johansson and Karlsson, 1996). These observations and our recent findings of increased thymidine incorporation into freshly isolated T lymphocytes from PNP-deficient mice (Yu et al., 2009), suggests that T-lymphocyte abnormalities in PNP deficiency may result from in vivo activation of peripheral lymphocytes, possibly secondary to unrecognized infections or uncontrolled systemic inflammation. Alternatively, PNP deficiency might disrupt lymphocyte intracellular signaling, as we have shown abnormal cytokine production by PNP-deficient lymphocytes (Arpaia et al., 2000; Dror et al., 2004; Toro and Grunebaum, 2006).

The effects of abnormal PNP activity on the brain and other organs have not been elucidated. GTP depletion due to inability to produce guanine or secondary to overconsumption of phosphoribosyl pyrophosphate interferes with de novo purine synthesis (Barankiewicz et al., 1982) and has been suggested as a cause for the neurological symptoms in PNP-deficient patients, similar to the effects of HPRT deficiency (Simmonds et al., 1987). However, direct proof in support of this hypothesis has not been provided.

Thus, characterization of the deficits associated with PNP deficiency, identification of the precise tissues and differentiation stages involved, and availability of tissues and animal models that recapitulate the symptoms seen in PNP-deficient patients are required to better understand the pathogenesis of the disease.

MOLECULAR BIOLOGY

MOLECULAR ORGANIZATION OF THE ADA GENE

The human gene for ADA (*ADA*) is localized on the long arm of chromosome 20 at 20q12-q13.1. Both the cDNA and the genomic DNA have been isolated and analyzed (Aronow et al., 1995; Daddona et al., 1984; Valerio et al., 1984, 1985; Wiginton et al., 1984, 1986). The cDNA for human ADA is at least 1.5 kb in length and contains a coding region of 1,089 nucleotides, including the initiation methionine codon ATG, predicting a polypeptide of 363 amino acids with a calculated M.W. of 40,638 Daltons. The ADA cDNA is contained in 12 exons within 32,040 nucleotides of genomic DNA, from the major cap site at position 95 from the ATG to the polyadenylation site. The first 230 bp upstream of the coding region are sufficient to promote expression of the ADA cDNA, as tested by DNA-mediated gene transfer of a minigene construct. The promoter is of the GC-rich type with binding sites for Sp1, now recognized in many housekeeping genes, and lacks obvious CAAT or TATA boxes. Additional regulatory sequences are present in the large (15 kb) first intron, including an enhancer that is responsible for high expression in T cells. Studies with transgenic mice indicate that sequences controlling differences in tissue expression are contained in the first intron, with enhancer elements and elements directing high expression in T lymphocytes as well as an element responsive to the transcription activator cMyb (Aronow et al., 1995). The seventh intron is very small and appears to be unspliced in a small, but detectable, portion of ADA mRNA in normals. The gene is very rich in repetitive sequences of the Alu type; 23 copies of Alu account for 18 of the total sequence. Seventeen Alu repeats are in the first two introns, with three additional Alu repeats in the 5 upstream region. Alu repeats throughout the genome are known to be sites for gene deletions and duplications resulting from misalignment when homologous chromosomes pair during meiosis followed by unequal recombination. Alu repeats have been shown to be involved in causing deletions in the ADA gene (see below).

MUTATION ANALYSIS OF ADA

The types and variety of mutations are not the same in all genetic diseases (see Chapter 2). The predominant mutations seen can vary at different genetic loci or with differing phenotypes at the same locus. Moreover, at different genetic loci there can be many different mutations or a few major mutations causing the majority of the disease cases. Finally, even when there are multiple different mutations, a particular population or ethnic group may demonstrate only a few mutations accounting for all patients with disease in that group.

Mutations in Immunodeficient Patients

In ADA deficiency there are multiple different mutations, but some are more common than others and are found in unrelated individuals (Fig. 14.5). Several of the more common mutations share ancestral origins, while others represent independent recurrences of mutation at "hot spots" within the ADA gene. In the initial cases reported, there was a predominance of single base-pair changes resulting in amino acid substitutions, or missense mutations at mutational hot spots. In later-onset patients, there appears to be an increased incidence of splice-site mutations. There is also an increasing number of recognized small deletions and insertions, as the methods of ADA patient diagnosis have turned to examination of genomic DNA. Some ethnic concentrations of particular mutations appear to be emerging.

Over 50 deleterious mutations have been identified in ADA-deficient immunodeficient patients. An additional 11 "partial" mutations have been identified. Table 14.5 lists published mutations, while Table 14.6 indicates mutations found in multiple unrelated patients by the Hirschhorn laboratory. Additional mutations have been identified but are not as yet published from this laboratory. Approximately two thirds of the deleterious mutations have been reported

by the Hershfield group (Duke University Medical Center). With respect to type of mutation, the majority of the clearly deleterious mutations (31) are missense mutations, followed by 11 deletions or insertions, 10 splice-site mutations, and 6 nonsense mutations. The missense mutations appear to be concentrated in exons 4, 5, and 7, regions known to encode amino acids involved in binding of substrate or significant for the catalytic mechanism. Despite the multiplicity of mutations, 12 mutations accounted for almost two thirds of mutant chromosomes in 52 patients studied in the Hirschhorn laboratory (Table 14.6). As a result, the majority of patients carry 1 of these 12 mutations on at least one chromosome. Additionally, the leucine-to-proline mutation at amino acid 107 (p.Leu107Pro) and neighboring proline-to-leucine at position 104 (p.Pro104Leu) have also been found in more than one patient, as has the Gln3stop mutation that has been found in several Somali patients (Sanchez et al., 2007; Santisteban et al., 1995b). As more patients from different areas are studied, this distribution is likely to change. Over two thirds of patients are heteroallelic for two different mutations, with the remainder homozygous for the same mutation. Homozygosity is typical of rare autosomal recessive diseases, for which consanguinity is an important risk factor. In the case of ADA deficiency, many patients with homozygous mutations are from populations with a high frequency of inbreeding, including the American Amish community in Pennsylvania (p.Gly216Arg), Swiss and French Canadians (deletion of five nucleotides of exon10), inhabitants of Newfoundland (p.Gly20Arg), Afro-Americans (p.Ala329Val), Canadian Mennonites (p.Arg142X), and Somali patients (p.Gln3X).

The presence of the same mutation in unrelated individuals can result from descent from an unidentified common ancestor or from independent recurrence, usually at a site that is a hot spot for mutation. Descent from a common ancestor can be suspected if there is a common ethnic background or if both patients are also identical for other uncommon DNA polymorphic markers within the ADA gene, suggesting an ancestral haplotype (Chapter 2). Conversely, independent recurrence is indicated by differences in alleles at closely associated polymorphic DNA markers. Hot spots for independent recurrence of mutations include CpG dinucleotides (representing 30 of all human disease-related mutations), highly repetitive sequences (such as Alu sequences), and small repeat sequences that have been identified empirically. Over half of the missense mutations described to date in ADA-deficient patients are at CpG dinucleotides, a frequency much greater than that reported in other diseases and setting the stage for independent recurrence. As an example, the p.Ala329Val mutation, the single most commonly occurring ADA mutation, is at a CpG hot spot, in which the C residue of the GCG codon for alanine is changed to T. The mutation is found on two different haplotypes, one in Afro-Americans and the second in Caucasians, consistent with independent recurrence in each of these groups at some time in the past.

One of the two reported large deletions, including the gene promoter region and exon 1, is relatively common and also appears to have arisen independently in different patients (Table 14.6) (Jiang et al., 1997; Shovlin et al., 1994). The deletion of the promoter and exon 1 occurs through homologous recombination between two Alu repeats surrounding the promoter and first exon. Such a deletion has been reported in three patients, but with different sequences at the junctions of the deletion, indicating independent recurrence. The presence of this deletion can be easily missed unless tested for specifically by currently used methods of mutation detection, including screening methods such as SSCP or analysis of cDNA or of PCR-amplified genomic DNA. In a study of 29 patients, we have found this mutation in four patients in whom we had been initially unable to identify the mutation on the second allele, indicating that this deletion is a relatively common mutation (R. Hirschhorn, unpublished data). By contrast with the independent recurrence of the promoter/exon 1 deletion, a 5-bp deletion in exon 10 has been identified in at least four unrelated patients but appears to have derived from a common ancestor in these apparently unrelated individuals. In all four patients, the deletion is found on an extremely rare chromosomal background defined by the presence of two rare nondeleterious missense mutations (normal variants) and, in the three patients studied more fully, of a rare combination of RFLPs (haplotype V) (Tzall et al., 1989). Nonetheless, the deletion occurs at a site empirically identified with an increased frequency of small deletions and has homology with a site for topoisomerase; the deletion of five bases would fit with loss of a half-turn of the helix due to breaks associated with topoisomerase. It is therefore possible for this mutation to recur independently.

A number of splice-site mutations have been reported in individuals with later onset of disease. It can be expected that more nonsense mutations, small deletions, small insertions, and splice-site mutations (all of which can result in unstable mRNA) will be found as the predominant method of analysis changes from examination of cDNA to sequence analysis of genomic DNA.

The cataloguing of mutations in ADA-deficient patients suggests that diagnosis of the specific mutation(s) present in a newly diagnosed patient may be aided by considering the frequency of different mutations and the ethnic distribution. For example, population studies in Somalis have shown that a common haplotype carrying the Gln3Stop mutation had a carrier frequency of 2.4 percent, indicating that ~1 of 5,000 to 10,000 Somali children may be expected to be born with ADA deficiency due to this mutation (Sanchez et al., 2007).

Mutations in Partially Deficient Individuals

In addition to mutations found in immunodeficient patients, 11 different missense mutations retaining differing amounts of easily detectable enzyme activity in nonerythroid cells have been identified in the course of screening erythrocytes from clinically normal individuals. These individuals were categorized as having partial ADA deficiency, based on the absence of red cell ADA but the presence of residual (5 to 80 percent of normal) ADA in nonerythroid cells and identification either by screening of normals or as an incidental finding in apparently healthy relatives of ADA-deficient subjects. Several ADA variants have been found in multiple individuals, many of whom derive from the same geographical area in the Caribbean or share African descent (Hirschhorn et al., 1990). One of these partial mutations, p.Arg211Cys, is listed with mutations in immunodeficient patients (Table 14.5). Originally identified through population screening of newborns, hetero-allelic with a null mutant allele, this mutation has now been identified in siblings with adult-onset immunodeficiency whose mutation on their opposite ADA allele is the del promoter-exon 1 (Table 14.4) (Daddona et al., 1983; Hirschhorn et al., 1990, 1997; Shovlin et al., 1993). It is possible that the original unaffected child identified through screening with the p.Arg211Cys mutation will develop immunodeficiency. The remaining two missense mutations were identified in healthy relatives of ADA-deficient patients (p.Gly 239Ser and p.Met310Thre) as was a second instance of the p.Ala215Thr mutation. Additional partial mutations that express very low, but easily detectable, ADA activity (p.Leu152Met), when hetero-allelic with null mutations, may be found in patients with later-onset immunodeficiency. It is noteworthy that the majority of patients are of "African" descent (including a !Kung tribesman), and a selective advantage for malaria is possible.

EFFECT OF DIFFERENT MUTATIONS ON RESIDUAL ADA ACTIVITY

As is most readily apparent from the study of mutations found in partially ADA-deficient immunocompetent individuals, mutations may not totally abolish enzyme activity (Table 14.7). This is also true for mutations found in immunodeficient individuals. In published and unpublished studies, we have compared the ability of over 20 different missense mutations to code for ADA with residual activity in vitro. The mutations fall into four different groups. Approximately half of the mutations found in immunodeficient patients do not express detectable enzyme activity. The remainder of the missense mutations in immunodeficient patients express detectable residual ADA activity, generally 0.5 to 2 percent of normal. (An exception is the mutation p.Arg211Cys, found in adult-onset immunodeficiency, which expresses somewhat more than 2 percent of normal activity.) A borderline group of ADA mutations expressing 3 to 6 percent of normal activity contains the above mutation p.Arg211Cys, originally found in heterozygosity in a child ascertained by newborn screening, but more recently found hetero-allelic with a large deletion in adult-onset immunodeficiency in siblings. Also in this category is the p.Leu152Met mutation present in homozygosity in a child ascertained by newborn screening who was currently healthy at 12 years of age but had a prior sibling who died in infancy with an infectious disease (Hirschhorn et al., 1997). Finally, mutations expressing 10 to 80 percent of normal activity are found by screening of normal individuals. These variants may confer instability upon the mutant enzyme or have a direct effect upon the binding of substrate, disruption of the zinc-interacting residues, or altering residues governing the catalytic mechanism. Although some of these effects can be hypothesized based on the crystalline structure of the murine ADA molecule, definitive conclusions await direct examination of mutant enzymes.

Analysis of activity of different mutations has also been measured by expression in bacteria (*E. coli*) that are genetically devoid of endogenous ADA activity (Arredondo-Vega et al., 1998; Hershfield and Mitchell, 2001). Based upon the activity expressed in *E. coli*, various mutations were divided into four different groups and appeared to correlate well with clinical and biochemical phenotype. Fourteen of the 29 mutations tested in *E. coli* had also been tested for expression in mammalian cells (Table 14.7, Hirschhorn and Yang, unpublished). Mutations with the highest activity (class IV and class III) were those seen in partially deficient patients.

GENOTYPE–PHENOTYPE CORRELATIONS

Correlations of phenotype with genotype are being examined for many inherited disorders, with the increased definition of mutations at multiple different disease loci. However, other genetic and nongenetic factors can greatly modify the disease phenotype, despite the presence of identical mutations in different patients. Phenotypic differences between siblings carrying the same mutation(s) could be due to modifying genes unlinked to the primary disease locus. Differences between unrelated individuals carrying the same mutation have been attributed to differences in chromosomal background within the gene. Environmental factors can also modify genetic disease phenotypes to a greater or lesser extent, depending upon the particular disease. Lastly, a milder phenotype than predicted by the specific mutation can result from somatic mosaicism.

In an autosomal recessive disorder due to defects in a monomeric enzyme, such as ADA, it would be expected that the presence of a null allele with a mutant allele expressing residual ADA activity would result in a mild phenotype. Homozygosity for two such mutant alleles could theoretically result in an even milder phenotype. The expression of residual ADA could result from a missense mutation that does not totally abolish enzyme activity or of a mutation at a splice site that demonstrates "leakiness" (that is, allows some degree of normal splicing). Critical evaluation of phenotype versus genotype would be best carried out by comparing unrelated patients with identical homozygous mutations to siblings carrying the same mutations. However, for a disorder as rare as ADA deficiency, definitive correlations may not be possible. Moreover, environment, particularly exposure to and incidence of infections, could play a major modifying role. As discussed more fully below, somatic mosaicism, due to de novo mutations during embryogenesis or to reversion to normal of one of the inherited mutations, can dramatically modify the phenotype.

Despite these caveats, correlations between specific mutations, metabolite concentrations, residual ADA activity, age of onset, and severity of disease appear to be present in ADA deficiency. Several mutations in homozygosity or quasi-homozygosity have been recognized in neonatal-onset patients that are consistent with the phenotype. These include a p.Gly20Arg, p.Glu217Lys, and p.Gly216Arg (hetero-allelic with a large deletion including the promoter through exon 5), all of which missense mutations are at critical areas of the molecule. The deletion of five nucleotides in exon 10 and possibly the p.Arg142X mutations may also be associated with neonatal-onset SCID. As noted above, several splice-site mutations and the p.Arg211Cys mutation expressing some activity appear to be associated with later onset and milder perturbations of immune function and of metabolites. While relative concordance between siblings (modified by early institution of supportive therapy) has been noted, marked discordance between one set of siblings has also been reported, suggesting the existence of modifying genes or other factors (Arredondo-Vega et al., 1994). The discordant siblings were heterozygous for two different splice mutations. One allele had in intron 2, at the invariant position IVS2 1, a guanine changed to an adenosine nucleotide. The other allele bore a complex 17-bp rearrangement in intron 8 of the 3′ splice site of IVS8; this mutation involved insertion of the purine-rich antisense strand of the PY tract between the conserved CAG and the normal PY tract of the 3 splice-site junction (Arredondo-Vega et al., 1994). The presence of mRNA with normal splicing indicated that one or both mutations were somewhat leaky, and the difference in phenotype between the siblings was attributed to genetic variation in splicing efficiency. Although it would not be surprising to find that there are modifying genes, in this family the more severely affected sibling was retrospectively diagnosed as having a hepatoblastoma at the time of diagnosis of immunodeficiency. Interestingly, this tumor manifested trisomy of chromosome 20, characteristic of hepatoblastomas, and this is the chromosome on which the ADA gene resides. The presence of the tumor could well have contributed to the earlier development of immunological manifestations (Umetsu et al., 1994).

SOMATIC MOSAICISM: DE NOVO AND BY REVERSION TO NORMAL OF INHERITED MUTATIONS

Somatic mosaicism is as a modifier of phenotype, most commonly in autosomal dominant disorders. In such cases, somatic mosaicism is caused by occurrence of a de novo mutation at some point during embryogenesis, resulting in a proportion of cells that carry a mutation and a proportion that are normal. Individuals with somatic mutation in general have a milder phenotype, but, if the mutation is present in their germ cells, their offspring, to whom they transmit the mutation, carry the mutation in all cells and have a more severely affected phenotype. Somatic mosaicism is more difficult to identify for autosomal recessive disorders and has most commonly been found in relatively common disorders such as cystic fibrosis and thalassemia. We have identified somatic mosaicism in two patients with ADA deficiency (Hirschhorn et al., 1994b, 1996); in one of them it had occurred by reversion to normal of an inherited mutation. In both patients, mosaicism was uncovered during investigations directed at understanding why there had been improvement, rather than deterioration, over time of the clinical phenotype despite the absence of any form of continuing or definitive therapy. In the first patient, somatic mosaicism was demonstrated by isolation of B-cell lines that expressed ADA and lacked one of the two mutations (c.33 + 1G>C) carried by this child (but retained the p.Arg101Gln mutation), as well as by demonstration of absence of the splice-site mutation in a proportion of peripheral blood DNA. DNA

was not available from the parents, and we therefore could not prove or disprove that mosaicism had resulted from the usual mechanism of a de novo mutation during embryogenesis (Hirschhorn et al., 1994b).

In the second child we determined that somatic mosaicism had occurred because of the unexpected reversion to normal of an inherited point mutation (Hirschhorn et al., 1996). A prior sibling had died of an immunodeficiency disorder that would now be categorized as SCID but was designated Nezeloff syndrome by his physicians at the time. Each parent carried a different point mutation at the ADA locus, each of which had been identified in other ADA-deficient patients with SCID (maternal = p.Arg156His; paternal = c.478 + 1G>A). However, the child's concentrations of abnormal metabolites were relatively low and residual ADA activity in peripheral blood cells was relatively high. Moreover, instead of deteriorating without therapy, which had been refused for religious reasons, the child progressively improved clinically. We identified multiple B-cell lines that expressed ADA and determined that these carried only the paternal mutation. However, the maternal chromosome that originally bore the maternal mutation (p.Arg156His) was still present in these B-cell lines, as evidenced by the presence of a unique maternally derived RFLP linked to the mutation. Approximately 15 of the clones isolated from peripheral blood also contained the maternal marker but did not carry a mutation, confirming that reversion had occurred in vivo. This detectable reversion to normal probably involved a selective advantage for survival of revertant cells. Whether or not there was an additional specific mechanism increasing the frequency of reversion at specific sites remained to be investigated.

Reversion to normal in additional cases of ADA deficiency has now been reported (Ariga et al., 2001b). In one case, probable reversion of the paternal p.Gln119X mutation was demonstrated in a polyclonal population of herpes virus saimiri-immortalized T cells that expressed half the normal levels of ADA. Revertant cells were not recovered from the peripheral blood of the patient and therefore could have been an in vitro event. The observation of the revertant was made after the patient was started on PEG-ADA treatment, although there is evidence supporting the occurrence of the reversion event in vivo, because the dAXP levels in the patient's red cells at diagnosis were markedly lower than those expected in ADA-deficient patients carrying the same mutation. In addition, ADA activity was detectable at diagnosis at ~8 nmol/min/10^8 cells and decreased to ~3 nmol/min/10^8 cells after PEG-ADA, which could be explained by the reduction in numbers of the revertant, ADA-expressing cells that lost their selective advantage over the remaining cells after the initiation of enzyme replacement treatment. In the second case, reversion of a p.Arg235Gln maternal mutation was detected; however, because the sample studied was a monoclonal T-cell line, it could not be excluded that the reversion had occurred in vitro (Ariga et al., 2001b).

More recently, somatic mosaicism was demonstrated in a 16-year-old patient from a family in which ADA deficiency was to due to homozygosity for an intronic mutation in the last splice acceptor site of the ADA gene (c.1079-15T>A). Aberrant splicing due to the original mutation resulted in change of the last four ADA residues and added a stretch of 43 amino acids that rendered the protein unstable. The genotypic characteristics of the mosaic patient were investigated because he had greater residual immune function and less elevated erythrocyte deoxyadenosine nucleotides than his 4-year-old affected sister. Studies revealed that the patient's T cells and EBV-B cell line had 75 percent of normal ADA activity and ADA protein of normal size by Western blot. In addition, DNA from peripheral blood mononuclear cells showed two mutant ADA alleles, both carrying the c.1079-15T>A splice-site mutation, but one with an acquired deletion of the 11 adjacent nucleotides (c.1079-4_-14del), which suppressed aberrant splicing and restored protein expression and function. Interestingly, enzyme replacement therapy with PEG-ADA was also in this case followed by a reduction of ADA activity in T cells, as well as a marked decrease of the peripheral blood lymphocytes carrying the "second-site" revertant allele (Arredondo-Vega et al., 2001).

In vivo reversion of an p.Arg156His mutation was also found in purified $CD8^+$ T cells from a patient who presented at 5 years of age with clinical signs of combined immunodeficiency and chronic lung disease, a presentation similar to that of delayed-onset ADA-deficient patients. However, peripheral blood lymphocyte counts and serum immunoglobulin levels were normal in this patient. Of note, most peripheral blood lymphocytes were $CD8^+$ T cells that had normal ADA enzyme activity. Functional immune evaluation, however, showed defective lymphocyte proliferation to mitogens and antigens, as well as lack of antibody responses to pneumococcal polysaccharide vaccination. The contribution of the revertant cells to the delayed-onset phenotype of this patient is unclear; however, it can be concluded that even in the presence of high numbers of ADA-expressing lymphocytes, detoxification effects compatible with normalization of lymphocyte populations and function may not be achieved (Liu et al., 2009).

Reversion to normal of inherited mutations has now been reported in several different disorders, including dermatological and metabolic disorders in addition to various immunological disorders additional to ADA deficiency. These disorders include X-linked SCID, Wiskott-Aldrich syndrome, Fanconi syndrome, Bloom syndrome, tyrosinemia, and epidermolysis bullosa (reviewed in Hirschhorn, 2003; Wada and Candotti, 2008). Mosaicism with or without reversion should be suspected when it occurs in patients with atypical or a mild presentation of immunodeficiency. Reversion is probably a more frequent occurrence in other disorders as well as in those reported, but is most easily ascertained in disorders such as those involving hematopoietic cells and skin, where phenotypic reversion can most easily be detected.

THE HUMAN PNP GENE

The human PNP gene is encoded by a single structural gene that has been assigned to human chromosome 14q13 by somatic cell hybridization techniques (Ricciuti and Ruddle, 1973) and by gene dosage studies (Aitken and Ferguson-Smith, 1978; George and Francke, 1976). Further studies have localized the human PNP gene to 14q13.1. The gene is approximately

7.5 kb in length and contains six exons (Williams et al., 1984). A cDNA of 1.7 kb has been cloned that contains a 289-codon open reading frame, encoding a 32-kDa protein (Goddard et al., 1983). The promoter of the human PNP gene in 2 kb of the 5 flanking region contains a TATA box, an inverted CCAAT sequence, and two GC-rich regions within a 216-bp segment (Jonsson et al., 1991). Interestingly, although PNP is ubiquitously expressed in human tissues, the PNP promoter does not conform to a normal GC-rich constitutively expressed housekeeping promoter. An enhancer element was identified in the first intron of the human PNP gene (Jonsson et al., 1994).

MUTATIONAL ANALYSIS OF HUMAN PNP GENE

Diagnosis of PNP deficiency is established by demonstrating markedly reduced or absent PNP enzyme activity. Nevertheless, demonstrating the defect in the PNP gene is extremely important as it helps confirm the diagnosis, enables genetic counseling, improves understanding of the disease pathogenesis, and possibly even determines treatment options. Only one human PNP gene variant has been reported, although a pseudogene on chromosome 2 was detected by RefSeq. Sequencing of *PNP* has not been confounded by this putative pseudogene (Roifman, unpublished). Results of mutation analysis in reported patients are summarized in Figure 14.6 and Table 14.8.

The first patient to be diagnosed with PNP deficiency was also the first in whom a *PNP* gene mutation was identified (Giblett et al., 1975). The patient suffered from recurrent respiratory tract infections, diarrhea, disseminated varicella, and anemia and had no measurable PNP activity in her erythrocytes. A homozygous c.265G>A mutation was found in exon 3, putatively causing a p.Glu89Lys amino acid substitution (Williams et al., 1987). The c.265G>A mutation was also detected on one allele of another patient, together with a c.520G>C mutation that putatively caused a p.Ala174Pro substitution (patient #4, Markert et al., 1997).

A c.181G>T transversion at the terminal nucleotide of exon 2 causing aberrant splicing, with skipping of exon 2 and production of a truncated polypeptide, was found in one allele of a PNP-deficient patient (Andrews and Markert, 1992). This female patient suffered from severe varicella and postinfectious encephalopathy. PNP activity in her EBV-transformed lymphoblastoid cell line was undetectable. Sequencing of her genomic DNA demonstrated that the other allele carried a deleterious c.701G>C mutation in exon 6 that putatively caused a p.Arg234Pro substitution (Markert et al., 1997). The latter mutation was also found in three other PNP-deficient patients. One of these patients presented with recurrent infections from 22 months of age, followed by severe varicella, chronic enteroviral meningoencephalitis, and ataxia. PNP activity in her EBV-transformed lymphoblastoid cell line was only 0.8 percent of normal. In addition to the c.701G>C mutation, she also carried a c.383A>G mutation that putatively caused a p.Asp128Gly substitution (Aust et al., 1992). This patient had several polymorphic changes in her DNA, including double A in the 3′ untranslated region (903), two tandem copies of a 10 base pair sequence in the 5′ flanking region (c.-41_-50dup), as well as c.60T>C and c.171T>C nucleotide substitutions that were not predicted to cause amino acid changes. Another mutation was also detected in the patient, a c.151A>G nucleotide substitution in exon 2, putatively causing a p.Ser51Gly change. However, the c.151A>G mutation expressed in COS cells did not affect PNP activity in these cells (Aust et al., 1992).

Another patient with the c.701C>G mutation also carried a splice mutation caused by a G-to-A substitution 18 base pairs upstream of exon 4 that created an alternative splice site and unstable mRNA. Despite this, small amounts of normal transcripts were produced from the normal splice site (Markert et al., 1997). This patient was diagnosed with cerebral palsy at 2 years of age but suffered from significant infections only after 4 years of age. Moreover, PNP activity in her erythrocytes was approximately 3 percent of normal (Broome et al., 1996). Thus, it was hypothesized that residual PNP activity contributed to the relatively mild phenotype (Markert et al., 1997). The c.701G>C mutation was also found in association with c.385_387delATC in exon 4 (patient #6, Markert et al., 1997).

The c.569G>T mutation, putatively causing a p.Gly190Val amino acid substitution, was found in one PNP-deficient patient (patient #5, Markert et al., 1997). This mutation was suspected to be homozygous; however, the authors could not exclude the possibility that the second allele carried a large deletion.

A frameshift mutation of the PNP gene was described in a child who presented at 6 months of age with neurological abnormalities that were followed by several episodes of pneumonia and sepsis. Analysis of the patient's DNA revealed that the frameshift was caused by a c.730delA deletion in exon 6 on one allele, while the other allele carried a c.575A>G transition in exon 5, putatively causing a p.Tyr192Cys substitution (Pannicke et al., 1996).

NCBI Reference Sequence: NM_000270.3

A homozygous c.70C>T mutation in exon 2 that putatively caused an p.Arg24Stop substitution was found in a Japanese male patient who suffered from recurrent urinary tract infections after birth and abnormal T-cell function. His erythrocytes had 2.3 percent PNP activity, with no immunoreactive PNP (Sasaki et al., 1998). We also identified the p.Arg24Stop mutation in a patient born to a Japanese mother and Caucasian father. This patient suffered from mild gross motor developmental delay and ataxia. At 2 years of age he developed erythrocyte aplasia after prolonged parvovirus infection, followed by recurrent herpes zoster and herpes simplex infections. PNP activity in his erythrocytes was not detectable. The patient inherited the c.172C>T transition from his mother, while the paternal allele carried a c.285 + 1G>A transition in intron 3, which resulted in skipping of exon 3, and addition of 29

nonrelevant amino acids before a premature stop codon (Dalal et al., 2001).

A homozygous c. 467G>C mutation in exon 5 that putatively caused a p.Gly156Ala substitution was reported in a Bahamian girl. She suffered from respiratory infections, mucocutaneous candidiasis, failure to thrive, hypotonia, and severe developmental delay from 8 months of age. Her T-cell numbers were markedly reduced, but cells did respond to stimulation. PNP activity in her erythrocytes was essentially absent. An additional homozygous c.649G>A mutation was found that putatively caused a p.Val217Ile substitution, but with no effect on PNP function (Moallem et al., 2002).

A homozygous c.349G>A mutation that putatively caused a p.Ala117Thr substitution was reported in a Tunisian girl who suffered from progressive spastic paraplegia from the first year of life. She also developed recurrent respiratory infections at 3 years of age and died of malignant lymphoma. Her younger sister presented at 6 months of age and suffered a similar course. PNP activity in erythrocytes and white blood cells was absent (Tabarki et al., 2003). The same mutation was reported in Turkish girl who suffered from motor and mental developmental delay in the first 2 years of life, recurrent respiratory tract infections, and failure to thrive. She died at 2.5 years of age after severe bronchopneumonia and herpes virus infection. PNP activity in her skin fibroblasts was less than 0.3 percent of normal (Ozkinay et al., 2007).

A homozygous c.212G>A substitution resulting in a putative p.Gly71Glu substitution was identified in a 6-year-old Iranian boy who suffered from delayed motor development and repeated respiratory infections from 4 years of age. He died at 6 years of age from pulmonary infection (Parvaneh et al., 2008). PNP activity in his cells was less than 2.5 percent. Another Iranian boy was found to have a homozygous c.475T>G mutation that putatively caused a p.Phe159Val substitution. This patient was well until 7 years of age, when he developed sinopulmonary infections, autoimmune arthritis, Coombs-positive hemolytic anemia, and spastic paraparesis. He died a year later of progressive multifocal leukoencephalopathy due to JC virus infection (Parvaneh et al., 2007). Although the PNP activity in his cells was not determined, Phe159 forms an essential part of the active catalytic site of the enzyme, and the mutation of this residue is therefore expected to significantly reduce the enzyme activity (Parvaneh et al., 2008).

Recently PNP deficiency was reported in two presumably unrelated girls from Saudi Arabia who suffered from severe lymphopenia and neurological abnormalities at an early age (Alangari et al., 2009). Sequencing of the PNP gene in one demonstrated a c.437C>T change putatively resulting in a p.Pro146Leu amino acid substitution. Expression of the mutated enzyme in *E. coli* indicated that the mutation greatly reduced, but did not completely eliminate, PNP activity.

Additional missense (p.His86Arg, p.Ser163Pro, p.His257Arg) and nonsense mutations (p.Arg67X, p.Gln82X) have been recently reported (Al-Saud et al., 2009; Somech et al, 2012; Walker et al., 2011).

Polymorphic changes predicted to be silent or to cause substitution of amino acids in the PNP gene without affecting PNP enzymatic activity are listed in Table 14.8. Additional polymorphisms in the PNP gene were recently described in European and Indigenous Americans (Yu et al., 2003). The contributions of these polymorphisms to various metabolic processes and neurological abnormalities are being investigated (De Chaudhuri et al., 2008; Tumini et al., 2007).

The mutations in PNP patients described above suggest that residual PNP enzyme activity may lead to less severe manifestations; however, establishing clear genotype–phenotype correlation and prediction of prognosis in this disease will require studying significantly larger numbers of patients. In contrast to ADA deficiency, no PNP patients with somatic mosaicism have been described, possibly because of the smaller number of PNP patients studied or due to a reduction in the selective advantage that PNP-proficient cells possess in a PNP-deficient environment.

STRATEGIES FOR DIAGNOSIS

Based upon the emerging phenotype of late- and adult-onset immunodeficiency disease due to ADA deficiency, any individual with lymphopenia of unexplained etiology and frequent infections of any type, with or without autoimmunity, should be tested for ADA deficiency; in this setting an initial screening assay of erythrocytes should be followed by an assay of ADA in nonerythroid cells.

Diagnosis of ADA deficiency in immunodeficient patients can be made by enzyme assay of several easily available cell types, including erythrocytes, lymphocytes, EBV-transformed B cells, and fibroblasts. If the patient has received a transfusion, erythrocytes are unreliable, and assay of a transformed B-cell line or of fibroblasts should be used. If the diagnosis is made by assay of red blood cells, an assay of lymphocytes and/or fibroblasts should also be performed to rule out the (unlikely) possibility of partial ADA deficiency, which would not be expected to give rise to immunodeficiency. Alternatively, analysis of DNA and identification of previously reported deleterious mutations can be performed. While there may not be sufficient lymphocytes for assay in the initial blood sample, there is usually sufficient DNA in the buffy coat that is removed prior to assay of red cells, and that should be saved and can be used to sequence all exons and flanking regions. Determination of deoxyATP and of deoxyadenosine in urine can also aid in diagnosis.

A variety of assays are available to measure the hydrolytic deamination of adenosine (Zielke and Sueltre, 1971). We have not found assays measuring release of ammonia to be reliable. For initial screening, we routinely utilize a linked spectrophotometric assay in which uric acid is the final end product (Edwards et al., 1971; Hirschhorn, 1979b). This assay is relatively sensitive, rapid, and easily performed. A second spectrophotometric method measuring the conversion of adenosine to inosine by loss of absorbance at the peak for adenosine is also simple and widely used, but it is much less sensitive because of the limitation in the concentration of substrate and in the amount of cell lysate that can be included in the assay. The most sensitive and specific assays are those

that utilize radiolabeled adenosine as substrate in the presence and absence of the inhibitor EHNA and separate the products from the substrate by methods such as thin-layer chromatography (Hirschhorn, 1979b). The amount of enzyme activity that is inhibited by EHNA measures the activity resulting from the ADA locus affected in ADA-deficient immunodeficiency. The alternate isozyme of ADA is encoded by a distinct locus not affected in ADA-deficient immunodeficiency. Although this locus accounts for only 1 to 2 percent of ADA activity in normal cells, its presence can confuse detailed characterization of residual ADA in the diagnosis of ADA deficiency. We have also utilized an HPLC assay using unlabeled adenosine and standard methods of separation (Hirschhorn et al., 1982), but this requires expensive machinery not commonly available. However, this assay could be easily automated with current available technology; it does not require radioactivity, and it is sensitive. Other methods amenable to automation have also been described (Carlucci et al., 2003). Among these, tandem mass spectrometry can be applied to newborn screening and has been demonstrated to be able to identify newborns with early- and delayed-onset ADA-SCID through analysis of dried blood spots collected at birth (Azzari et al., 2011; la Marca et al., 2012). Interestingly, SCID newborn screening methods based of TRECs may miss delayed/late-onset ADA-deficient cases (la Marca et al., 2012; Speckman et al., 2012), which supports the application of alternative screening methods, such as tandem mass spectrometry and KRECs.

PNP deficiency should be suspected in patients presenting with recurrent bacterial, viral, or fungal infections, associated with reduced T-cell numbers and function. Unexplained neurological abnormalities associated with reduced T-cell immunity should also raise the possibility of PNP deficiency, although other etiologies including DiGeorge syndrome, ADA deficiency, XLF-Cernunnos and DNA ligase 4 deficiency, dyskeratosis congenita, Bloom syndrome, ataxia-telangiectasia, Nijmegen breakage syndrome, and others should be considered. A decreased uric acid concentration in the blood (<2 mg/dL, but usually <1 mg/dL) and/or urine is an important clue to the diagnosis of PNP deficiency; however, severe neurological manifestations associated with hypouricemia can also be caused by molybdenum cofactor deficiency and phosphoribosyl pyrophosphate synthetase deficiency. Liver disease, malnutrition, proximal renal tubular disease, xanthinurea, as well as other conditions and medications can reduce the concentration of uric acid in the blood and urine. Increased concentrations of dGTP in erythrocytes and high levels of inosine, deoxyinosine, guanosine, and deoxyguanosine in the serum and urine are characteristic for PNP deficiency (Cohen et al., 1978; Hershfield and Mitchell, 2001), but these assays are not readily available in most laboratories.

The diagnosis of PNP deficiency is usually confirmed by demonstrating markedly reduced (<5 percent) or absent PNP enzyme activity in erythrocyte lysates (or other cells if the patient recently received red blood cell transfusions) by radiochemical or spectrophotometric assays. Measurements of PNP activity can be performed in dried blood spots using reversed-phase HPLC (van Kuilemburg et al., 2010). ADA activity is often measured in the same sample used for PNP detection, because of the significant clinical and immunological overlap between these two immunodeficiency diseases and as an internal control to confirm that handling of the sample did not affect enzyme activity. Measuring activity of both enzymes is particularly important with the linked spectrophotometric assay because the ADA assay depends upon endogenous PNP activity, and therefore an absence of PNP can initially be misinterpreted as ADA deficiency.

PRENATAL DIAGNOSIS AND CARRIER DETECTION

Prenatal diagnosis of ADA deficiency has been made by enzyme assay on chorionic villous samples, amniotic cells, and fetal blood (Durandy et al., 1982; Hirschhorn, 1979b, 1979c; Hirschhorn et al., 1975, 1992; Linch et al., 1984; Simmonds et al., 1983, and Hirschhorn, unpublished). We have performed prenatal diagnosis in over 20 cases by enzyme assay of amniotic cells and correctly diagnosed the expected 25 percent to be affected. Predictions were confirmed either by postnatal ADA assay of erythrocytes and/or identification of mutations on both chromosomes in amniotic cells; infants predicted to be unaffected had ADA activity by assay of erythrocytes after birth. There was a clear separation between affected fetuses and fetuses at risk but not affected. However, homozygous normals versus carriers could not be definitively identified by enzyme assay in cases where we could identify carriers by heterozygosity for a mutation.

DNA-based diagnosis can definitively diagnose carriers, affected subjects, and normals in a setting where both ADA mutant alleles are known; this is feasible if the mutations have been studied in a previously affected child in the family or can be rapidly determined in the parents or samples preserved from a deceased affected child. Although RFLPs, when informative, could in theory also be used for diagnosis, we suggest that the AluVpA polymorphism described upstream of the first exon not be used for diagnosis, as we have identified a crossover in this region (Hirschhorn et al., 1994b). Direct detection of the specific pathological mutations or enzyme assay is preferable, and identification of the mutations present can be performed easily, given the availability of PCR and rapid sequence analysis.

Prenatal diagnosis can be valuable not only if parents wish to terminate an affected pregnancy but also for facilitating therapy of an affected infant after birth. A number of families have chosen to carry the pregnancy of an affected child to term (Jiang et al., 1997). HLA typing has then allowed for rapid bone marrow transplantation (both histocompatible and T-depleted haploidentical) before the onset of infections (Pollack et al., 1983). Prenatal diagnosis has also allowed for harvesting of cord blood for gene therapy (Kohn et al., 1995, 1998).

Similarly to ADA deficiency, both amniotic cell culture and chorionic villus sampling have been used successfully to identify affected fetuses by assessing PNP enzymatic activity (Carapella De Luca et al., 1986; Kleijer et al., 1989; Perignon et al., 1987). Direct PNP gene sequencing was also shown to

Table 14.9 **THERAPEUTIC OPTIONS FOR ADA DEFICIENCY**

1. Preventive
a. Prenatal diagnosis with selective pregnancy termination
b. Prenatal diagnosis to assist postnatal therapy—HLA typing, germ-free delivery, immediate antibiotics, etc.
c. Preimplantation diagnosis with selective implantation of nonmutant, histocompatible embryos to serve as hematopoietic stem cell donors at birth
2. Hematopoietic Stem Cell Transplantation
a. Potential donors
i. Histocompatible-related donor (usually sibling)[a]
ii. Haploidentical-related donor (usually parent)
iii. Matched unrelated donor
b. Potential sources of hematopoietic stem cells
i. Bone marrow
ii. Mobilized peripheral blood
iii. Cord blood
3. Enzyme replacement
a. Partial exchange transfusion (no longer used)
b. PEG-conjugated calf intestinal ADA (Adagen)
4. Gene therapy; introduction of retrovirally carried correct gene sequence into:
a. Cultured expanded T cells
b. $CD34^+$ stem cells
i. Cord blood
ii. Bone marrow

[a]Therapy of choice, if available

accurately identify the PNP status of a fetus from a family with a previously identified PNP-deficient sibling (Roifman, unpublished).

Determination of heterozygous carriers can be attempted by assay of ADA in erythrocytes and demonstration of anomalous inheritance within the family of the normal ADA polymorphism (Chen et al., 1974; Hirschhorn, 1992; Hirschhorn et al., 1975; Scott et al., 1974). However, there is a large range of normal ADA activity; values follow a normal distribution only after log conversion. Most obligate carriers demonstrate, as expected, approximately half-normal ADA activity, but approximately 10 to 20 percent of carriers fall within the normal range, and 1 percent of normals have activity in the carrier range. Most troubling are those individuals at risk for being carriers who are at the borderline of normal. DNA-based mutation detection now offers a definitive test in most families. In the case of a pregnancy at risk for SCID of unknown etiology, a prenatal diagnosis of SCID can be made by examining lymphocytes in fetal blood, at which time ADA deficiency can be diagnosed with the erythrocytes obtained. Preferably, ADA can be assayed in cultured amniocytes. Clearly, a consensus is needed as to the most efficient, sensitive, and specific strategies to be used for prenatal diagnosis of SCID that would avoid fetal blood sampling.

Carriers for PNP deficiency frequently have decreased PNP activity in red cell and white cell lysates. If the mutations of the affected offspring are known, DNA-based mutation analysis will determine carrier status in the family.

TREATMENT AND PROGNOSIS

Several clinical management options are available for ADA deficiency. These are listed in Table 14.9 and include both prevention (e.g., prenatal diagnosis with selective pregnancy termination) and therapeutic approaches based on hematopoietic stem cell transplantation (HSCT), enzyme replacement, and gene therapy (Gaspar et al., 2009). In contrast to ADA deficiency, management of PNP deficiency is often limited to preventive and supportive measures. HSCT transplants are not commonly performed because of low success rates, while enzyme or gene therapies are not yet available.

Bone Marrow/ Hematopoietic Stem Cell Transplantation

Allogeneic HSCT from a histocompatible sibling or other close relative in inbred communities is an established form of therapy for ADA deficiency (Amrolia et al., 2000; Antoine et al., 2003; Bertrand et al., 1999; Boulieu et al., 1988; Buckley et al., 1986, 1993, 1999; Cancrini et al., 2010; Chen et al., 1978; Fischer, 1992; Fischer et al., 1986, 1990; Friedrich et al., 1985;

Gaines et al., 1991; Haddad et al., 1998; Hassan et al., 2012; Markert et al., 1987; Parkman, 1991; Parkman et al., 1975; Rubocki et al., 2001; Serana et al., 2010; Silber et al., 1987; Wijnaendts et al., 1989; Zegers and Stoop, 1983) (Honig et al., 2007). This therapeutic maneuver has the greatest efficacy, does not necessarily require prior marrow ablation or permanent ongoing therapy, and has a relatively low morbidity and mortality. After successful HSCT, deoxyadenosine-based metabolites are dramatically lower than in untreated patients but are still detectably higher than normal (Hirschhorn et al., 1981). The diminution of adenosine concentrations is not as dramatic, and this observation is to be expected based on the fact that the ADA enzyme has a greater affinity (lower Km) for deoxyadenosine than for adenosine. Surprisingly, adenosine can persist in plasma at very high levels and this remains a concern based on the observation that in ADA-deficient mice, elevated adenosine has significant effects (see the section "Animal Models" below), . Additionally, SAH hydrolase activity remains low, reflecting retention of increased amounts of metabolites (Hirschhorn et al., 1981). The incomplete metabolic correction may explain the persistence of nonimmunological manifestations in transplanted patients such as sensorineural deafness and cognitive and behavioral abnormalities (Albuquerque and Gaspar, 2004; Rogers et al., 2001; Tanaka et al., 1996), despite the fact that the bony abnormalities disappear rapidly. Genetic deficiency of SAH hydrolase is now known to result in mental deterioration, hypotonicity, and myopathy as well as multiple biochemical aberrations, including hypermethionemia, but without signs of immunodeficiency (Baric et al., 2004). The ability of dietary manipulation to reverse the metabolic abnormalities and apparently the mental deterioration in SAH-deficient patients (Baric et al., 2004) raises the need to assess the correction of SAH pathways in post-BMT ADA-deficient patients and offers a possible role for dietary manipulation in ADA-, but also PNP-, deficient patients with cognitive defects. Finally, it is also not known whether transplantation from an ADA-heterozygous carrier has different effects than from a homozygous normal. Metabolites have not been reported in patients transplanted following marrow ablation sufficient to result in replacement of all hematopoietic elements with donor-derived precursors.

Unfortunately, in an outbred population with small family size, as typically exists in the United States, fewer than 25 percent of patients have an HLA-matched related donor. Haploidentical transplantation from a related donor has higher morbidity and mortality in all forms of SCID than HLA-matched transplantation. It usually requires pretreatment myeloablation, but it is performed in the absence of preparative chemotherapy in some centers (Buckley et al., 1999) and can result in permanent engraftment (see Chapter 60). The European Bone Marrow Transplantation working party (EMBT) and the European Society for Immunodeficiency have published the analysis of a multicenter retrospective study on the outcome of BMT in 106 patients with ADA-SCID. BMT from matched sibling and family donors had significantly better survival (86% and 81%) in comparison with BMT from matched unrelated (66%; $P < .05$) and haploidentical donors (43%; $P < .001$). The vast majority of surviving patients achieved recovery of both cellular and humoral immunity (Hassan et al, 2012). Currently, therefore, it appears that ADA-deficient patients are poorer candidates for haploidentical transplantation than other forms of SCID, in which the average survival is greater than 54 percent (Antoine et al., 2003). The EBMT/ESID study showed that patients who received unconditioned transplants had superior overall survival in comparison with myeloablative procedures (81% vs 54%; $P < .003$). Reduced intensity conditioning protocols are being tested to reduce toxicity while achieving adequate donor engraftment (Cancrini et al, 2010). While BMT continues to be an intensive procedure with potential severe adverse effects, studies have shown that it provides enhanced immune reconstitution in comaparison with ADA enzyme replacement therapy (Serana et al., 2010; Kanegane et al., 2013).

Enzyme Replacement Therapy

Enzyme replacement therapy for ADA-deficient SCID does not require uptake of the enzyme into cells. Therapy is based, first, upon the fact that metabolites are present in plasma and body fluids, where they can be degraded by administered enzyme present in the plasma; second, additional toxic metabolites such as dATP are in equilibrium with the precursors in plasma (Hershfield, 1995a, 1995b, 2000; Hershfield et al., 1987, 1993; Hirschhorn et al., 1980a; Hopp et al., 1985; Ochs et al., 1992; Polmar et al., 1976; Weinberg et al., 1993).

Therefore, lowering of substrate concentrations in plasma results in lowering of intracellular concentrations of metabolites as well (Fig. 14.7). The first attempts at enzyme therapy utilized partial exchange transfusion with normal, irradiated erythrocytes, based on the fact that erythrocytes have transport sites for both adenosine and deoxyadenosine as well as containing adenosine deaminase. Partial exchange transfusion lowered metabolite concentrations dramatically, restored normal growth and development, and prolonged survival in at least six patients. However, this treatment did not alter immunological responsiveness in most patients; moreover, any improvement in immunological parameters was often short-lived (Ochs et al., 1992). Additionally, transfusion carried the risk of transmission of infectious agents and resulted in iron overload. Three patients first treated with transfusion therapy survived until over 10 years of age and were then placed on enzyme replacement therapy with intramuscular bovine ADA (see below); two of these are siblings were still alive at approximately 20 years of age. Of note, infusions of autologous red blood cells loaded with bovine ADA have been used in one patient with reported beneficial results (Bax et al., 2007).

The development of PEG-ADA enzyme replacement therapy (polyethylene-glycol-modified calf intestinal ADA; pegadamase bovine [Adagen]) has completely replaced the original enzyme replacement treatments. The modification, involving the addition of PEG to lysine residues, is designed to mask the enzyme so that its half-life is markedly prolonged. While dosages recommended are from 15 to 30 U/kg of body weight weekly, regimens may be individualized, based on monitoring

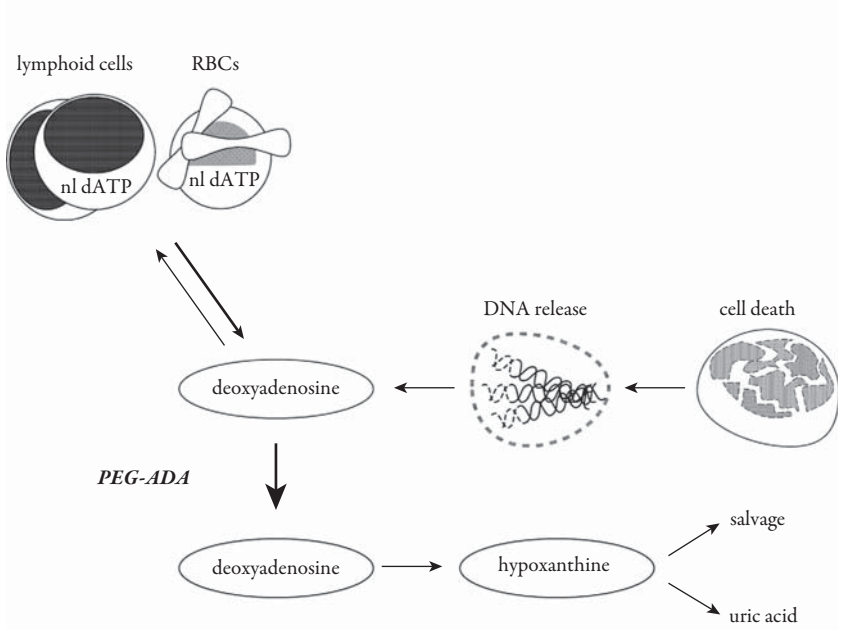

Figure 14.7 ADA deficiency: effects of enzyme therapy.

of plasma ADA activity. In practice, early-onset SCID patients are being treated with twice-weekly intramuscular injections of 30 to 60 U/kg, based on ideal body weight, for the first several months of therapy. There may be a diminished half-life of the enzyme in these very ill infants and/or poorer responses to usual doses. Monitoring of dATP, total deoxyadenosine nucleotides, and SAH hydrolase activity is recommended since the increase in deoxynucleotides and decrease in SAH hydrolase activity have been associated with a reduction of lymphocyte counts and function (Chun et al., 1993). Periodic testing for development of anti-ADA antibodies is also advisable.

PEG-ADA therapy has completely replaced partial exchange transfusion because it is safer; it can deliver greater amounts of enzyme and therefore more completely lower metabolites; and, in addition to restoring normal growth and development and prolongation of life, it results in the development of protective, although not normal, T-cell immunity in ~80 percent of the treated patients. To date, more than 180 patients have been treated with PEG-ADA worldwide, with a survival rate of approximately 80 percent (Gaspar et al., 2009). Virtually all patients on PEG-ADA develop antibodies against the bovine ADA protein that in ~10 percent of the cases are neutralizing antibodies for the function of the injected enzyme and require increasing the dosage or discontinuation in an attempt to achieve desensitization (Chaffee et al., 1992; Chun et al., 1993; Hershfield, 2004). Other complications seen in patients on PEG-ADA treatment include autoimmune hemolytic anemia and EBV-positive lymphoproliferative syndrome, which have required therapeutic attempts with HSCT. One of the patients responsive to transfusion treatment died of uncontrollable autoimmune hemolytic anemia following a viral infection (Ratech et al., 1985). A second died at 6 years of age of overwhelming varicella when exposure was not recognized in time to administer appropriate preventive therapy. Of note, elective HSCT after PEG-ADA treatment has resulted in survival of ~50 percent of cases, suggesting that the use of PEG-ADA to stabilize the metabolic status of patients after diagnosis and before transplantation can be beneficial (Gaspar et al., 2009).

Overall, although reconstitution of immunity appears to be suboptimal, the clinical response of children on PEG-ADA has been good, as measured by normal growth and development, ability to attend school, absence of opportunistic infections, and normal recovery from varicella and other viral diseases. Early mortality appears to be limited to early-onset cases with severe infectious complications. Immune reconstitution, as measured by lymphocyte counts and in vitro function, has been less complete, and ~20 percent of patients, predominantly with infantile onset of disease, show slower and lesser improvement. An increase in B cells usually precedes the increase in T cells and the appearance of mitogen responses. Although mitogen responses improve from the initial 0 to 10 percent of normal, they then fluctuate between 25 and 90 percent of normal. After the first year, most patients remain lymphopenic. Specific antibody responses have been detected in half of the patients, and half no longer receive regular intravenous immunoglobulin replacement (Hershfield, 2004). Elegant studies of two patients with ADA-deficient SCID of early onset during their first year of enzyme therapy have provided evidence that the therapy results in apparent rescue of immature lymphocyte progenitors. It was shown that mature immunocompetent lymphocytes were recruited from progenitors, recapitulating ontogeny, rather than merely expanding a small pool of relatively mature cells (Weinberg et al., 1993). Thus PEG-ADA therapy, adjusted as needed to normalize SAH hydrolase activity, resulted in the sequential appearance of $CD3^{dim}$ cells, followed by transient appearance of cells expressing both CD4 and CD8, and finally the mature

phenotype of $CD3^{bright}$ cells expressing either CD4 or CD8. These changes were observed between 3 and 5 months following the start of therapy. The appearance of mature T cells was then followed by IL-2-dependent mitogen responses and then rapidly by IL-2-independent responses and antigen-specific responses, also initially transiently IL-2 dependent. Other studies have demonstrated normalization of the antibody response, as indicated by the appearance of responses to the bacteriophage ΦX174 (Ochs et al., 1992).

Enzyme replacement therapy results in dramatic lowering of metabolites, most notably in returning the SAH hydrolase activity to normal or almost normal. The activity of SAH hydrolase appears to be the most sensitive indicator of total body concentration of toxic metabolites. The major questions remaining as to PEG-ADA therapy are whether immune function will remain improved over the years and whether the efficacy will be limited by the underlying phenotype or by a prior history of infections that have presumably destroyed a significant portion of the pool of "rescueable" lymphocyte precursors. A retrospective study designed to assess the long-term effectiveness of PEG-ADA treatment on nine ADA-deficient SCID patients (age 5 to 15) showed that despite initial improvements, the lymphocyte counts of all of the PEG-ADA–treated patients were below the normal range at all times. The study also showed that a gradual decline of mitogenic proliferative responses was evident after a few years of treatment and normal antigenic response occurred less than expected (Chan et al., 2005). In addition to the possible transitory efficacy of the treatment, the other major disadvantages of PEG-ADA therapy are its high cost, the necessity for weekly, life-long therapy (possibly requiring ongoing monitoring of metabolites for adjustment of dose), and the possibility of developing clinically significant anti-enzyme antibody. The cost and need for ongoing therapy are important although not insurmountable. A recombinant human form of the enzyme is under study and could solve or reduce the problems of anti-ADA antibody.

Gene Therapy

ADA-deficient SCID has been the pioneer disorder for the development of human gene therapy trials (see Chapter 61) (Aiuti et al., 2002; Blaese et al., 1995; Bordignon et al., 1995; Hoogerbrugge et al., 1996; Kohn et al., 1995; Onodera et al., 1998). ADA deficiency appeared to be an excellent candidate for gene therapy, based on the knowledge that the disease could be corrected by bone marrow transplantation; that manipulation of bone marrow cells ex vivo prior to transplantation is routine and could be easily adapted to allow for introduction of the ADA cDNA into cells; and that regulated expression did not appear to be required. Experiments in mice indicating that lymphoid cells containing the ADA gene have a marked advantage over ADA-deficient cells in an ADA-sufficient environment, a surrogate model for enzyme therapy (Ferrari et al., 1991), and results of bone marrow transplantation consistent with the hypothesis that endogenous ADA is more effective than exogenous ADA provided a rationale for attempts at gene therapy for ADA deficiency despite the availability of alternative modes of therapy (e.g., bone marrow transplants, PEG-ADA). The development of gene therapy was supported by its important theoretical advantages, such as avoiding the threat of graft-versus-host disease and availability to all patients. To be successful, efficient and stable gene transfer into patients' cells is a prerequisite and, ideally, genetic correction of hematopoietic stem cells should be achieved.

Gene therapy for the treatment of ADA deficiency by introduction into hematopoietic cells of a normal ADA cDNA contained in a retroviral vector has been pursued in five different countries: the United States, the Netherlands, Italy, the UK, and Japan. As of 2013, ~60 patients have enrolled in these trials, although published data are not available for all of the cases. Most patients have been treated using a retroviral vector containing the normal ADA cDNA and with ex vivo gene transfer. Very recently, trials using lentiviral vectors have begun and enrolled a few patients. In the U.S., gene therapy was initially performed in two patients using T cells expanded in vitro as the target cells (Blaese et al., 1995; Mullen et al., 1996; Muul et al., 2003) and subsequently $CD34^+$ cells isolated from the patients' cord blood in three newborns diagnosed prenatally (Kohn et al., 1995, 1998). Patients treated with T-cell gene therapy showed improvement of a series of immunological parameters (Blaese et al., 1995), although the concomitant PEG-ADA treatment makes it difficult to attribute these results to gene therapy alone. Nevertheless, this trial has demonstrated that retroviral-mediated ADA gene transfer into T cells can achieve long-term (15+ years) presence and expression of the exogenous gene (Muul et al., 2003).

The design of the first Italian trial included both peripheral blood mononuclear cells and T-cell–depleted bone marrow cells corrected with distinguishable ADA gene transfer vectors. The results from the initial two treated patients indicated that short-term marking was achieved from cells derived from peripheral blood, whereas ADA-corrected cells detected in patients after 1 year were from bone-marrow–derived cells (Bordignon et al., 1995).

While restoration of immune function through these initial experiments was incomplete or absent, the clinical and technical experience generated by these investigations was remarkable and represented a stepping stone on which more recent successes were built. Indeed, ongoing trials implementing more efficient culture condition and gene transfer vectors have recently demonstrated that gene therapy can be successful in ADA deficiency (Kohn and Candotti, 2009). Indeed, multilineage engraftment of gene-corrected cells, metabolic correction, and improvement of immune function was achieved in eight of ten ADA-deficient patients who were not treated with PEG-ADA and received genetically modified $CD34^+$ cells after preparative nonmyeloablative chemotherapy (Aiuti et al., 2002, 2009a). These results are superior to those of other groups that have treated ADA-deficient patients in the UK, United States, and Japan (Gaspar et al., 2006, 2012; Candotti et al., 2012) and suggest that additional improvements are necessary for gene therapy to become a widespread alternative treatment option for ADA deficiency. Among these, is the development of lentiviral vectors (Carbonaro et al., 2006; Mortellaro et al., 2006) that are expected to be the main gene

transfer tool in future trials. These vectors are are known to be less prone to integration near gene transcriptional start sites and are therefore considered less likely to cause insertional oncogenesis adverse events such as those occurred in gene therapy trials for X-linked severe combined immunodeficiency, chronic granulomatous disease and Wiskott-Aldrich syndrome (Aiuti et al., 2012; Cavazzana-Calvo et al., 2012).

Management of PNP-Deficient Patients

Management of PNP-deficient patients includes extensive and frequent immunological, hematological, and neurological assessments, as the clinical and laboratory features of this disease fluctuate and deteriorate over time. Intravenous immunoglobulin replacement is indicated for PNP-deficient patients, particularly when abnormal production of antibodies is demonstrated. Patients should receive prophylaxis for *Pneumocystis jiroveci* pneumonia. PNP-deficient patients who are able to produce antibodies and are not receiving intravenous immunoglobulins should be vaccinated, but not with live viral vaccines. All blood products given to PNP-deficient patients should be CMV-negative (if the patient has not had CMV infection previously) and irradiated to prevent graft-versus-host disease. Despite all these supportive measures, PNP-deficient patients invariably die in their first or second decade of life from disseminated viral infections, uncontrolled autoimmune hematological cytopenia, or malignancy. The extremely poor outcome for PNP-deficient patients has prompted attempts to correct the metabolic toxicity, thereby restoring immune function, or directly correcting the immune abnormalities.

To alleviate some of the effects of abnormal purine metabolism, deoxycytidine, which bypasses ribonucleotide reductase inhibition, was given together with tetrahydrouridine to inhibit deoxycytidine deaminase (Markert, 1991). This combination did decrease dGTP concentrations and increase GTP; however, the two treated PNP-deficient patients died of infections. One patient received uridine to correct potential pyrimidine starvation with no significant immune benefit. Another patient, who received guanine to increase intracellular GTP, experienced only a brief improvement in T-cell function. Similarly, treatments with adenine, uridine, hypoxanthine, or allopurinol did not improve lymphocyte responses to stimulation (Staal et al., 1980a).

PNP enzyme replacement with repeated erythrocyte transfusions, similar to the treatment initially used for ADA deficiency, was given in an attempt to reverse the metabolic abnormalities in PNP-deficient patients. It was hypothesized that toxic deoxyguanosine would follow its concentration gradient and exit from the patient's PNP-deficient lymphocytes through the serum and into the donated PNP-proficient erythrocytes, where it would be metabolized. Transfusion of normal erythrocytes did decrease nucleoside accumulation and increase uric acid production in PNP-deficient patients, followed by a transient increase in lymphocyte counts and a partial restoration of T-cell–dependent immunity (Rich et al., 1980; Staal et al., 1980a; Zegers et al., 1978). Disappointingly, immune reconstitution remained subtherapeutic and did not prevent devastating infections (Sakiyama et al., 1989). Moreover, the frequent erythrocyte transfusions were associated with iron overload and an increased risk of infections. The failure to restore T-cell immunity with erythrocyte transfusions could be due to inadequate and nonsustained PNP levels in target tissues or from the continuation of other metabolic consequences of PNP deficiency, such as depleted GTP production, in the cells.

Following the success of PEG-ADA in restoring immune function, a mutated form of *E. coli* PNP was covalently attached to PEG (Hershfield et al., 1991). PEG extended the activity of the bacterial PNP in vitro and reduced its immunogenicity in normal mice. Repeated PEG-PNP injections in PNP-deficient mice substantially increased whole-blood PNP activity to 20 percent of wild type, alleviated the secondary loss of dGK activity, and reduced urinary secretion of PNP substrates. PEG-PNP also reduced the concentration of dGTP in thymocytes of PNP-deficient mice, although not to normal levels. Treatment was followed by an increase in thymocyte numbers, improved lymphocyte responses to foreign antigens, and extended survival of the mice, even when housed in a nonsterile environment (Roifman and Grunebaum, unpublished). However, data indicating that PEG-ADA provides only partial and temporary immune reconstitution in ADA deficiency (Chan et al., 2005; Husain et al., 2007), possibly because the enzyme is not delivered to its native intracellular location, suggested that PEG-modified enzyme replacement may be suboptimal also for PNP deficiency. In addition, difficulties in production of PEG-PNP and the high cost of similar PEG-modified enzymes prompted us to evaluate alternative enzyme replacement therapy, such as PTD–PNP.

Protein transduction domains (PTDs), including the HIV TAT, are peptides capable of crossing biological membranes (Gump and Dowdy, 2007). PTDs deliver molecules attached to them into cells in a receptor-independent manner and cross the blood–brain barrier (Schwarze et al., 1999). Human PNP, fused with the 11 amino acids of TAT required for transcellular transport, maintained its enzyme activity. The PTD–PNP fusion protein was further improved and used in in vitro studies demonstrating that the PTD–PNP was able to rapidly enter PNP-deficient lymphocytes, increased PNP activity in cells for more than 96 hours, and was distributed in the cytoplasm, in a similar manner as endogenous PNP (Toro and Grunebaum, 2006). PTD–PNP administration increased PNP activity in all organs tested and urinary uric acid excretion in PNP-deficient mice. Twice-weekly injections of PTD–PNP corrected thymocyte development and T-lymphocyte function in PNP-deficient mice, improved weight gain, and significantly extended the survival of the mice, with no apparent toxicity (Toro and Grunebaum, 2006). Further preclinical studies are being conducted to establish the potential benefit of PTD–PNP for PNP-deficient patients.

Other therapeutic approaches have focused on directly improving immune function in PNP-deficient patients. A few patients have received fetal thymic transplants or thymic factors, but without significant benefit (Markert, 1991). In contrast, HSCT has been able to provide long-term immune reconstitution, albeit in only a few patients, and is currently considered the treatment of choice for PNP deficiency. The

initial review of HSCT in PNP deficiency was disappointing, with only one of five patients achieving immune reconstitution (Markert, 1991). However, subsequent reports have been more encouraging (Aytekin et al., 2008; Baguette et al., 2002; Carpenter et al., 1996 ; Classen et al., 2001; Delicou et al., 2007; Hallett et al., 1999; Isoyama et al., 2003; Myers et al., 2004). Bone marrow cells from HLA-matched family sibling donors were used in the majority of HSCTs for PNP deficiency (Aytekin et al., 2008; Baguette et al., 2002; Carpenter et al., 1996; Classen et al., 2001; Delicou et al., 2007). In addition, two PNP-deficient patients were transplanted with umbilical cord blood cells from unrelated donors. The first patient died 3 months after an HLA-matched cord blood transplant, which had been given subsequent to failing a previous transplant (Isoyama et al., 2003). The second patient received an umbilical cord blood transplantation following conditioning with busulfan, cyclophosphamide, and antithymocyte globulin (Myers et al., 2004). One year later, more than 98 percent of lymphoid and myeloid cells were of donor origin, with a significant improvement in the number of $CD4^+$ T lymphocytes and responses to mitogens. Difficulty in engrafting donor cells and graft rejection have been reported in several PNP-deficient patients, particularly after receiving T-cell–depleted haploidentical HSCT (Isoyama et al., 2003; Markert, 1991). Because most PNP-deficient patients have some residual T-cell immune function, it is not surprising that myeloablative conditioning, usually including cyclophosphamide and busulfan, was associated with improved engraftment (Carpenter et al., 1996; Rich et al., 1980; Staal et al., 1980a). However, the excessive vulnerability of PNP-deficient patients to chemotherapy (Blatt, 1990) together with the increased sensitivity of PNP-deficient cells to irradiation (Dror et al., 1993) prompted investigations into the use of less toxic conditioning regimens. One patient had normal T-cell numbers and adequate responses of T cells to antigens 1.5 years after an HLA-identical bone marrow transplant with busulfan and fludarabine conditioning (Classen et al., 2001). Another patient, who received bone marrow cells from an HLA-matched uncle with no conditioning, had 100 percent donor T cells 30 months after transplant and was able to overcome a disseminated BCG infection. B cells remained of recipient origin and the patient required intravenous immunoglobulin replacement (Aytekin et al., 2008). While these results are promising, the small number of patients assessed thus far prevents recommendation of an ideal conditioning regimen or stem-cell source for PNP deficiency.

The effects of HSCT on neurological outcome in PNP deficiency have been described in only a few patients, with just 1 to 4 years of follow-up. Some have reported that spastic paresis and tonus abnormalities remained static (Aytekin et al., 2008; Classen et al., 2001; Hallett et al., 1999), while ataxia, mobility, and cognitive function even improved (Aytekin et al., 2008; Classen et al., 2001; Myers et al., 2004; Singh, 2012), although the latter may also reflect improved overall medical status posttransplantation.

For the majority of PNP-deficient patients without genotypically HLA-identical donors, HCT with autologous cells that are corrected with the normal gene may have the benefit of avoiding the immunological complications of allogenic HCT. Retroviruses expressing murine PNP under the control of the murine leukemia virus were shown to increase PNP activity in T lymphocytes from PNP-deficient patients and partially correct the response of these cells to mitogens (Nelson et al., 1995). Recently we developed a lentivirus-based vector expressing human PNP under the control of the housekeeping human elongation factor 1 alpha (Liao et al., 2008). This lenti–PNP virus efficiently transduced lymphocytes from PNP-deficient patients as well as fibroblasts and bone marrow cells from PNP-deficient mice. Transplantation of nonlethally irradiated PNP-deficient mice with PNP-deficient bone marrow cells transduced with the lenti–PNP virus resulted in a transient increase of uric acid production, thymocyte maturation, and extended survival of the mice. However, 12 weeks after transplantation, PNP expression in corrected cells and the percentage of donor cells in the bone marrow of the mice decreased significantly (Liao et al., 2008). Optimizing the myeloablative conditioning given to recipients and ensuring long-term gene expression are among the factors expected to improve gene therapy for PNP-deficient patients.

In conclusion, the disappointing long-term prognosis for PNP-deficient patients treated with only supportive measures suggests that HCT should be offered to all patients with a genotypically HLA-identical or phenotypcally closely matched HLA donor. For the remaining patients, until effective enzyme or gene replacement therapies are available, the risks and benefits of transplantation using alternative sources of cells should be discussed.

ANIMAL MODELS

No naturally occurring animal models of ADA or PNP deficiency are known. However, targeted gene knockout mice have been generated to model both human conditions. An increasing amount of knowledge is being generated by studying these animals. It is worth noting, however, that while the knockout animals are obviously useful to direct the investigators' attention to relevant mechanistic and pathogenetic aspects of the conditions, the caveat exists that observations in mice may not immediately translate to the human diseases.

ADA Knockout Mice

At least two groups have succeeded in generating ADA knockout mice (Blackburn et al., 1995; Migchielsen et al., 1995, 1996; Wakamiya et al., 1995). However, the absence of ADA in mice leads to perinatal lethality. This is in contrast to the situation in humans, where individuals homozygous for deletion of the promoter and exon 1 have been born and presented with a disease indistinguishable from other patients with ADA-deficient SCID. Pathologically, newborn knockout mice exhibit marked hepatocellular degeneration, atelectasis, and intestinal cell death. In contrast to humans with ADA-deficient SCID, in whom marked lymphopenia is evident by 18 to 20 weeks of gestation, there were only minor reductions in $CD4^+/CD8^+$ lymphoid cells in livers of ADA knockout mice.

The problem of perinatal lethality was addressed with two different approaches. Expression of a human ADA transgene containing human regulatory elements rescued the mice (Migchielsen et al., 1996), demonstrating that the lethality was not due to disruption of a gene within the ADA gene. More significantly, however, mice could be rescued by expression of a transgene containing a promoter element restricting expression to the placenta and gastrointestinal tract (Blackburn et al., 1995). Normal mice have very high ADA activity in placenta and foregut, and the knockout mice were rescued by a minigene construct that selectively expressed ADA in these tissues. Several of the metabolic abnormalities seen in humans were reproduced in these mice, including increased deoxyadenosine and dAMP in the thymus and reduced SAH hydrolase in the thymus, spleen, and liver. The mice showed moderate reductions in size of the thymus and spleen and in absolute numbers of lymphocytes in these organs. In summary, evidence for a mild immunodeficiency was found. It is possible that the postnatal expression of ADA in intestinal tissues provided partial immunological rescue, suggesting that oral therapy might be ameliorative in human ADA deficiency. As an alternative explanation for the absence of profound immunodeficiency in the partially corrected mice, compensating pathways may exist in mouse that alter the pathophysiology of ADA deficiency. It is well recognized that the final common pathway for purine metabolism, ending in uric acid, is quite different in humans compared to virtually all other species. In addition, it is not infrequent that immunological knockouts give phenotypes that differ between man and mouse.

Filling the need for a better model of the human disease, a mouse deficient for ADA that does manifest combined immunodeficiency was then created by a two-stage genetic engineering strategy (Blackburn et al., 1998). These mice appear to reproduce not only the biochemical but also the immunological abnormalities of the human disease. This animal model may therefore help clarify the role of enzyme deficiency in production of various human phenotypic features. ADA-deficient splenic B lymphocytes show defects in proliferation and activation with a high propensity to undergo B-cell-receptor–mediated apoptosis. As a result, profound loss of germinal center architecture is noted, which may be responsible for impaired B-cell development (Aldrich et al., 2003). In addition, the finding of renal pathology in these animals suggests that the renal abnormalities previously reported in humans with ADA deficiency are a pleiotropic effect of ADA deficiency (Ratech et al., 1985). Treatment of these mice with PEG-ADA showed that while low doses could prevent the pulmonary insufficiency, the immunodeficiency could be ameliorated only by high doses of PEG-ADA, thus demonstrating a different impact of the therapy at the level of different tissues (Blackburn et al., 2000). Further, these mice provided evidence that the respiratory failure was attributable to IL-13–mediated accumulation of activated alveolar macrophages and eosinophils and mast cell degranulation with airway hyperresponsiveness (Blackburn et al., 2000, 2003; Chunn et al., 2001), thus offering insights into the mechanisms potentially responsible for asthmatic conditions and pulmonary insufficiency observed in some ADA-deficient humans. Furthermore, studies in these mice showed the development of lung and dermal fibrosis in association with increased levels of adenosine and key mediators of fibrosis, including transforming growth factor beta1, connective tissue growth factor, IL-13, and platelet-derived growth factors (Chunn et al., 2005, 2006; Fernandez et al., 2008). Treatment of ADA-deficient mice with the A(2A) receptor antagonist ZM-241385 prevented the development of dermal fibrosis in this model and confirmed a fibrogenic role for adenosine in the skin that may be speculated to contribute to the high incidence of dermatofibrosarcoma protuberans observed in ADA-deficient patients (Kesserwan et al., 2012). Finally, these mice have a specific bone phenotype characterized by alterations of structural properties and impaired mechanical competence as the result of decreased osteoclastogenesis and defective osteoblast function. The bone abnormalities observed in these ADA-deficient mice appear to have consequences on the bone marrow microenvironment and cause reduced in vitro and in vivo hematopoiesis (Sauer et al., 2009). These abnormalities may help explain the skeletal abnormalities characteristic of ADA-deficient humans and the myeloid dysplastic features recently observed in these patients.

PNP Knockout Mice

There are no known naturally occurring models for PNP deficiency. Several groups attempted to chemically induce transient PNP deficiency in dogs, rats, and mice; however, the metabolic and immune abnormalities differed from those observed in PNP-deficient patients (Bantia et al., 1996; Osborne and Barton, 1986; Osborne et al., 1986; Slichter et al., 1990). Subsequently, N-ethylnitrosourea mutagenesis was used to create three mice strains with different missense mutations in the PNP gene. PNP activity in the erythrocytes of these mice was severely reduced (1 to 4.6 percent) but not absent (Mably et al., 1989; Snyder et al., 1997). Progressive thymic hypocellularity due to a reduction of $CD4^+$ $CD8^+$ double-positive thymocytes was observed in these mice, which also showed a marked reduction in peripheral T-lymphocyte numbers and function. Although these mice shared some similarities with the human phenotype, the residual levels of PNP activities, the lack of dGTP accumulation in thymocytes, the delayed onset of the immune deficiency, and the normal lifespan of the mice were not representative of PNP-deficient patients (Snyder et al., 1997). Therefore, efforts were devoted to generate another PNP-deficient mouse model targeting the catalytic site of the murine PNP gene (Arpaia et al., 2000). These PNP-deficient mice share most of the metabolic, immune, and nonimmune abnormalities described in typical PNP-deficient patients, including very early death at 8 to 12 weeks of life (Table 14.10). PNP activity in the blood of PNP-deficient mice is less than 0.2 percent of normal, and their urine contains large amounts of the four PNP substrates (Arpaia et al., 2000). Uric acid production in PNP-deficient mice is diminished and the mice fail to gain weight (Toro and Grunebaum, 2006). At 3 weeks of age, the thymus of PNP-deficient mice is small and lacks proper corticomedullary distinction, with a marked reduction in total

thymocytes, primarily due to a reduced number of $CD4^+$ $CD8^+$ double-positive thymocytes, which have undergone accelerated apoptosis (Arpaia et al., 2000). The increased apoptosis of PNP-deficient double-positive thymocytes can be replicated ex vivo with low concentrations of deoxyguanosine, which induce significant apoptosis preferentially in the double-positive thymocyte population. Abnormal differentiation occurs also in the $CD4^-$ $CD8^-$ (double negative, DN) thymocytes, primarily among the $CD25^-$ $CD44^-$ DN4 population, while thymocyte proliferation, determined by BrDU incorporation, and T-cell-receptor V-beta chain rearrangements are unaffected (Papinazath et al., 2011). TRECs in the peripheral T lymphocytes of PNP-deficient mice are reduced, further indicating that PNP deficiency interferes with thymocyte development. In mitochondria isolated from PNP-deficient thymocytes, a marked increase in dGTP is found, which supports the hypothesis that accumulation of dGTP in the mitochondria of susceptible thymocytes is the basis for PNP immunodeficiency. Interestingly, dGK activity is reduced in PNP-deficient thymocytes, as well as all other tissues examined, which suggests that dGTP inhibits dGK (Arpaia et al., 2000). The number of peripheral T lymphocytes in PNP-deficient mice is markedly reduced, and these cells are unable to respond to mitogens or allogeneic stimulations. T lymphocytes from PNP-deficient mice are also more sensitive to ionizing irradiation and secrete reduced amounts of IL-2. As seen in many PNP-deficient patients, the B-cell compartment in PNP-deficient mice is less affected, with no changes in the frequency of mature B lymphocytes. All mice demonstrate a severely enlarged spleen, which contains reduced white pulp and T cells with increased numbers of inflammatory cells, including pre-B, myeloid, and plasma cells (Arpaia et al., 2000).

The frequent neurological defects seen in PNP-deficient patients led us to investigate for similar abnormalities in PNP-deficient mice. We found evidence of ataxia and abnormal motor coordination in the mice, together with changes in cerebellar Purkinje cells. These abnormalities are already evident in 2-week-old PNP-deficient mice, indicating that the neurological damage from PNP deficiency occurs early in life (Mansouri et al., 2012).

PNP-deficient mice also suffer from hepatomegaly, with significantly elevated bilirubin and liver transaminases, which has been reported in ADA-deficient patients and mice (Bollinger et al., 1996; Somech et al., 2009; Wakamiya et al., 1995) but not in PNP-deficient patients. Histological examination of the liver from PNP-deficient mice demonstrates marked hepatitis with distorted liver cells, inflammatory cell infiltrates (particularly plasma cells), and bile plugs (Grunebaum, unpublished). Despite extensive investigations, no infectious etiology could be detected.

In addition to revealing pathogenic mechanisms responsible for phenotypic abnormalities, PNP-deficient mice allow us to assess potential therapeutic options for PNP deficiency (Liao et al., 2008; Toro and Grunebaum, 2006). Among the different treatments studied extensively in our PNP-deficient mice, best results were obtained with PTD–PNP enzyme replacement, which corrected the metabolic and immune abnormalities as well as liver dysfunction, while prolonging survival for more than 1 year. Transplantations using normal bone marrow cells also corrected immune abnormalities, although liver manifestations continued, possibly because the metabolic improvement was only partial. Importantly, many PNP-deficient mice transplanted with normal cells lose the graft, suggesting that the survival advantage that PNP-proficient cells possess in a PNP-deficient environment may be inadequate.

Table 14.10 **COMPARISON BETWEEN PNP-DEFICIENT PATIENTS AND MURINE MODEL OF PNP DEFICIENCY**

	PNP-DEFICIENT PATIENTS	PNP-DEFICIENT MICE
Accumulating toxicity over time	Yes	Yes
Typical age of clinical symptoms	1–5 years	5–7 weeks
Deoxyguanosine and dGTP	Increased	Increased
Guanine and GTP	Decreased	Decreased
Uric acid production	Decreased	Decreased
$CD4^+$ T-lymphocyte numbers	Reduced	Reduced
T-lymphocyte responses	Reduced	Reduced
Hypoplastic thymus	Yes	Yes
Immune dysregulation	Yes	Yes
Large spleen	Occasional	Yes
Humoral immunity	Spared	Spared
Neurological abnormalities	Yes	Yes
Liver abnormalities	Not reported	Yes
Sensitivity to irradiation	Yes	Yes
Engraftment failure after transplant	Common	Common
Age of death without treatment	5–10 years	8–12 weeks

Transplanting gene-corrected PNP-deficient bone marrow cells into PNP-deficient mice was also associated with improved metabolic and immune functions, but these were transient and inferior to both enzyme replacement therapy and normal bone marrow transplantation. Interestingly, none of the therapeutic interventions corrected the neurological abnormalities in PNP-deficient mice, possibly because treatments were initiated at 3 to 4 weeks of age, after irreversible damage to the nervous system had already occurred. This emphasizes the importance of diagnosing and correcting PNP deficiency as early as possible.

Mouse models are undoubtedly providing valuable insights into the pathogenesis of immunodeficiency due to defects of purine nucleotide metabolism. However, important differences may exist between mice and humans regarding both critical metabolic networks and alternative biochemical pathways. Definitive conclusions on the significance of the findings observed in ADA and PNP knockout animals will therefore have to be supported by confirmatory results obtained from studies in human patients.

FUTURE DIRECTIONS AND CHALLENGES

Even though ADA deficiency and PNP deficiency have been known to be the molecular basis of immunodeficiency and have been extensively investigated for over two decades, major challenges remain. These range from diagnostics to new forms of therapy to insights as to basic biology that are yet to be obtained.

The discovery of the molecular basis of the various immunodeficiency disorders discussed in this volume makes it important to develop an overall strategy for diagnosing immune disorders. Currently, in a severely ill child, the first step is determining the presence or absence of ADA deficiency, since enzyme replacement therapy can provide a life-saving intervention. With the development of other therapeutic options for additional disorders, this commonly used strategy may well become outdated. With respect to diagnostics, ADA deficiency is an inherited disorder and therefore involves a family. The importance of experienced genetic counselors in helping family members to deal with issues of identification as carrier cannot be overemphasized. We are often contacted by family members to determine if they are carriers of the mutations(s) in their families. Currently, these investigations are "cottage industry" in approach. The development of "chip" technology for rapid scanning for mutations, now being applied on a research basis, could revolutionize rapid diagnosis. However, given the rarity of the disease, automated mutation detection is unlikely to be developed by industry. Should there be an "orphan drug" equivalent for diagnostics? Such an approach would greatly facilitate relatively noninvasive prenatal diagnosis not only for prevention but also for early institution of therapy when available. These concerns apply to virtually all of the immunodeficiency disorders.

With respect to basic biology, the role of ADA and adenosine is an area that is increasingly being investigated. Adenosine interacts with multiple adenosine receptors that have opposing actions in different cell types. ADA bound to CD26 at the cell surface plays a role in regulating local concentrations of adenosine. The potential role of adenosine in the clinical aspects of ADA deficiency has been ignored for some time. Based on the observation that children, after bone marrow transplant, were immunocompetent despite persistently elevated plasma adenosine concentrations, no major involvement of adenosine in the pathophysiology of immunodeficiency was assumed. However, adenosine appears to be important in the pathogenesis of asthma, which may be more common in ADA-deficient patients than in the general population, and has important roles in the skin and the cardiovascular and nervous systems. ADA also shows localization to the nervous system, and more recent in vitro experiments indicate a role for adenosine in regulating intracellular signaling pathways. One additional line of evidence of the importance of adenosine at the SNC level comes from the clinical observation that methotrexate-induced coma is caused by elevated levels of adenosine and can be resolved by administration of adenosine receptor antagonist (i.e., aminophylline). In addition, one of the most widespread clinical observations of physicians treating ADA-deficient children for immunodeficiency has been that alertness improves following enzyme replacement therapy. Insufficient data are available, however, in long-term survivors of ADA-deficient SCID after HSCT to rule out that these patients may show an intellectual or attention deficit.

With respect to therapy, the challenges are obviously high. A combined role for PEG–ADA and gene therapy could provide an alternative management option for ADA-deficient patients lacking suitable transplant donors, once the risks of gene transfer into the hematopoietic stem cells for this disease are carefully considered. As the clinical importance of adenosine receptor-mediated effects is clarified, interventions based on the use of receptor antagonist and/or inhibitors may be considered and developed.

Progress in the clinical management of PNP deficiency is acutely needed to modify what is currently a severe prognosis. The availability of effective enzyme replacement therapy for PNP deficiency, analogous to the use of PEG–ADA in ADA deficiency, is likely to change patient management, enabling temporary correction of the abnormal purine metabolism until definitive treatments such as allogeneic stem cell transplantation or autologous gene-corrected cells are available. Importantly, the effects of PNP deficiency on nonhematopoietic cells, such as neuronal cells, need to be determined, as this may lead to significant changes in understanding the pathogenic effects of PNP deficiency and choosing optimal treatments for patients. The availability of an animal model that closely reflects the human disease is critical for all of these goals. Finally, some of the toxic effects of PNP deficiency may not be reversible with treatment, emphasizing the need for early recognition of affected patients through newborn screening and an increased awareness among health care providers.

SCID DUE TO DEFECTS IN T-CELL-RECEPTOR-ASSOCIATED PROTEIN KINASES (ZAP-70 AND LCK)

Naomi Taylor and Melissa E. Elder

ZAP-70 is a ζ-chain-associated protein of 70,000 kDa (MIM + 176947). Deficiency of ZAP-70 leads to a rare autosomal recessive form of severe combined immunodeficiency (SCID) characterized by the selective absence of $CD8^+$ T cells and abundant $CD4^+$ T cells in the peripheral blood that are unresponsive to T-cell-receptor (TCR)-mediated stimuli in vitro. Peripheral T lymphocytes from most affected patients demonstrate defective signaling following TCR engagement by antigen because of inherited mutations within the kinase domain of the cytoplasmic protein tyrosine kinase (PTK) ZAP-70. ZAP-70 deficiency provided the first evidence that PTKs, and ZAP-70 in particular, are required for normal human T-cell development and function. Deficiency of another critical PTK, Lck, has been associated with a SCID phenotype in isolated patients as well.

T-CELL SIGNAL TRANSDUCTION

The processes involved in CD4 versus CD8 selection during T-cell ontogeny are known to require intact signal transduction through the TCR of differentiating thymocytes (Cheng and Chan, 1997; Palacios and Weiss, 2004, 2007; Pfeffer and Mak, 1994; Robey and Fowlkes, 1994;). The signal transduction events mediated by the TCR on thymocytes are similar to those responsible for the activation of mature T cells. Propagation of antigen-binding signals from the TCR to the nucleus is primarily dependent on the activation of the PTKs Lck and ZAP-70 (reviewed in Cheng and Chan, 1997; Palacios and Weiss, 2004, 2007; Wange and Samelson, 1996; Weiss and Littman, 1994). PTK activation is a rapid and critical event that results in phosphorylation of downstream proteins, including phospholipase Cγ1 (PLCγ1), linker for activation of T cells (LAT) and Src homology 2 (SH2) domain-containing 76 kDa leukocyte protein (SLP-76; reviewed in Palacios and Weiss, 2004, 2007; Rudd, 1999; Wange and Samelson, 1996). These tyrosine phosphorylation events are critical for the recruitment of numerous other signaling molecules required for the mobilization of intracellular free calcium ($[Ca^{2+}]_i$) and activation of downstream pathways that culminate in the activation of T cells and initiation of T-cell-specific responses, described in more detail in Chapter 6.

T-CELL-RECEPTOR-ASSOCIATED PROTEIN TYROSINE KINASES

Stimulation of the TCR results in activation of certain nonreceptor cytoplasmic PTKs whose functions are critical for lymphocyte responses to antigens (see Chapter 6). The importance of these PTKs to T-cell development and function has been established by findings of immunodeficiency in both humans and PTK-deficient mice. Of the PTKs that have been described in T cells, the function of Lck is best understood. Lck is a 56 kDa Src family PTK that is expressed at high levels in peripheral T cells and in thymocytes at all stages of maturation (Perlmutter et al., 1988). Numerous in vivo and in vitro studies have confirmed the importance of Lck to normal T-cell signal transduction. Recruitment of ZAP-70 to the TCR is primarily dependent on the phosphorylation of consensus immunoreceptor tyrosine-based activation motifs (ITAMs) in the CD3 ε and TCRζ chains by Lck (Au-Yeung et al., 2009; Gauen et al., 1994; Iwashima et al., 1994; Weil et al., 1995; Weiss and Littman, 1994). The ITAMs are found either singly or multiply (3 copies) in the CD3ε and TCR ζ chains, respectively, and mediate TCR interactions with PTKs involved in signal transduction and with ZAP-70 in particular (Gauen et al., 1994; Irving et al., 1993; Weiss and Littman,

1994). Lck is also primarily responsible for mediating ZAP-70 phosphorylation, thereby triggering critical downstream signaling events required for T-cell activation (Au-Yeung et al., 2009; Chan et al., 1995; Watts et al., 1994).

Studies in genetically altered mice demonstrate that Lck is required for differentiation events in the transition of double-negative (DN; pre-TCR$^+$ CD4$^-$ CD8$^-$) thymocytes to double-positive (DP; TCR$^+$ CD4$^+$ CD8$^+$) thymocytes (Levin et al., 1993; Molina et al., 1992;). Disruption of Lck results in a SCID phenotype characterized by markedly decreased DP thymocytes and few single-positive (SP; CD4$^+$ or CD8$^+$) thymocytes or peripheral T cells (Molina et al., 1992). This block in T-cell development is related to a requirement for Lck in signaling through the pre-TCR CD3 complex (Levelt et al., 1995; Mombaerts et al., 1994; Palacios and Weiss, 2004). Lck is expressed prior to TCRβ chain rearrangement, and its activation induces thymocyte proliferation (between the DN and DP stages); moreover, it initiates TCRα chain rearrangement and allelic exclusion of TCRβ chain gene rearrangement (Anderson et al., 1993). ZAP-70 is a 70 kDa Syk family PTK expressed exclusively in all thymocyte subpopulations, peripheral T cells, natural killer (NK) cells, and aberrantly in neoplastic CD19$^+$ CD5$^+$ CD23$^+$ B cells in a subpopulation of patients with poor-prognosis B-cell chronic lymphocytic leukemia (Chan et al., 1992; Chiorazzi et al., 2005; Palacios and Weiss, 2007). Recruitment of ZAP-70 to the TCR is essential for its subsequent activation and for induction of downstream signaling events critical for induction of T-cell-specific responses (Au-Yeung et al., 2009; Wange et al., 1995b; Weil et al., 1995; Weiss and Littman, 1994). As described above, Lck mediates the phosphorylation of both tyrosine residues within each ITAM of TCRζ and CD3ε that occurs prior to ZAP-70 recruitment to the TCR (see Fig.6.2 in Chapter 6) (Gauen et al., 1994; Iwashima et al., 1994; Straus and Weiss, 1992; van Oers and Weiss, 1995; Weil et al., 1995). High-affinity binding of ZAP-70 to ζ and CD3ε requires the cooperative binding of both ZAP-70 SH2 domains (Au-Yeung et al., 2009; Gauen et al., 1994; Hatada et al., 1993; Isakov et al., 1995; Iwashima et al., 1994; Wange et al., 1993). Although association of ZAP-70 with the phosphorylated ITAM-containing subunits of the TCR releases ZAP-70 from its autoinhibited conformation, binding to the TCR alone is insufficient to induce ZAP-70 kinase activity (Au-Yeung et al., 2009; Madrenas et al., 1995; van Oers et al., 1994). ZAP-70 itself must be phosphorylated at specific tyrosine residues to increase its catalytic function (Chan et al., 1995; Neumeister et al., 1995; Wange et al., 1995a, 1995b; Watts et al., 1994). Tyrosine phosphorylation of ZAP-70 is mediated by Src family PTKs and by autophosphorylation activity (Au-Yeung et al., 2009; Chan et al., 1995; Neumeister et al., 1995; Wange et al., 1995a; Watts et al., 1994). Much of the increase in ZAP-70 catalytic function following TCR stimulation is associated with specific phosphorylation of tyrosine residue 493 by Lck or ZAP-70 itself (Au-Yeung et al., 2009; Chan et al., 1995; Watts et al., 1994). However, ZAP-70 enzymatic activity is also negatively regulated by phosphorylation of the adjacent tyrosine residue 492 (Chan et al., 1995; Wange et al., 1995a; Zhao and Weiss, 1996). Additional tyrosine residues within interdomain B, a region bridging the SH2 and kinase domains of ZAP-70, are phosphorylated and function as positive regulators of TCR signaling; these include tyrosine 315 (the binding site for the Vav guanine nucleotide exchange factor and CT10 regulator of kinase II, CrkII) and tyrosine 319, which is a binding site for PLCγ1 and Lck (Au-Yeung et al., 2009; Di Bartolo et al., 1999; Gelkup et al., 2005; Gong et al., 2001; Zhao and Weiss, 1999; Wu et al., 1997; Williams et al., 1999). Tyrosines 315 and 319 may also participate in regulation of ZAP-70 catalytic activity via an autoinhibitory switch mechanism (Au-Yeung et al., 2009). In contrast, phosphorylation of tyrosine 292 within interdomain B of the ZAP-70 protein inhibits TCR signaling by serving as a binding site for the E3 ubiquitin ligase c-Cbl, which targets ZAP-70 for ubiquitination and degradation (Lupher et al., 1996; Meng et al., 1999; Rao et al., 2000; Wang et al., 2000).

Following ZAP-70 phosphorylation and activation, multiple downstream signaling events occur that result in T-cell activation. Phosphorylated ZAP-70 triggers recruitment of other molecules to the signaling complex, resulting in transduction of the TCR-mediated signal. Specific in vivo substrates for ZAP-70 include LAT and SLP-76 (Wardenburg et al., 1996; Williams et al., 1998, 1999; Zhang et al., 1998). Recruitment to the signaling complex is mediated by the SH2 domains contained within each protein. Additional SH2 domain-containing signaling molecules recruited to the TCR via interactions with ZAP-70 or ZAP-70 substrates include c-Cbl, PLCγ1, CrkII, Vav, and the p85 subunit of PI3 kinase (Au-Yeung et al., 2009; Duplay et al., 1994; Finco et al., 1998; Katzav et al., 1994; Neumeister et al., 1995; Raab et al., 1997; Straus et al., 1996; Wardenburg et al., 1996; Wu et al., 1997; Yablonski et al., 1998). Formation of these protein complexes at the plasma membrane results in signal amplification and culminates in the transcription of genes involved in T-cell activation.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF ZAP-70 DEFICIENCY

Eight children from five families were originally described with SCID due to ZAP-70 deficiency (Arpaia et al., 1994; Chan et al., 1994a; Elder et al., 1994; Gelfand et al., 1995). These patients included six children from three genetically isolated Mennonite kindreds and two children from separate, unrelated (Hispanic and Caucasian) families, who were products of consanguineous relationships. Similar to other forms of SCID, each affected child presented within the first 2 years of life with a history of recurrent infections and failure to thrive (Table 15.1) (Elder et al., 1995; Gelfand et al., 1995; Monafo et al., 1992; Roifman et al., 1989). Seven of these children did well following allogeneic bone marrow transplantation (BMT); one child of Mennonite background died 2 months after BMT (Monafo et al., 1992). Additional patients with ZAP-70 deficiency have since been described and have had similar clinical presentations (Elder et al., 2001; Matsuda et al., 1999; Meinl et al., 2000; Noraz et al., 2000; Toyabe et al., 2001; Turul et al., 2009).

Table 15.1 CLINICAL FINDINGS IN EIGHT PATIENTS WITH ZAP-70 DEFICIENCY

FINDINGS	NUMBER OF AFFECTED CHILDREN
Infections	
Bacterial (otitis media, pneumonia)	**4**
P. jiroveci pneumonia	3
Cytomegalovirus retinitis or other infection	**2**
Parainfluenza pneumonitis	**1**
Chronic diarrhea or rotaviral enteritis	**6**
Severe or disseminated varicella	**1**
Oral or cutaneous candidiasis	**3**
Failure to thrive	**4**
Physical Findings	
Presence of lymph tissue	**5**
Hepatosplenomegaly	**1**
Chronic eczematoid rash	**2**
Thymic shadow on chest X-ray	**8**

Most ZAP-70–deficient patients have detectable lymphoid tissue and normal or elevated peripheral blood lymphocyte counts. Thymic histology in ZAP-70 deficiency is remarkable for normal percentages of DP and SP $CD4^+$ thymocytes, although there are very few, if any, SP $CD8^+$ cells (Gelfand et al., 1995; Roifman et al., 1989). With regards to the actual structure of the thymus, the formation of the thymic medulla appears to be defective (Negishi et al., 1995).

LABORATORY FINDINGS IN ZAP-70 DEFICIENCY

All patients have normal to elevated numbers of circulating lymphocytes (Table 15.2). Phenotypic analysis of their peripheral blood lymphocytes by flow cytometry reveals normal or increased percentages of $CD3^+$ (38 to 80 percent) and $CD4^+$ T cells (37 to 75 percent) because of the lack of $CD8^+$ T cells (0 to 3 percent) (Elder et al., 1995, 2001; Gelfand et al., 1995; Matsuda et al., 1999; Monafo et al., 1992; Noraz et al., 2000; Roifman et al., 1989). Expression of T-cell surface proteins other than CD8 is normal. In those patients in whom human leukocyte antigen (HLA) typing and Southern blot analysis have been performed, peripheral blood T cells were demonstrated to be polyclonal and not maternal in origin (Arpaia et al., 1994; Elder et al., 1995). Absent proliferative responses to alloantigen and to a variety of mitogens in vitro, including phytohemagglutinin (PHA), pokeweed mitogen (PWM), concanavalin A, *Candida albicans*, and anti-CD3 monoclonal antibody (MAb), are noted on testing of patient lymphocytes, confirming the diagnosis of SCID. Failure to reject an allogeneic skin graft was demonstrated in one ZAP-70–deficient patient (Roifman et al., 1989). NK-cell numbers and activity are relatively normal (Elder et al., 1994). All patients have normal numbers of B cells, but some differences in B-cell function have been noted between patients. Normal serum immunoglobulins and specific antibody production have been demonstrated in a minority of patients (Roifman et al., 1989), but most patients have hypogammaglobulinemia and lack specific antibody production, necessitating monthly intravenous immunoglobulin administration (Elder et al., 1995, 2001; Gelfand et al., 1995). One child had IgE reactive with food allergens but did not demonstrate atopy or intestinal symptoms related to food ingestion (Toyabe et al., 2001).

In the original eight patients with ZAP-70 deficiency, the markedly abnormal distribution of peripheral T-cell subsets and the absence of T-cell proliferation to any stimulus transduced by the TCR led to studies that documented defects within the proximal TCR signaling pathway, later proven to be due to absence of ZAP-70 function. The patients' T lymphocytes exhibited diminished or absent $[Ca^{2+}]_i$ mobilization after stimulation with anti-CD3 MAb (Arpaia et al., 1994; Chan et al., 1994a; Elder et al., 2001; Gelfand et al., 1995). Furthermore, induction of most cytoplasmic tyrosine phosphoproteins was defective after co–cross-linking of the TCR on patient T cells with either anti-CD3 or a combination of anti-CD4 and anti-CD3 MAbs (Arpaia et al., 1994; Elder et al., 1995, 2001). In contrast to their absence of cell proliferation to TCR-mediated stimuli, ZAP-70–deficient lymphocytes proliferate normally to phorbol myristic acetate (PMA) plus ionomycin, agents that bypass proximal TCR signaling events by mimicking actions of the second messengers Ras and $[Ca^{2+}]_i$, respectively. In addition, interleukin (IL)-2 production is detected when lymphocytes are stimulated with PMA plus ionomycin, in contrast to the lack of detectable IL-2 production when T cells are incubated with anti-CD3 or PHA (Arpaia et al., 1994; Elder et al., 1995).

MOLECULAR BASIS OF ZAP-70 DEFICIENCY

In most affected patients, ZAP-70 protein is not detected by immunoblot (Arpaia et al., 1994; Chan et al., 1994a; Elder et al., 1994; Gelfand et al., 1995; Matsuda et al., 1999; Noraz et al., 2000; Toyabe et al., 2001). In contrast, normal levels of other PTKs are present in patient T cells. Additional studies in one patient demonstrated that Lck function was normal: it could be coprecipitated with CD4, was inducibly phosphorylated in response to cross-linking of surface CD3 and CD4, and exhibited normal autophosphorylation activity in vitro (Elder et al., 1995). One child with SCID had undetectable ZAP-70 mRNA, but his underlying mutation(s) were not identified (Gelfand et al., 1995). The majority of patients have normal levels of full-length ZAP-70 mRNA as compared to controls.

At least 16 separate mutations in the gene encoding ZAP-70 (gene symbol *ZAP70* or *SRK*, Syk-related tyrosine kinase) have been identified in affected children (Arpaia et al.,

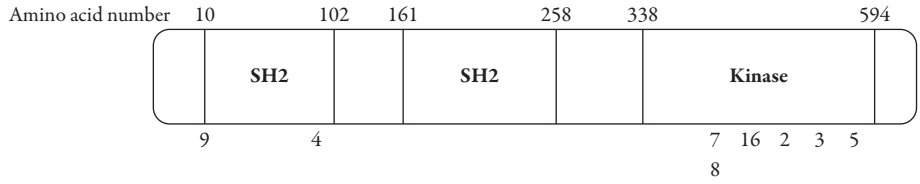
Table 15.2 LABORATORY FINDINGS IN PATIENTS WITH ZAP-70 DEFICIENCY

TESTS	RANGE OF PATIENT VALUES	NORMAL RANGE
Lymphocyte Phenotype		
Absolute lymphocyte count	4.0–20.0 × 10^9/L	3.5–8.0 × 10^9/L
$CD3^+$ cells	35–80%	50–85%
$CD4^+$ cells	35–75%	25–70%
$CD8^+$ cells	0–10%	12–40%
$CD3^+$ $CD8^+$ cells	0–3%	10–40%
TCRα/β^- cells	55–80%	50–85%
TCRγ/δ^- cells	0.2–?%	1–10%
$CD3^+$ $CD69^+$ cells	0–3%	25–55%
$CD16^+$ $CD56^+$ cells	5–15%	5–30%
$CD19^+$ cells	13–40%	6–25%
Serum Immunoglobulin Levels		
IgG (pre-IVIG)	40–1,250 mg/dL	350–1,250 mg/dL
IgA	40–160 mg/dL	10–50 mg/dL
IgM	65–170 mg/dL	40–200 mg/dL
Isohemagglutinins	0–<1:1 titer	0–1:128 titer
Specific antibody production	1 pt (levels not reported)	
Lymphocyte Proliferative Function		
Mitogens (PHA, PWM)	0–1,100 cpm	35,000–230,000 cpm
Soluble antigen (tetanus, candida)	0–750 cpm	1,500–100,000 cpm
Alloantigen (MLC)	125–5,000 cpm	10,000–150,000 cpm
Anti-CD3	200–1,000 cpm	20,000–95,000 cpm
IL-2	1,000–20,000 cpm	1,000–6,000 cpm
PMA	15,000–50,000 cpm	1,500–110,000 cpm
PMA plus ionomycin	40,000–200,000 cpm	25,000–170,000 cpm
PMA plus IL-2	100,000–150,000 cpm	50,000–120,000 cpm
SAC (B-cell mitogen)	5,000–25,000 cpm	5,000–25,000 cpm
IL-2 Production		
PHA, anti-CD3	none	
PMA plus ionomycin	normal	
NK cell cytotoxicity	20–30%	20–50%

1994; Chan et al., 1994a; Elder et al., 1994, 2001; Matsuda et al., 1999; Meinl et al., 2000; Noraz et al., 2000; Picard et al., 2009; Toyabe et al., 2001; Turul et al., 2009; and E. Faria, J. Chinen, M. Hoenig, I. Barlan, personal communications). Most mutations occur within the kinase domain of the ZAP-70 protein and significantly affect both protein stability and catalytic activity (Fig. 15.1).

ZAP-70 MUTATION ANALYSIS

Pedigree analyses have confirmed that ZAP-70 deficiency is an autosomal recessive genetic syndrome and that affected children have failed to inherit a normal allele of the ZAP-70 gene located on human chromosome 2q12 (Chan et al., 1994a). The molecular defects reported to date are listed in Figure 15.1. All six children from the three genetically related Mennonite families inherited at least one mutant ZAP-70 allele with a splicing error due to a G-to-A transition within an intron, generating a new splice acceptor site upstream of the normal splice site. Specifically, three children from two families were homozygous for a 9 bp insertion (CTTGAGCAG) into the coding sequence after nucleotide 1832. This mutation results in the addition of three amino acid residues, leucine, glutamic acid, and glutamine (LEQ), within the ZAP-70 catalytic domain following residue 541 (K541insLEQ)



Mutant allele	DNA Mutation	Consequence to Protein
1	13 bp deletion (nts 1719–1731)	Deletion/frameshift/premature termination after 35 codons (K504_P508delfs×35)
2	C to A transition at nt 1763	Missense (S518R)
3	G to A transition at nt 1833	Splicing error (K541_K542insLEQ)
4	C to A transition at nt 448	Missense (P80Q)
5	A to T transition at nt 1923	Missense (M572L)
6	C to T at nt 1729	Missense (A507V)
7	C to T at nt 1602	Missense (R465C)
8	G to A at nt 1603	Missense (R465H)
9	? (no ZAP-70 mRNA)	

Figure 15.1 Schematic depiction of wild-type ZAP-70 protein and the identified mutant alleles. GenBank accession number is L05148 for the human AP-70 cDNA sequence.

(Arpaia et al., 1994). Three children from the remaining Mennonite family inherited this mutant allele along with a second mutant allele and were thus compound heterozygotes for two ZAP-70 mutations (Chan et al., 1994a). The second mutation in these Mennonite cases is a C-to-A transition at position 1763, which results in a serine-to-arginine substitution at amino acid 518 (S518R) within a highly conserved region of all Syk family PTK catalytic domains.

In a fourth affected and unrelated family, a single patient with ZAP-70 deficiency was homozygous for a 13bp deletion at nucleotides 1719 to 1731 (Elder et al., 1994). This deletion results in a translational frameshift after residue 503 and introduces a premature stop 35 codons downstream, yielding a mutant protein truncated by 82 amino acids (K504_P508delfsX35). One Japanese patient with CD8 deficiency was a compound heterozygote for temperature-sensitive mutations in ZAP-70: a C-to-A transition at position 448 resulting in a proline-to-glutamine substitution at residue 80 (P80Q), and an A-to-T transition at position 1923 that substitutes a leucine for methionine at amino acid 572 (M572L) within the ZAP-70 protein (Matsuda et al., 1999). Homozygous mutations resulting in Leu337Arg and Cys564Arg substitutions have recently been described in two other patients (Turul et al., 2009).

Three infants with SCID inherited a homozygous missense mutation within the highly conserved DLAARN motif in the ZAP-70 kinase domain (Elder et al., 2001; Toyabe et al., 2001). In two children, the mutation was a C-to-T transition at bp 1602, which results in an arginine-to-cysteine conversion at residue 465 (R465C). Unlike other described ZAP-70 mutations, this mutation only modestly affects protein stability, but it abrogates ZAP-70 catalytic function. Moreover, R465C is comparable to the mutation (R464C) that spontaneously arose in the inbred Strange (ST) mouse colony (Wiest et al., 1997). In contrast to ST mice, which lack any SP thymocytes and peripheral T cells, these patient had typical findings of ZAP-70 deficiency and lacked only circulating $CD8^+$ T lymphocytes (Elder et al., 2001). This case provides the first description of identical mutations in ZAP-70 having distinct T-cell developmental consequences in humans and mice. Subsequently, an unrelated patient was determined to be homozygous for a G-to-A transition at position 1603, resulting in an arginine-to-histidine (R465H) conversion at the same critical residue within the DLAARN motif (Toyabe et al., 2001). However, this latter patient lacked ZAP-70 protein expression.

Interestingly, identical ZAP-70 mutations can apparently result in phenotypic heterogeneity; an Ala507His substitution in the ZAP-70 kinase domain was found to result in the absence of ZAP-70 protein expression and $CD8^+$ T cells in two siblings and an apparently unrelated third patient (Noraz et al., 2000; Turul et al., 2009). While the two siblings had a typical SCID phenotype necessitating hematopoietic stem cell transplantation (HSCT; Noraz et al., 2000), the third had a mild clinical phenotype until the age of 3 years, when she was diagnosed with a B-cell lymphoma (Turul et al., 2009, and O. Sanal, personal communication). This significant clinical variability is reminiscent of that observed in CD3γ deficiency (Recio et al., 2007), and while not understood in either disease, likely reflects the involvement of other genetic and/or environmental factors.

In the published literature, all identified mutations, with the exception of the R465C mutation, significantly decrease the stability of ZAP-70 protein in vitro (Chan et al., 1994a; Elder et al., 1994; Matsuda et al., 1999; Noraz et al., 2000). Furthermore, most mutations that change the sequence of the kinase domain of ZAP-70 affect its enzymatic activity. However, newly described mutations in the SH2 domain affect ZAP-70 function without interfering with protein stability (Chinen and Taylor, unpublished observations). In vitro kinase assays have confirmed that mutant forms of ZAP-70 are catalytically inactive (Chan et al., 1994a; Elder et al., 1994, 2001; Noraz et al., 2000).

FUNCTIONAL ASPECTS OF ZAP-70 DEFICIENCY

The phenotype of ZAP-70 deficiency in humans presents a notable paradox: although a single signaling pathway had previously been assumed to be required for both thymic selection and peripheral T-cell activation, the abundant $CD4^+$ T cells in this disorder, which presumably were selected positively in the thymus, are refractory to TCR-mediated activation in the periphery. Thymic tissue from three ZAP-70–deficient patients revealed mostly DP thymocytes and normal numbers of SP $CD4^+$ cells, but very few if any SP $CD8^+$ thymocytes (Gelfand et al., 1995; Roifman et al., 1989).

ZAP-70 has been shown in mice to be specifically required for normal progression of DN thymocytes to DP and SP cells (Chu et al., 1999; Palacios and Weiss, 2007). However, results in ZAP-70–deficient patients confirm that ZAP-70 is critical for CD8 selection and peripheral $CD4^+$ and $CD8^+$ T-cell signaling but is dispensable for CD4 selection in the thymus in humans. An explanation for the presence of normal numbers of $CD4^+$ T cells is that the ZAP-70–related PTK Syk, which is expressed at higher levels in the thymus than in the periphery and is required for initial pre-TCR signaling, is able to rescue CD4 selection in the absence of ZAP-70 (Au-Yeung et al., 2009; Chan et al., 1994b; Gelfand et al., 1995; Palacios and Weiss, 2007). A role for Syk in pre-TCR signaling during thymocyte selection is supported by findings that DP thymocytes from a ZAP-70–deficient patient were able to mobilize $[Ca^{2+}]_i$ upon CD3 cross-linking (Gelfand et al., 1995). Comparable induction of tyrosine phosphoproteins was seen in a human T-cell leukemia virus (HTLV)-1-transformed $CD4^+$ thymocyte line. ZAP-70–deficient thymocytes demonstrated higher basal Syk expression and increased Syk phosphorylation after TCR stimulation than control HTLV-1-transformed thymocytes. Increased Syk activity in ZAP-70–deficient thymocytes may thus compensate at least in part for the lack of ZAP-70 function. In support of this finding, downregulation of Syk expression during thymocyte differentiation occurs later in humans than in mice (Au-Yeung et al., 2009; Cheng and Chan, 1997; Chu et al., 1999).

Although the differential ability of Syk to replace ZAP-70 in CD4 versus CD8 selection events remains unclear, CD4 lineage cells develop in the absence of ZAP-70 function. Moreover, Syk activity, which is downregulated in mature T cells, cannot compensate for the loss of ZAP-70 function that is required for peripheral $CD4^+$ T-cell signal transduction in affected patients (Au-Yeung et al., 2009; Chu et al., 1999; Siggs et al., 2007). Peripheral T cells from some ZAP-70–deficient patients have been shown to express high levels of Syk after long-term culture and under these specific conditions are capable of partial TCR signaling (Noraz et al., 2000). However, findings have been more variable in freshly isolated ZAP-70–deficient T cells and suggest that survival of these cells does not require ZAP-70–mediated TCR signaling or upregulation of Syk expression (Elder et al., 2001; Toyabe et al., 2001) and likely depends on cytokine signals such as those mediated by IL-7. Further studies are needed to characterize how the absence of ZAP-70 and expression of the related Syk PTK may modulate the antigen specificity and TCR repertoire of $CD4^+$ T cells differentiating in patients with ZAP-70 deficiency.

ZAP-70 AND AUTOIMMUNITY

Recent studies in mice have shown that decreases in TCR signaling, caused by point mutations in the ZAP-70 gene, can alter the TCR repertoire of mature T cells and result in autoimmunity (Hirota et al., 2007; Jakob et al., 2008; Sakaguchi et al., 2003; Siggs et al., 2007). Indeed, two independently performed screens for cellular immunodeficiencies in mice treated with the N-ethyl-N-nitrosourea mutagen revealed the causative affected gene to be ZAP-70 (Jakob et al., 2008; Siggs et al., 2007). In both models, hypomorphic mutations in the ZAP-70 kinase domain (homozygous W163G and composite I368F/W504R substitutions) resulted in the excessive production of autoantibodies and immunoglobulin E, likely due to defects in negative selection (Jakob et al., 2008; Siggs et al., 2007). Moreover, an independent spontaneous hypomorphic mutation in the SH2 domain of ZAP-70 (W163C) was shown to result in a chronic arthritis, and in this latter case, the self reactive $CD4^+$ T cells have been found to preferentially differentiate into IL-17–secreting Th17 cells (Hirota et al., 2007; Sakaguchi et al., 2003). Thus, hypomorphic mutations in ZAP-70 can alter TCR signaling capacities, compromising immunological tolerance.

Notably, the first patient with a hypomorphic ZAP-70 mutation has recently been reported (Picard et al., 2009). In this case, a homozygous G-to-A transition in intron 7 of the genomic ZAP-70 DNA (836+121) resulted in an 80 percent decrease in ZAP-70 protein in a 9-year-old patient with decreased $CD4^+$ and $CD8^+$ T cells. The abnormally spliced ZAP-70 product appears to be rapidly degraded and the low level of detected protein was the wild-type splice form. The clinical consequences in this patient were attenuated as compared to patients totally lacking ZAP-70 protein, and significantly, this patient did not shown signs of autoimmunity. It is nonetheless important to note that in contrast with mice suffering from ZAP-70–associated autoimmunity, the ZAP-70 protein expressed in this patient's T cells was wild type. Other patients with defects in ZAP-70 have presented with eczematous lesions, skin infiltrates, and manifestations of ulcerative colitis, which may be due to autoimmunity (Katamura et al., 1999; Parry et al., 1996). As such, it is likely that ZAP-70–associated defects will be found to result in autoimmune symptoms in patients, but confirmation will require more detailed characterization of patients with hypomorphic ZAP-70 mutations.

STRATEGIES FOR DIAGNOSIS OF ZAP-70 DEFICIENCY

Patients with SCID characterized by variable hypogammaglobulinemia, relatively normal numbers of peripheral blood lymphocytes, normal or only modestly decreased T cells, but notable absence of $CD8^+$ T cells (<5 percent) should

be screened for ZAP-70 deficiency. The diagnosis would be suggested by lack of T-cell proliferation in vitro to TCR stimuli, such as PHA and anti-CD3 MAb, but proliferation to PMA plus ionomycin comparable to that of normal T cells. Further studies to confirm a proximal TCR signaling defect include defective $[Ca^{2+}]_i$ mobilization and poor tyrosine phosphoprotein induction after stimulation through the TCR. In most cases, blotting for ZAP-70 protein demonstrates lack of ZAP-70 protein expression. If phosphotyrosine induction is abnormal but ZAP-70 protein is present, cDNA or genomic DNA sequencing will be required to characterize the mutation(s).

CARRIER DETECTION AND PRENATAL DIAGNOSIS

If the ZAP-70 mutations are known in an affected proband, then both carrier detection in relatives and prenatal diagnosis of an at-risk fetus can be performed. Individuals heterozygous for a mutant ZAP-70 allele are immunologically normal. Therefore, molecular techniques would be required to establish heterozygosity. However, since ZAP-70 deficiency is extremely rare and has primarily been demonstrated in consanguineous and genetically inbred families, carrier detection is useful for only a very few individuals in isolated population groups.

TREATMENT AND PROGNOSIS

Patients with ZAP-70 deficiency require HSCT for cure of SCID. Six of the original ZAP-70–deficient patients who were successfully transplanted received one of the following regimens: (1) histocompatible BMT from a sibling after conditioning with busulfan and cytoxan (BuCy) and antithymocyte globulin (ATG) (one child; A. H. Filipovich, personal communication); (2) T-cell–depleted BMT from a parent either without prior conditioning (one child; E. W. Gelfand, personal communication) or after cytoxan/ATG conditioning (one child; Elder et al., 1995) or after BuCy/ATG conditioning (one child; A. H. Filipovich, personal communication); (3) HLA-matched unrelated BMT after BuCy/ATG conditioning (one child; A. H. Filipovich, personal communication); or (4) partial HLA-matched unrelated BMT after BuCy/ATG conditioning (one child; A. H. Filipovich, personal communication). Mobilized peripheral blood stem cells from a parent have also been used with variable success to reconstitute ZAP-70–deficient children (Elder et al., 2001; Skoda-Smith et al., 2001; Toyabe et al., 2001). In one case, a paternal mobilized peripheral blood stem cell transplant followed by treatment with anti-CD20 MAb (Rituximab) successfully reconstituted a ZAP-70–deficient child who developed Epstein-Barr virus (EBV)-negative non-Hodgkin's B-cell lymphoma following an attempted maternal T-cell–depleted haploidentical BMT (Skoda-Smith et al., 2001). Monthly intravenous gammaglobulin therapy is often required for some time following HSCT.

ANIMAL MODEL OF ZAP-70 DEFICIENCY

Genetically altered mice lacking the entire ZAP-70 locus exhibit markedly defective T-cell activation and development (Negishi et al., 1995). In contrast to findings in ZAP-70–deficient patients, T-cell ontogeny in ZAP-70 knockout mice is blocked at the DP stage of thymocyte differentiation. Thymocytes from mutant mice fail to mobilize $[Ca^{2+}]_i$ after TCR cross-linking by anti-CD3 mAb, and neither SP $CD4^+$ nor $CD8^+$ thymocytes develop, and peripheral T cells are absent. These findings, as well as the demonstration that SP $CD4^+$ and $CD8^+$ T-cell development could be rescued by expression of a functional human ZAP-70 cDNA in mutant thymocytes, suggest that ZAP-70 is required for selection of both major thymocyte subsets in mice (Negishi et al., 1995; Palacios and Weiss, 2007). A comparable lymphocyte phenotype is seen in ST mice, which develop SCID due to a spontaneously arising mutation (R464C) within the highly conserved DLAARN motif of ZAP-70 that is essential for PTK enzymatic function (Wiest et al., 1997). Analysis of TCR signaling in ST thymocytes demonstrates that R464C abrogates ZAP-70 kinase activity, but the mutant protein is expressed and can be phosphorylated. These results confirm that ZAP-70 function is required for TCR activation and development of mature murine T lymphocytes.

The absence of $CD4^+$ T cells in ZAP-70–deficient mice contrasts with their presence in humans with ZAP-70 deficiency. Although the nature of the underlying mutations in human ZAP-70 deficiency may allow for some residual PTK activity in vivo, the disparate effects of identical ZAP-70 mutations suggest instead that human and murine thymocytes have different dependencies on ZAP-70 function during development. One explanation for this discrepancy is the ability of Syk to contribute to pre-TCR and TCR signaling is substantially different between humans and mice (Au-Yeung et al., 2009). In mice, Syk expression is downregulated to levels seen in peripheral T lymphocytes following pre-TCR signaling, and the residual Syk activity in DP thymocytes of ZAP-70–deficient mice is not sufficient to rescue CD4 selection in the absence of ZAP-70 (Au-Yeung et al., 2009; Chu et al., 1998, 1999). In contrast, Syk expression has been shown to be significantly higher in human thymocytes and is not downregulated to levels seen in peripheral T lymphocytes until after positive selection has commenced (Au-Yeung et al., 2009; Chu et al., 1999; Palacios and Weiss, 2007). This explanation is supported by evidence that peripheral $CD4^+$ and $CD8^+$ T-cell development in ZAP-70–deficient mice can be restored with human Syk transgene expression in the thymus (Gong et al., 1997). As a consequence of its relative abundance in human DP thymocytes, Syk may partially compensate for loss of ZAP-70 during positive selection in ZAP-70–deficient patients. However, downregulation of Syk expression in the periphery could explain the signaling defect in ZAP-70–deficient peripheral $CD4^+$ T cells (Au-Yeung et al., 2009; Chu et al., 1999).

LCK DEFICIENCY

In contrast to ZAP-70, in which SCID patients lack peripheral $CD8^+$ T cells, human Lck deficiency has been associated with a selective CD4 lymphopenia (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001). The underlying genetic defects resulting in decreased expression of functional Lck protein in a small number of sporadic cases are unknown. The clinical presentation of patients with selective CD4 lymphopenia and Lck deficiency is variable and may include SCID or common variable immunodeficiency (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001).

CLINICAL AND LABORATORY FINDINGS IN LCK DEFICIENCY

In addition to CD4 lymphopenia (range 4 to 22 percent; 100 to 350 cells/mm^3), affected individuals have decreased numbers of peripheral blood lymphocytes (780–1,890 cells/mm^3) and $CD3^+$ T cells (507 to 1,200 cells/mm^3); $CD8^+$ cell percentages and numbers are normal or increased (27 to 65 percent, or 430 to 1,058 cells/mm^3). However, $CD8^+$ T cells from a Lck-deficient SCID patient poorly expressed the costimulatory molecule CD28 (Goldman et al., 1998). Although less responsive than control lymphocytes, Lck-deficient T cells do proliferate to mitogens, anti-CD3 MAb, and IL-2 and demonstrate normal alloantigen responses (Goldman et al., 1998; Hubert et al., 2000; Sawabe et al., 2001). B-cell and NK-cell numbers are appropriate for age, but some patients have hypogammaglobulinemia and require intravenous immunoglobulin therapy.

Clinically, the single Lck-deficient child with SCID had infections similar to those of other children with combined primary immunodeficiencies and required a BMT from a matched unrelated donor (Goldman et al., 1998). One elderly adult with CD4 lymphopenia and decreased Lck function presented initially with cryptococcal meningitis (Hubert et al., 2000).

LCK MUTATION ANALYSIS

The single child reported with Lck-deficient SCID was found to express an aberrantly spliced Lck mRNA lacking exon 7, which encodes the PTK ATP binding site and kinase domain (Straus and Weiss, 1992). Expression of a similar Lck mRNA lacking exon 7 is also found in the Jurkat cell line JCaM. 1 (Straus and Weiss, 1992). As a result, the JCaM. 1 cell line does not express Lck protein and exhibits profoundly defective proximal TCR signal transduction. However, decreased but detectable amount of Lck protein was seen in patient T cells by immunoblot; this signal was attributed to expression of the unstable mRNA lacking exon 7. Although less than in control lymphocytes, a significant amount of normal Lck mRNA was found in patient T cells as well. A relatively normal pattern of tyrosine phosphorylation was induced by TCR engagement despite defective expression of Lck; this is in obvious contrast to the JCaM. 1 line (Straus and Weiss, 1992). Although TCR stimulation resulted in MAPK activation and $[Ca^{2+}]_i$ mobilization at levels comparable to that of control cells, significant upregulation of CD69 expression was not observed in the patient's $CD8^+$ T cells. The underlying genetic defect resulting in defective Lck expression has not been identified.

CONCLUSIONS AND FUTURE DIRECTIONS

The defective TCR signaling observed in ZAP-70–deficient patients has established a critical role for a functional ZAP-70 PTK in normal TCR-mediated signal transduction. The failure of the TCR to mediate signals in thymocytes from mice deficient in ZAP-70 further supports the requisite role of ZAP-70 in TCR signal transduction. Despite findings that activation of Lck alone via co–cross-linking of CD4 or CD8 does not fully induce the PTK cascade and the other signaling reactions that occur as a result of TCR stimulation, a critical role for Lck in TCR signaling has been established on the basis of findings in mutant cell lines, Lck-deficient mice, and a patient. These observations indicate that both Src and Syk family PTKs play unique and critical roles in TCR signal transduction.

In summary, TCR-associated PTKs are pivotally involved in distinct developmental events required for T-cell maturation. Lck is required for signaling in thymocytes and disruption of Lck severely affects peripheral T-cell development and function in mice and humans. ZAP-70 deficiency provided the first evidence that PTKs, and ZAP-70 in particular, are required for development of normal human T-cell numbers and function. Further elucidation of the role of ZAP-70 in TCR signal transduction should be invaluable to the understanding of CD4 and CD8 selection in the thymus, as well as the pathogenesis of this form of SCID. Whether mutations in ZAP-70 result in significant autoimmunity in patients and whether other molecules involved in TCR signaling produce abnormal T-cell phenotypes in humans remain to be determined. Possible use of gene therapy as an alternative to HSCT for cure of ZAP-70 deficiency remains to be explored.

16.

MOLECULAR BASIS OF MAJOR HISTOCOMPATIBILITY COMPLEX CLASS II DEFICIENCY

Walter Reith, Capucine Picard, and Alain Fischer

Major histocompatibility complex class II (MHCII) molecules, also called class II human leukocyte antigens (HLA) in humans, are heterodimeric transmembrane glycoproteins consisting of α and β chains. The three different human MHCII isotypes (HLA-DR, HLA-DQ, and HLA-DP) are encoded by distinct α and β chain genes clustered in the D region of the MHC on the short arm of chromosome 6. MHCII molecules occupy a central position in the adaptive immune system because they present peptides to the antigen receptor of $CD4^+$ T cells. In the thymus, MHCII–peptide complexes drive the positive and negative selection processes that guide the development of $CD4^+$ T cells. In the periphery, MHCII molecules present peptides to $CD4^+$ T lymphocytes, thereby inducing antigen-specific immune responses against pathogens and tumors. The presentation of self-peptides by MHCII molecules is also critical for the maintenance of peripheral T-cell tolerance. Given these essential functions, it is not surprising that defects in MHCII expression have profound immunopathological consequences.

Patients suffering from a rare primary immunodeficiency syndrome caused by the absence of MHCII expression were first identified in the late 1970s and early 1980s (Griscelli et al., 1980; Hadam et al., 1984, 1986; Kuis et al., 1981; Lisowska-Grospierre et al., 1983; Schuurmann et al., 1979; Touraine, 1981; Touraine et al., 1978). The lack of MHCII expression results in severely impaired cellular and humoral immune responses to foreign antigens and is consequently characterized by an extreme susceptibility to viral, bacterial, fungal, and protozoal infections, primarily of the respiratory and gastrointestinal tracts (reviewed in Elhasid and Etzioni, 1996; Griscelli et al., 1993; Klein et al., 1993). Severe malabsorption with failure to thrive ensues, often leading to death in early childhood.

The disease was formally named *major histocompatibility complex class II deficiency* (MHCII deficiency) (Rosen et al., 1992) and has been assigned the MIM (Mendelian Inheritance in Man) number 209920. It is also frequently referred to as the bare lymphocyte syndrome (BLS). However, the term *BLS* was first used to describe a defect in MHC class I (MHCI) expression in patients in which MHCII expression was not examined (Touraine et al., 1978), and it has been used synonymously for all defects involving expression of MHCI (BLS type I), MHCII (BLS type II), or both (BLS type III) (Touraine et al., 1992). Here we will discuss only the syndrome associated with a defect in MHCII expression, and will thus use the term *MHCII deficiency*.

More than 100 unrelated patients have been reported worldwide. The majority of patients are of North African origin (Algeria, Tunisia, and Morocco) (Griscelli et al., 1993; Klein et al., 1993; Lisowska-Grospierre et al., 1994). The remaining patients are of diverse ethnic backgrounds, including Spain, Italy, Turkey, France, Holland, the United States, Israel, Saudi Arabia, and Pakistan (Bejaoui et al., 1998; Casper et al., 1990; Clement et al., 1988; Haas and Stiehm, 1987; Hadam et al., 1984, 1986; Hume et al., 1989; Kuis et al., 1981; Lisowska-Grospierre et al., 1994; Peijnenburg et al., 1995; Wiszniewski et al., 2000). There is a high incidence of consanguinity in the affected families (Lisowska-Grospierre et al., 1994).

MHCII deficiency has an autosomal recessive mode of inheritance. A comparison between the patterns of inheritance of the disease and the MHC genotype in affected families has demonstrated that the genetic lesions responsible for MHCII deficiency lie outside the MHC (de Preval et al., 1985; Griscelli et al., 1993). This suggested that the disease is due to defects in transacting regulatory factors required for expression of MHCII genes. Elucidation of the molecular defects responsible for MHCII deficiency has confirmed this. The affected genes are now indeed known to encode

regulatory factors controlling transcription of MHCII genes. Four regulatory genes—*CIITA* (MIM number 600005), *RFXANK* (MIM number 603200), *RFX5* (MIM number 601863), and *RFXAP* (MIM number 601861)—have been isolated and shown to be mutated in MHCII deficiency patients (reviewed in Masternak et al., 2000a; Reith and Mach, 2001).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Comprehensive accounts of the clinical and pathological manifestations associated with MHCII deficiency have been reviewed previously (Elhasid and Etzioni, 1996; Griscelli et al., 1993; Klein et al., 1993). The major findings are summarized in Table 16.1. Clinical manifestations include primarily septicemia and recurrent infections of the gastrointestinal, pulmonary, upper respiratory, and urinary tracts. The patients are prone to bacterial, fungal, viral, and protozoal infections. The fungus isolated most frequently from the lung is *Pneumocystis jirovoci*, and the most common protozoal agent is *Cryptosporidium parvum*. Infections start within the first year of life; the mean age at first infection is 4.3 months. Subsequent evolution of the disease is characterized by an inexorable progression of the infectious complications until death ensues. Although some children reach puberty and a few attain adulthood, the majority die before the age of 10 years (see Table 16.4). All of the pathological manifestations of MHCII deficiency are related to the infectious complications, and with the exception of the absence of MHCII expression, there are no features that are specific for this particular immunodeficiency.

Table 16.1 CLINICAL MANIFESTATIONS

	PATIENTS	
MANIFESTATION	NUMBER	%
Repeated severe infections	81	99
Protracted diarrhea	68	83
Lower respiratory tract infections	66	80
Failure to thrive	56	68
Upper respiratory tract infections	55	67
Severe viral infections	49	58
Mucocutaneous candidiasis	24	29
Progressive liver disease	13	16
Cryptosporidiosis	13	16
Sclerosing cholangitis	7	9
Autoimmune cytopenia	5	6

Mean age at first infection is 4.3 months (range, 6 weeks to 12 months). Included are 63 patients from Hospital Necker-Enfants Malades (Picard, unpublished data), 9 Tunisian patients (Bejaoui et al., 1998), and 10 patients reported by Saleem et al. (2000). Not included are four patients with an atypical clinical presentation in two unrelated families belonging to complementation group A (Quan et al., 1999; Wiszniewski et al., 2001).

Bacterial infections in various locations are dominant. These include intestinal infections, pneumonitis, bronchitis, and septicemia. The bacteria isolated most frequently from stools include *Pseudomonas aeruginosa*, *Escherichia coli*, *Salmonella enteritidis*, *Klebsiella pneumoniae*, *Enterobacter cloacae*, *Campylobacter jejuni*, *Proteus mirabilis*, and *P. morgani*. In almost all patients, bacterial infections of the intestinal tract, together with *Candida albicans*, *Giardia lamblia*, and *C. parvum* infections, are responsible for protracted diarrhea, malabsorption, and failure to thrive as of the first year of life. As in CD40L deficiency, intestinal and hepatic involvement due to *C. parvum* colonization appears to be more frequent in MHCII deficiency than it is in other immunodeficiencies. Histological examinations of the intestinal mucosa revealed varying degrees of villous atrophy, frequently associated with intraepithelial infiltration by lymphocytes, macrophages, and plasma cells.

Hepatic involvement is frequent, but the manifestations are not uniform. Many patients exhibit either symptoms suggestive of viral hepatitis, or hepatic involvement resulting from cholangitis, parenteral nutrition, or the use of hepatotoxic drugs. The most frequent cause of hepatitis is infection with cytomegalovirus (CMV). Pseudosclerosing cholangitis is a frequent complication of chronic *C. parvum* infection in patients older than 4 years of age.

Recurrent bronchopulmonary infections have been observed in all patients. Diffuse interstitial pneumonia caused by *P. jirovici* or viruses (CMV, respiratory syncytial virus, enterovirus, adenovirus) are frequently observed. The most frequently isolated bacteria during pneumonia and/or sepsis were *Streptococcus pneumoniae, Staphylococcus aureus*, and *Haemophilus influenzae*. Recurrent upper respiratory tract infections including otitis, rhinitis, and sinusitis were observed in almost all patients.

Neurological manifestations due to viral infections have been diagnosed in a number of patients. These include poliomyelitis, meningoencephalitis, and chronic lymphocytic meningitis caused by live attenuated poliovirus vaccination, herpes simplex virus, enterovirus, and adenovirus.

Hematological manifestations are characterized by transient eosinophilia, neutropenia, autoimmune hemolytic anemia, and thrombopenia.

The clinical features vary considerably from one patient to another. This variability does not show any correlation with the genetic heterogeneity in the cause of the disease (see below). Interestingly, several patients having an atypical clinical course have been identified (Hauber et al., 1995; Nekrep et al., 2002; Prod'homme et al., 2003; Wiszniewski et al., 2001; Wolf et al., 1995). The clinical manifestations in these patients are less severe or even absent, and their survival is considerably longer. Several patients over 20 years of age have been identified (see Table 16.4). The unusual capacity of these patients to cope with infections depends on genetic, immunological, and/or environmental differences that remain largely unknown. However, in certain cases it has been attributed to partial loss-of-function mutations in the affected genes (Nekrep et al., 2002; Prod'homme et al., 2003; Wiszniewski et al., 2001).

LABORATORY FINDINGS AND IMMUNOLOGICAL FEATURES

The immunological characteristics of MHCII deficiency (reviewed in Griscelli et al., 1993; Klein et al., 1993) are summarized in Table 16.2. Most of the immunological manifestations can be accounted for by the absence of antigen presentation via MHCII molecules. The most striking and constant consequence of the defect in MHCII expression is, as expected, the absence of cellular and humoral immune responses to foreign antigens. Patients are unable to mount T-cell–mediated immune responses to specific antigens, as assessed by delayed-type hypersensitivity skin tests. This correlates with an absence of T-cell responses in vitro to antigens with which the patients had been immunized or sensitized to by infections. Also consistent with the absence of MHCII expression is the finding that lymphocytes from patients have a decreased capacity to stimulate HLA-nonidentical lymphocytes in the mixed lymphocyte reaction.

Patients have T-cell lymphopenia. $CD4^+$ T-cell counts are reduced, whereas $CD8^+$ T-cell counts can be normal or decreased. The diminished $CD4^+$ T-cell count reflects abnormal development of $CD4^+$ thymocytes, resulting from defective MHCII expression in the thymus. Surprisingly, however, the remaining $CD4^+$ T-cell population appears to be phenotypically and functionally normal. The patient's $CD4^+$ T cells exhibit only relatively minor differences with respect to the normal TCR repertoire (Henwood et al., 1996; Rieux Laucat et al., 1993) and behave normally in terms of alloreactivity and proliferative responses to mitogens (Griscelli et al., 1993; Klein et al., 1993).

Although numbers of circulating B lymphocytes are normal, humoral immunity is severely impaired. Most patients have hypogammaglobulinemia, some have a decrease in one or two immunoglobulin isotypes, and certain exhibit a hyper-IgM profile. Antibody responses to immunizations and infections by microbial agents are absent, except for the production of T-independent antibodies against encapsulated bacteria. Interestingly, autoantibodies associated with autoimmune disorders have been found in several patients. In conclusion, most patients were severely immunodeficient, with low $CD4^+$ T-cell counts and profoundly impaired antigen-specific T- and B-cell responses.

Table 16.2 SUMMARY OF IMMUNOLOGICAL FINDINGS

PARAMETER MEASURED	FINDINGS	PATIENTS
HLA Class II Expression[†]		n = 63
B cells	<1%	76%
B cells	1–43%*	24%
Monocytes	< 1%	89%
Monocytes	1–17%*	11%
HLA Class I Expression[†]		n = 38
Mononuclear cells	Reduced	79%
T-cell Immunity		n = 59
$CD4^+$ lymphopenia		91.5%
Lymphocyte proliferative responses to:		
- PHA	Normal	97%
- Antigen	Absent or strongly reduced	100%
B-cell Immunity		n = 34
Serum immunoglobulins		
- IgG	Decreased	82%
- IgM	Decreased	65%
- IgM	Increased	9%
- IgA	Decreased	50%
Antibody Response		
DTP immunizations	Negative	95%

Data are from 63 patients treated at Hospital Necker-Enfants Malades between 1977 and 2009 (Picard, unpublished data).

[†]Tested by fluorescence-activated cell sorting or microscopy.

*Numbers indicate the percentage of "dull" stained cells.

MOLECULAR BASIS

DEFECTIVE EXPRESSION OF MHCII MOLECULES

The hallmark of MHCII deficiency is the absence of MHCII molecules on the surface of all cells that normally express them, and the demonstration of this lack of expression remains the mainstay of diagnosis. In normal individuals, two modes of MHCII expression, constitutive and inducible, are observed (reviewed in Glimcher and Kara, 1992; Guardiola and Maffei, 1993; Mach et al., 1996). Constitutive expression is largely restricted to professional antigen-presenting cells (B lymphocytes, cells of the monocyte/macrophage lineage, and dendritic cells) and epithelial cells in the thymus. Inducible expression can be observed in virtually all cell types in response to a variety of stimuli, of which the most potent is interferon-γ (IFN-γ). In MHCII-deficient patients, both the constitutive and inducible expression modes are abolished (reviewed in Griscelli et al., 1993; Klein et al., 1993, Mach et al., 1996). The absence of MHCII molecules concerns all professional antigen-presenting cells, including B lymphocytes, cells of the macrophage/monocyte lineage, and dendritic cells. Activated T cells remain MHCII negative. Thymic epithelial cells, and endothelial and epithelial cells of the intestinal and bronchial mucosa, also lack MHCII molecules. Finally, MHCII expression cannot be restored in any cell type by stimulation with IFN-γ.

The inability to express MHCII molecules constitutively or in response to IFN-γ has been demonstrated in vitro using peripheral blood lymphocytes (PBLs), Epstein-Barr virus (EBV)-transformed B-cell lines, interleukin-2 (IL-2)-dependent T-cell lines, and primary or transformed fibroblasts derived from MHCII deficiency patients (de Preval et al., 1985, 1988; Griscelli et al., 1993; Klein et al., 1993; Lisowska-Grospierre et al., 1985). Studies on

EBV-transformed B-cell lines from patients indicated that expression of MHCII genes could not be detected at the levels of the cell surface, intracellular protein, or mRNA (de Preval et al., 1985; Lisowska-Grospierre et al., 1985). In fibroblasts, the expression of MHCII genes cannot be induced by IFN-γ (de Preval et al., 1988). The lack of constitutive and inducible expression concerns all classical MHCII genes, including those encoding the α and β chains of HLA-DR, HLA-DP, and HLA-DQ (de Preval et al., 1985, 1988; Lisowska-Grospierre et al., 1985). There are also defects in expression of the invariant chain (*Ii*) gene (*CD74*), and the *HLA-DM* and *HLA-DO* genes (Kern et al., 1995; Nagarajan et al., 2002; Nocera et al., 1993; Seguín-Estévez et al., 2009; Taxman et al., 2000), which encode proteins required for antigen presentation by MHCII molecules (Alfonso and Karlsson, 2000; Busch et al., 2005; Cresswell, 1996; Denzin et al., 2005).

Although a complete absence of MHCII molecules is the general rule, certain patients have a "leaky" phenotype (Griscelli et al., 1993; Klein et al., 1993). Residual levels of MHCII expression have been observed in several patients on various cell types, including B cells, monocytes, activated T cells, Langerhans cells, intestinal endothelial cells, and thymic stromal and dendritic cells (Hadam et al., 1986; Klein et al., 1993; Schuurman et al., 1985). Low levels of expression of certain MHCII genes have also been observed in EBV-transformed B-cell lines and IFN-γ-treated fibroblasts derived from certain patients (Griscelli et al., 1993; Klein et al., 1993; Lennon-Dumenil et al., 2001; Peijnenburg et al., 1995).

In addition to the profound defect in MHCII expression, a reduction in cell-surface expression of MHCI and β2 microglobulin (β2m) is observed on fresh PBLs, cultured fibroblasts, SV40-transformed fibroblasts, and EBV-transformed B-cell lines from MHCII deficiency patients (Griscelli et al., 1980; Hadam et al., 1984, 1986; Sabatier et al., 1996; Schuurmann et al., 1979; Touraine et al., 1978). A reduction in MHCI expression is observed to a variable degree in over 75% of the patients (Table 16.2) (Klein et al., 1993).

MHCII DEFICIENCY IS DUE TO REGULATORY DEFECTS IN MHCII GENE TRANSCRIPTION

Direct measurements of the transcriptional activity of MHCII genes have demonstrated that the lack of expression in patients is due to a deficiency in transcription (Reith et al., 1988). This finding suggested that the disease is due to defects in regulatory factors controlling transcriptional activation of MHCII genes. Direct evidence for this interpretation was provided by four independent observations. First, family studies demonstrated that the genetic lesions responsible for the disease do not cosegregate with the MHC (de Preval et al., 1985; Griscelli et al., 1993). Second, reporter genes fused to the DNA sequences controlling transcription of MHCII genes remain silent upon transfection into cells from patients (Hasegawa et al., 1993; Riley and Boss, 1993). Third, nuclear extracts from patients' cells are unable to activate transcription from MHCII promoters in in vitro transcription experiments (Durand et al., 1994). Finally, expression of the endogenous MHCII genes of the patients' cells can be reactivated in somatic cell fusion experiments (see below).

GENETIC HETEROGENEITY IN MHCII DEFICIENCY

Somatic cell-fusion experiments performed with cell lines derived from patients first indicated that the causes of MHCII deficiency are genetically heterogeneous (Bénichou and Strominger, 1991; Hume and Lee, 1989; Lisowska-Grospierre et al., 1994; Seidl et al., 1992). Several experimentally generated cell lines (Accolla, 1983; Calman and Peterlin, 1987; Gladstone and Pious, 1978) exhibiting an MHCII-negative phenotype indistinguishable from the patients' cell lines were also included in the cell-fusion studies. The results of these experiments indicated that the patients and experimentally derived cell lines can be assigned to four complementation groups (Table 16.3, groups A to D), reflecting the existence of mutations in four MHCII regulatory genes. Most patients (43 unrelated families) fall into complementation group B (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a, Picard, unpublished data). Group A contains patients from ten different families (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a) as well as three experimentally derived mutants, of which the best known is RJ2.2.5 (Accolla, 1983). Group C contains patients from seven families (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a). Group D was first defined by cell-fusion experiments with the experimentally generated cell line 6.1.6 (Gladstone and Pious, 1978). Subsequent cell-fusion experiments and isolation of the gene affected in 6.1.6 permitted the classification of patients from seven unrelated families in this group (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a).

The spectrum of clinical and immunological manifestations associated with the disease encompasses all four complementation groups (Griscelli et al., 1993; Klein et al., 1993). No distinctive features restricted to only certain complementation groups have been identified. Despite the genetic heterogeneity in the cause of MHCII deficiency, the syndrome is therefore phenotypically homogeneous.

ATYPICAL FORM OF MHCII DEFICIENCY

Twin brothers exhibiting an atypical and less severe form of MHCII deficiency have been described (Douhan et al., 1996; Hauber et al., 1995; Wolf et al., 1995). In contrast to the situation observed in the "classical" form of MHCII deficiency, defective expression in these patients does not concern all MHCII genes equally and does not affect all cell types to the same extent. In EBV-transformed B cells from these patients, the *HLA-DRB*, *HLA-DQB*, and *HLA-DPA* genes are silent whereas the *HLA-DRA*, *HLA-DQA*, and *HLA-DPB* genes are expressed. In mononuclear cells, there is a significant level of *HLA-DRB*, *HLA-DQB*, and *HLA-DPA* expression. Investigations of MHCII-dependent immune functions in these patients indicated the presence of competent MHCII-positive antigen-presenting cells (Hauber et al., 1995; Wolf et al., 1995). Impairment of the immune response is

*A–D, nomenclature for complementation groups used in Bénichou and Strominger (1991) and Lisowska-Grospierre et al. (1994); I–IV, alternative nomenclature used in Seidl et a bl. (1992).

†Numbers are based on somatic cell-fusion experiments and/or mutation analysis of the affected genes.

‡Tested on at least one cell line in each complementation group.

**Also called RFX-B in Nagarajan et al. (1999).

consequently much less evident than in classical MHCII deficiency. Characterization of the genetic defect in these patients has demonstrated that they belong to complementation group C (Nekrep et al., 2002) rather than to a fifth complementation group as initially believed (Douhan et al., 1996).

BIOCHEMICAL HETEROGENEITY IN MHCII DEFICIENCY

MHCII expression is regulated primarily at the level of transcription by a short DNA segment situated immediately upstream of the transcription initiation site of each MHCII gene (reviewed in Benoist and Mathis, 1990; Mach et al., 1996). This promoter proximal region contains four cis-acting DNA elements—called the *S*, *X*, *X2*, and *Y* boxes—that are highly conserved in their sequence and organization with respect to orientation, order, and spacing relative to each other (Fig. 16.1A). This conservation is apparent not only in all MHCII genes from all species that have been examined, but also in the invariant chain, *DM* and *DO* genes.

In the hope of elucidating the molecular mechanisms controlling transcription of MHCII genes and identifying the regulatory genes that are mutated in MHCII deficiency, numerous studies were performed to identify and isolate DNA binding proteins that interact specifically with MHCII promoters (reviewed in Mach et al., 1996). These studies led to the identification of several key transcription factors, particularly the X box binding complex called RFX (regulatory factor X) (Reith et al., 1988).

RFX was first identified in nuclear extracts from MHCII-positive B-cell lines on the basis of its ability to bind in vitro to the X box of MHCII promoters (Reith et al., 1988). It was purified by affinity chromatography and shown to be a heteromeric protein consisting of three subunits of 75kDa, 36kDa, and 33kDa (Durand et al., 1994, 1997; Masternak et al., 1998). The DNA-binding activity of RFX was analyzed extensively by in vitro studies using nuclear extracts from cell lines derived from MHCII deficiency patients and from experimentally generated regulatory mutants (Durand et al., 1994; Hasegawa et al., 1993; Herrero-Sanchez et al., 1992; Reith et al., 1988; Stimac et al., 1991). Based on the presence or absence of RFX binding activity, two types of mutant cells were recognized (Table 16.3, Fig. 16.1); RFX binding activity was normal in cell lines classified in complementation group A but deficient in cell lines assigned to complementation groups B, C, and D (reviewed in Mach et al., 1996).

Examination of DNAse I hypersensitive sites (Gonczy et al., 1989) and in vivo footprint experiments (Kara and Glimcher, 1991, 1993) revealed that the lack of RFX binding activity correlates with a bare promoter in vivo (Table 16.3, Fig. 16.1) (reviewed in Mach et al., 1996). In RFX-positive cells (normal MHCII-positive B cells as well as B cells from complementation group A), MHCII promoters exhibit characteristic DNAse I hypersensitive sites and are occupied by DNA-binding proteins in vivo. In RFX-deficient B cells (complementation groups

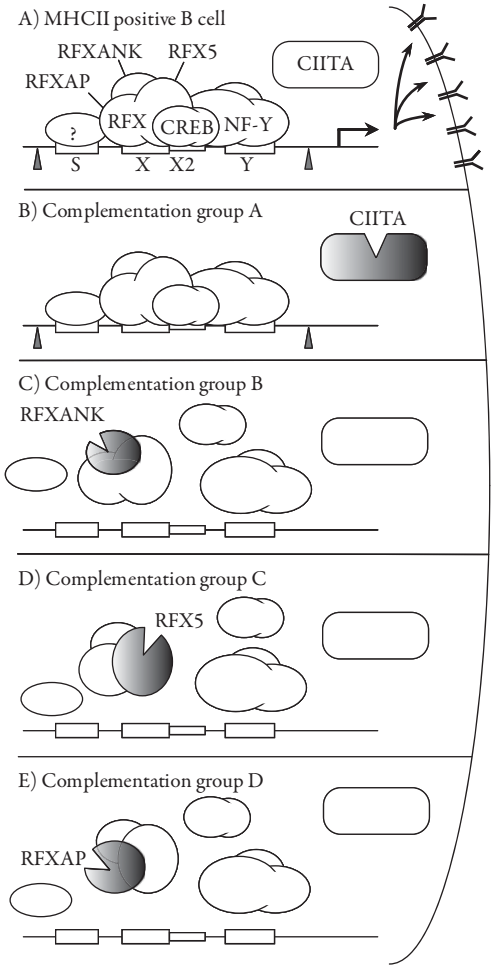

Figure 16.1 Molecular defects in MHCII deficiency. MHCII promoter occupancy and transcription status are represented schematically for normal B cells (A) and B cells from complementation groups A to D (B–E). Open boxes represent the S, X, X2, and Y sequences. RFX, CREB, and NF-Y bind to the X, X2, and Y boxes to form a nucleoprotein complex called the MHCII enhanceosome. The identity of the protein that binds to the S box remains unknown. The MHCII enhanceosome forms a platform to which CIITA is recruited (see Fig. 16.2). Arrowheads represent DNAse I hypersensitive sites that flank the S-X-X2-Y region and are diagnostic of promoter occupation. CIITA is mutated in complementation group A. Mutations in CIITA do not modify promoter occupation in vivo. In complementation groups B, C, and D, the RFX5, RFXANK, and RFXAP subunits of RFX are mutated. A deficiency in RFX leads to a bare promoter in vivo.

B-D), the DNAse I hypersensitive sites are missing and all of the MHCII promoter elements are unoccupied.

IDENTIFICATION OF *CIITA*, THE GENE AFFECTED IN COMPLEMENTATION GROUP A

A genetic approach relying on cDNA expression cloning was developed to identify the genes affected in MHCII deficiency (Steimle et al., 1993). Briefly, cell lines established from patients, or experimentally generated cell lines, were transfected with cDNA expression libraries and complemented cells carrying cDNA clones capable of restoring MHCII expression were selected for. This approach was first successful in the case of RJ2.2.5, an experimentally generated cell line from complementation group A. Complementation of RJ2.2.5 led to isolation of the MHCII transactivator CIITA (Steimle et al., 1993). The human *CIITA* gene is localized on chromosome 16 (16p13), and the corresponding mouse gene is situated in a syntenic region of mouse chromosome 16. This localization is in accordance with the findings that regulatory genes present on human and mouse chromosomes 16 are required for expression of MHCII genes (Accolla et al., 1986; Bono et al., 1991).

IDENTIFICATION OF *RFXANK,* THE GENE AFFECTED IN COMPLEMENTATION GROUP B

The gene affected in complementation group B, which contains the largest number of patients (Table 16.3), was isolated by a biochemical approach based on purification of the RFX complex (Masternak et al., 1998). It was baptized *RFXANK* because the protein that it encodes contains four ankyrin repeats, which are well-known protein–protein interaction motifs. The same gene was subsequently also called *RFX-B* (Nagarajan et al., 1999). *RFXANK* encodes the 33kDa subunit of the RFX complex (Fig. 16.1). The chromosomal localization of *RFXANK is* 19p12.

IDENTIFICATION OF *RFX5,* THE GENE AFFECTED IN COMPLEMENTATION GROUP C

The same complementation approach used to isolate CIITA was successful in elucidating the molecular defect leading to the lack of RFX binding activity in patients from complementation group C. Complementation of a cell line derived from patient SJO (Casper et al., 1990) led to the isolation of a cDNA encoding the 75kDa subunit of RFX (Fig. 16.1) (Steimle et al., 1995). The gene was called *RFX5* because it encoded the fifth member of a family of X box binding proteins sharing a highly characteristic DNA binding domain (DBD) (Aftab et al., 2008; Emery et al., 1996; Steimle et al., 1995). This RFX DBD has been strongly conserved in evolution and has been identified in a variety of proteins having diverse regulatory functions in organisms ranging from yeast to humans (Aftab et al., 2008; Emery et al., 1996). The structure of the DBD of one member of the RFX family (RFX1) has been determined and shown to belong to the winged-helix subfamily of helix-turn-helix (HTH) proteins (Gajiwala et al., 2000). Surprisingly, the RFX1 DBD binds DNA in a fashion that is radically different from that observed for all other known HTH proteins (Gajiwala et al., 2000). The amino acids implicated in site-specific binding of the RFX1 DBD are strongly conserved in RFX5, implying that the latter interacts with its X box target site in a similar fashion (Gajiwala et al., 2000). The human *RFX5* gene is situated in a subcentromeric region of the long arm of chromosome 1 (Villard et al., 1997b). The corresponding mouse gene maps to a syntenic region of chromosome 3.

IDENTIFICATION OF *RFXAP*, THE GENE AFFECTED IN COMPLEMENTATION GROUP D

The experimentally generated cell line 6.1.6 (Gladstone and Pious, 1978) was initially the only representative of complementation group D (Bénichou and Strominger, 1991; Hume and Lee, 1989; Lisowska-Grospierre et al., 1994; Seidl et al., 1992). The gene affected in 6.1.6 was isolated by a biochemical approach based on purification of the RFX complex. It was shown to encode a novel protein corresponding to the 36 kDa subunit of RFX (Fig. 16.1) (Durand et al., 1997). This protein was called RFX-associated protein (RFXAP) because it is a subunit of the RFX complex but does not contain the DBD characteristic of the RFX family of DNA binding proteins (Durand et al., 1997). Isolation of the *RFXAP* gene permitted the identification of MHCII-deficiency patients belonging to complementation group D (Durand et al., 1997; Villard et al., 1997a). The *RFXAP* gene is localized on the long arm of chromosome 13 (Villard et al., 1997a).

ELUCIDATION OF THE MOLECULAR DEFECT IN ATYPICAL PATIENTS

The gene affected in the atypical patients turned out to be RFX5, thereby placing these patients in complementation group C (Nekrep et al., 2002). The defect in the patients is a point mutation that replaces a critical residue in the DBD of RFX5. The unusual pattern of residual MHCII expression and atypical phenotype of these patients are probably a result of the fact that this mutation does not compromise binding of RFX to all MHCII promoters to the same extent (Nekrep et al., 2002).

FUNCTION OF THE AFFECTED MHCII REGULATORY FACTORS

STRUCTURE AND MODE OF ACTION OF CIITA

CIITA contains several well-defined protein motifs (see Fig. 16.3) (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Ting and Trowsdale, 2002). Its N-terminus contains a region rich in acidic amino acids, followed by three segments rich in proline, serine, and threonine. The central part of the protein contains a nucleotide binding and oligomerization domain (NOD), which comprises a GTP binding domain (GBD). Finally, the C-terminus contains a leucine-rich repeat (LRR)-based protein–protein interaction motif. These features are all required for the function of CIITA, although their precise roles have been determined only partially (see below).

CIITA is a member of a large family of proteins characterized by the presence of a centrally placed nucleotide binding domain (NBD) and a C-terminal LRR domain (Harton et al., 2002; Inohara et al., 2005; Meylan et al., 2006; Ting et al., 2008). Although a variety of different names have been used to describe this family, a recent initiative has proposed the unifying designation NLR (for NBD and LRR containing) (Ting et al., 2008). In a manner analogous to CIITA for MHCII genes, another family member, NLRC5, functions as a transactivator of MHCI genes (Kobayashi and van den Elsen, 2012) The other family members are cytoplasmic proteins playing roles in apoptosis, inflammation, and innate immunity (Inohara et al., 2005; Meylan et al., 2006; Ting et al., 2008). Several are associated with immunological and inflammatory disorders (Inohara et al., 2005; Meylan et al., 2006; Ting et al., 2008).

CIITA does not contain a recognizable DNA-binding domain and does not bind to DNA. However, chromatin immunoprecipitation experiments have demonstrated that CIITA is nevertheless recruited to the promoters of the MHCII, *Ii*, *HLA-DM*, and *HLA-DO* genes in vivo (Beresford and Boss, 2001; Hake et al., 2000; Krawczyk et al., 2008; Masternak et al., 2000b, 2003; Masternak and Reith, 2002). Recruitment of CIITA to MHCII promoters is mediated by multiple protein–protein interactions with DNA-bound factors (Fig. 16.2A). Factors bound to the S, X, X2, and Y boxes are all required for the recruitment of CIITA (DeSandro et al., 2000; Hake et al., 2000; Masternak et al., 2000b; Zhu et al., 2000).

Once tethered to MHCII promoters, CIITA is believed to activate transcription via N-terminal transcription activation domains (Fig. 16.2A) (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Ting and Trowsdale, 2002). The acidic and proline/serine/threonine-rich regions found in the N-terminus of CIITA are reminiscent of the transcription activation domains present in other transcription factors. Moreover, they can activate transcription when fused to heterologous DNA-binding proteins and can be replaced by activation domains from other transcription factors (Riley et al., 1995; Zhou and Glimcher, 1995).

Several mechanisms have been implicated in the activation of transcription by CIITA (Fig. 16.2A). First, CIITA can interact with the general transcription factors $TF_{II}B$, $TAF_{II}32$, and $TAF_{II}70$, suggesting that it activates transcription initiation by recruiting the general transcription machinery (Fontes et al., 1997; Mahanta et al., 1997; Masternak and Reith, 2002; Masternak et al., 2003). Second, it has been proposed that CIITA stimulates promoter clearance by RNA polymerase II and transcription elongation by promoting the recruitment of $TF_{II}H$ and P-TEFb (Kanazawa et al., 2000; Mahanta et al., 1997; Spilianakis et al. 2003). Third, CIITA has been proposed to enhance chromatin accessibility by inducing recruitment of the ATP-dependent chromatin remodeling factors Brg1 and Brm1 (Mudhasani and Fontes, 2002; Spilianakis et al. 2003). Fourth, CIITA is believed to promote the acetylation of histones H3 and H4 by recruiting histone acetyl transferases, such as pCAF, GCN5, CBP, and SRC1 (Beresford and Boss, 2001; Fontes et al., 1999; Kretsovali et al., 1998; Masternak and Reith, 2002; Masternak et al., 2003; Spilianakis et al., 2000; Tzortzakaki et al., 2003; Zhu and Ting, 2001). CIITA has also been reported to have an intrinsic histone acetyl transferase activity (Raval et al., 2001). Finally, it has been reported that CIITA can promote methylation of histone H3 by recruiting the histone methyl transferase CARM1 (Zika et al., 2005).

Analysis of the intracellular distribution of CIITA has shown that a substantial amount of the protein is localized in

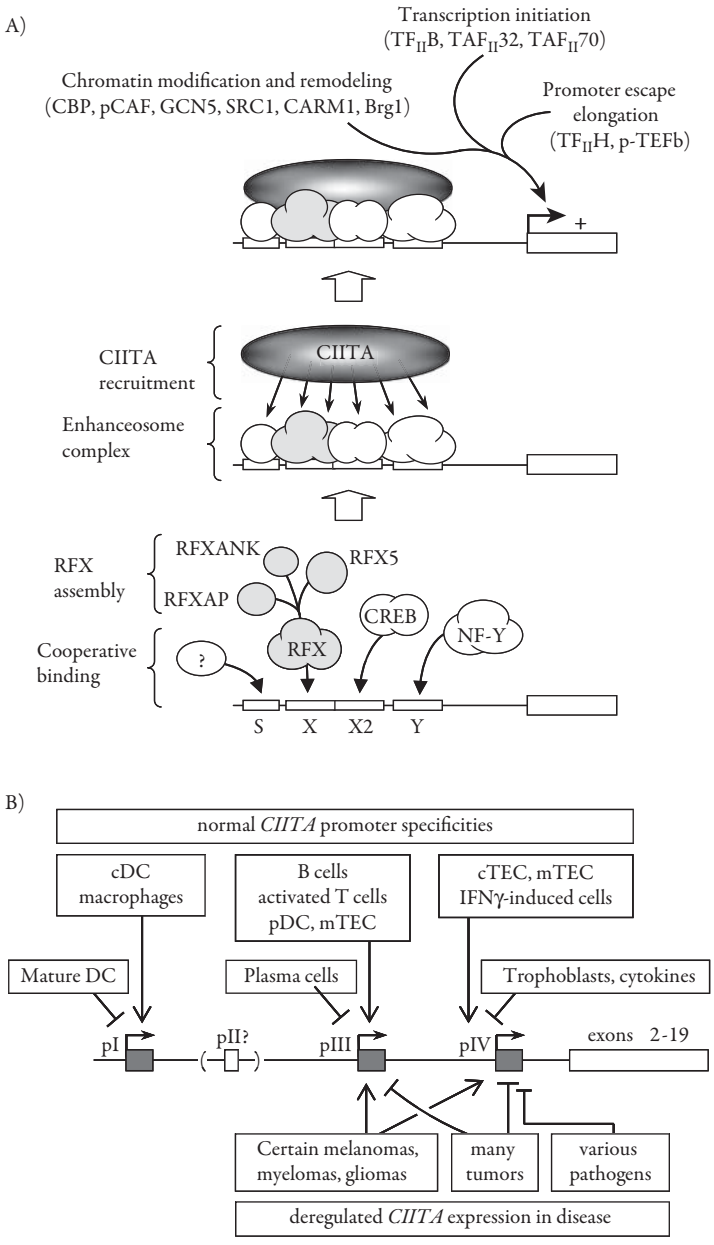

Figure 16.2 Overview of MHCII gene regulation. (A) The ubiquitously expressed factors RFX, CREB, and NF-Y assemble into an enhanceosome complex on the promoters of MHCII genes. The highly regulated non–DNA-binding coactivator CIITA is recruited to the enhanceosome by multiple protein–protein interactions. CIITA is believed to promote chromatin remodeling by interacting with histone acetyl- and methyl-transferases, and nucleosome remodeling factors. CIITA can also recruit components of the general transcription initiation machinery and factors involved in promoter clearance and transcription elongation. Brg1, Brahma-related gene 1; CARM1, coactivator-associated arginine methyltransferase 1; CBP, CREB-binding protein; CREB, cAMP response element-binding protein; GCN5, general control of amino acid synthesis 5; NF-Y, nuclear factor Y; pCAF, p300/CBP-associated factor; P-TEFb, positive transcription elongation factor b; SRC1, steroid receptor coactivator 1; TAF, TBP-associated factor; TBP, TATA-box-binding protein; $TF_{II}B$ and $TF_{II}H$, general transcription factors for RNA polymerase II. (B) Regulation of CIITA expression. Transcription of the *CIITA* gene is controlled by four independent promoters (pI, pII, pIII, and pIV) preceding four alternative first exons. Three of these promoters (pI, pIII, and pIV) are conserved in the mouse *CIIta* gene. These three promoters exhibit well-defined cell-type specificities and responsiveness to IFN-γ. pI is used mainly in macrophages and conventional dendritic cells (cDC). pIII is used in B cells, activated T cells, plasmacytoid dendritic cells (pDC), and medullar thymic epithelial cells (mTEC). pIV is used in both cortical and medullar thymic epithelial cells (cTEC, mTEC) and is induced by IFN-γ in cells of nonhematopoietic origin. pI, pIII, and pIV are silenced in mature DCs, plasma cells, and trophobasts, respectively. Activation of pI is also inhibited by certain anti-inflammatory cytokines. Aberrant activation or silencing of pIII and pIV is observed in various tumors and infectious diseases. The function of pII is not known.

the nucleus. Several regions within CIITA have been implicated in nuclear targeting of the protein. Three nuclear localization signals (NLS) have been identified (Fig. 16.3). One of these lies within a region that was found to be deleted in a BLS patient (Cressman et al., 1999). The GTP-binding domain also appears to be required for nuclear import (Harton et al., 1999). Finally, a detailed mutational analysis of the LRR region has shown that it is important for directing CIITA to the nucleus (Hake et al., 2000).

Several studies have shown that CIITA can associate with itself to form homomeric complexes. Although there is some controversy concerning the precise sequences that mediate self-association, the LRR and NOD domains have been implicated by several studies (Kretsovali et al., 2001; Linhoff et al., 2001; Sisk et al., 2001). The precise role of self-association of CIITA remains unknown.

TARGET GENE SPECIFICITY OF CIITA

Classical MHCII genes, and the *Ii* (CD74), *HLA-DM*, and *HLA-DO* genes required for antigen presentation by MHCII molecules, are the best-documented target genes of CIITA (Chang and Flavell, 1995; Kern et al., 1995; Krawczyk et al., 2008; Steimle et al., 1993). As all clinical manifestations and immunological abnormalities associated with MHCII deficiency can be explained by defective expression of these genes, it appeared unlikely that CIITA would play essential roles in other systems. It therefore came as a surprise when a series of studies proposed that CIITA can modulate the expression of numerous other genes involved in diverse functions within and outside the immune system (reviewed in LeibundGut-Landmann et al., 2004a). Collectively, these reports suggested that CIITA might have widespread functions extending beyond its role in the control of MHC

expression, a notion that was at odds with the highly specific defects observed in MHCII deficiency. To address this discrepancy, genome-wide searches were recently performed to define the complete set of CIITA target genes (Krawczyk et al., 2007, 2008). These searches identified only a handful of new bona-fide target genes, several of which encode proteins that are known or likely to be implicated in processes related to antigen presentation. CIITA was thus confirmed to be remarkably dedicated for the regulation of genes implicated in MHCII-mediated antigen presentation.

EXPRESSION OF CIITA

CIITA functions as a "master regulator" of MHCII genes. Numerous studies have demonstrated that it is mainly the expression pattern of CIITA that governs the cell-type specificity, induction, and level of MHCII expression. (reviewed in Harton and Ting, 2000; Reith and Mach 2001; Reith et al., 2005; Ting and Trowsdale, 2002). MHCII expression by antigen-presenting cells (B cells, macrophages, and dendritic cells), activated T cells, and thymic epithelial cells is driven by CIITA expression (Chang et al., 1996b; Irla et al., 2008; Landmann et al., 2001; LeibundGut-Landmann et al., 2004b; Otten et al., 1998; Steimle et al., 1993; Waldburger et al., 2001, 2003). Induction of MHCII expression by IFN-γ is mediated by activation of the *CIITA* gene (Chang et al., 1994; Chin et al., 1994; Steimle et al., 1994; Waldburger et al., 2001). Repression of MHCII expression in plasma cells, trophoblasts, mature dendritic cells, and certain tumors is due to silencing of the CIITA gene (Holling et al., 2006; Landmann et al., 2001; Morris et al., 1998, 2000; Reith et al., 2005; Silacci et al., 1994). Cytokines that inhibit MHCII expression—such as TGFβ, IL-4, and IL-10—achieve this by inhibiting CIITA expression. Finally, a variety of pathogens have developed the ability to inhibit CIITA expression—and thus MHCII expression—as a strategy to evade recognition by the immune system (reviewed in LeibundGut-Landmann et al., 2004a). Examples include CMV, HIV, varicella-zoster virus, *Mycobacterium bovis*, *Mycobacterium tuberculosis, Toxoplasma gondii,* and *Chlamydia* (Abenroth et al., 2000; Kanazawa et al., 2000; Le Roy et al., 1999; Luder et al., 2003; Miller et al., 1998; Pai et al., 2003; Wojciechowski et al., 1999; Zhong et al., 1999).

Expression of the *CIITA* gene is directed by four independent promoters (I, II, III, and IV), which precede four alternative first exons (Fig. 16.2B). Three of these promoters (I, III, and IV) are conserved in the mouse *CIIta* gene. The *CIITA/CIIta* promoters differ in their cell-type specificity and response to IFN-γ (Fig. 16.2B). It is thus the differential activity of the *CIITA/CIIta* promoters that ultimately determines the cell-type specificity and inducibility of MHCII gene expression (reviewed in Harton and Ting, 2000; Reith and Mach, 2001; Reith et al., 2005; Ting and Trowsdale, 2002). Promoter I is used mainly in macrophages and most dendritic cells subsets (Irla et al., 2008; Landmann et al., 2001; LeibundGut-Landmann et al., 2004b; Muhlethaler-Mottet et al., 1997). Promoter III drives expression of CIITA in B cells, activated T cells, and a unique dendritic cell subset known as plasmacytoid dendritic cells (LeibundGut-Landmann et al., 2004b). Promoter IV is essential for IFN-γ–induced expression in non-bone-marrow–derived cells and for expression in cortical thymic epithelial cells (Irla et al., 2008; Muhlethaler-Mottet et al., 1998; Waldburger et al., 2001, 2003). Medullar thymic epithelial cells rely on both promoters III and IV (Irla et al., 2008).

Deregulation of the *CIITA* promoters is associated with diseases (reviewed in Holling et al., 2006; LeibundGut-Landmann et al., 2004a; Reith et al., 2005) (Fig. 16.2B). Both silencing and aberrant activation of promoters III and IV have been associated with various types of tumors. Several pathogens have developed mechanisms for avoiding immune recognition by inhibiting IFN-γ–induced activation of promoter IV.

FUNCTION AND MODE OF ACTION OF RFX

In contrast to CIITA, the RFX complex is expressed widely in all cell types examined, even in MHCII-negative cells. However, like CIITA, the MHCII, *Ii* (*CD74*), *HLA-DM*, and *HLA-DO* genes are the major target genes of RFX. RFX is also implicated in expression of MHCI and β2m genes (Gobin et al., 1998; van den Elsen et al., 1998). It is unlikely that RFX plays a major role in other systems, because all clinical and immunological features of RFX-deficient patients (groups B, C, and D) can be attributed to defects in MHC expression.

In vivo footprint experiments (Kara and Glimcher, 1991, 1993) and DNAse I hypersensitivity studies (Gonczy et al., 1989) have shown that MHCII promoters are completely unoccupied in RFX-deficient patients (Table 16.3, Fig. 16.1). This indicated that occupation of the promoter by DNA-binding factors such as the X2 box binding protein X2BP (Hasegawa and Boss, 1991), which contains CREB (Moreno et al., 1999), and the Y box binding protein NF-Y (Mantovani, 1999) is dependent on binding of RFX to the adjacent X box. An explanation for these findings was provided by in vitro binding studies demonstrating that RFX binds cooperatively with X2BP(CREB) and NF-Y to form a higher-order protein–DNA complex containing all three proteins (Fig. 16.2A) (Durand et al., 1994; Louis-Plence et al., 1997; Moreno et al., 1995; Reith et al., 1994a, 1994b). This nucleoprotein complex has been coined the MHCII "enhanceosome" complex (Masternak et al., 2000b). In the MHCII enhanceosome, the interactions of RFX, X2BP(CREB), and NF-Y with their respective target sites are strongly stabilized (Louis-Plence et al., 1997; Moreno et al., 1995; Reith et al., 1994a, 1994b). This stabilization is sufficiently strong to permit recruitment of RFX, X2BP(CREB), and NF-Y to all MHCII promoters, even to those that contain only very-low-affinity binding sites for these proteins (Louis-Plence et al., 1997; Reith et al., 1994a). These cooperative binding interactions are essential for stable occupation of MHCII promoters in vivo (Wright et al., 1994). The bare promoter phenotype observed in groups B, C, and D is thus a direct consequence of the deficiency in RFX (Fig. 16.1). The fact that the occupation of MHCII promoters requires cooperative binding interactions between RFX, X2BP(CREB),

and NF-Y also explains the observations that the order, orientation, and spacing of the X, X2, and Y sequences are highly conserved and critical for their activity (Reith et al., 1994b; Vilen et al., 1991, 1992).

One of the main functions of the enhanceosome is to serve as a platform for the recruitment of CIITA (Fig. 16.2A). However, there is growing evidence that the enhanceosome also plays several important CIITA-independent functions. First, at certain MHCII promoters, the enhanceosome is sufficient for inducing histone acetylation and recruitment of the general transcription machinery and RNA polymerase II (Masternak et al., 2002). Second, enhanceosome assembly plays a critical role in evicting nucleosomes from MHCII promoters, a process that is required for defining the correct position of the transcription initiation sites of MHCII genes (Leimgruber et al., 2009). Finally, the enhanceosome has recently been shown to protect MHCII genes against the establishment of epigenetic silencing by DNA methylation (Seguín-Estévez et al., 2009).

MUTATION ANALYSIS

Nine different mutations of the *CIITA* gene have been characterized (Fig. 16.3) (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a). These include two nonsense mutations, two missense mutations, a small in-frame deletion, and four splice-site mutations. These mutations all affect either the central segment of CIITA containing an NLS and the NOD domain, or the C-terminal region containing a second NLS and the LRR domain. One of the missense mutations was found to be responsible for a mild form of MHCII deficiency (Wiszniewski et al., 2001). An additional patient was found to exhibit a strong decrease in CIITA mRNA expression, which was attributed to a putative regulatory mutation in the CIITA gene (Dziembowska et al., 2002). Mutations affecting the two alleles of *CIITA* in the in vitro-generated RJ2.2.5 cell line have also been defined (Steimle et al., 1993).

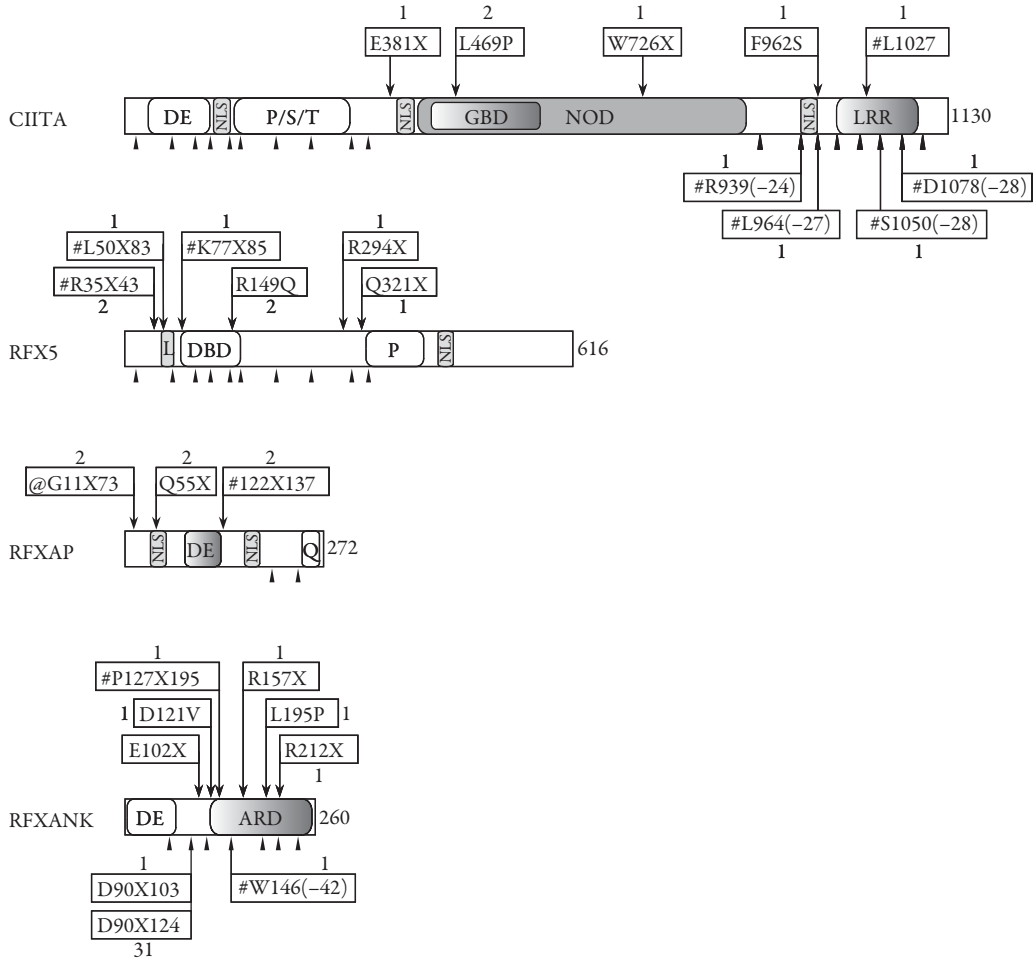

Figure 16.3 Structure and mutations of the factors that are affected in MHCII deficiency. Maps of CIITA, RFX5, RFXAP, and RFXANK are drawn to scale. The sizes in amino acids of the proteins are indicated at the right. Arrowheads below the maps indicate the positions of introns. Boxed text is used to describe mutations: boxes above the proteins correspond to mutations in coding regions, whereas boxes below correspond to mutations in splice sites. X denotes a stop codon. The number following an X indicates the position of a premature stop codon created by a frameshift. # indicates a deletion. @ indicates an insertion. Numbers in parentheses indicate the number of amino acids removed by an internal deletion. Numbers above or below the boxes indicate the number of patients in which the same mutation was found. Key protein domains are indicated: ARD, ankyrin repeat domain; DBD, DNA-binding domain; DE, rich in acidic amino acids (glutamic and aspartic acid); GBD, GTP-binding domain; L, leucine-rich stretch; LRR, leucine-rich repeats; NES, nuclear export signal; NLS, nuclear localization signal; NOD, nucleotide-binding and oligomerization domain; P, proline-rich; P/S/T, proline, serine, and threonine-rich; Q, glutamine-rich.

Nine different mutations of the *RFXANK* gene have been characterized (Fig. 16.3) (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a; Picard, unpublished data). These include three nonsense mutations, two missense mutations, a deletion leading to a frameshift, and three splice-site mutations. Eight of the mutations affect the integrity of the ankyrin repeat region, which is known to be essential for the function of RFXANK (Krawczyk et al., 2005; Nekrep et al., 2001). One is a missense mutation lying within the third ankyrin repeat. The remaining seven lead to the synthesis of proteins lacking all or part of the ankyrin repeat region. A 26 bp deletion disrupting a splice site has been found in 31 unrelated North African patients, indicating the existence of a founder effect (Wiszniewski et al., 2000; Picard, unpublished data). Another splice-site mutation was found to be responsible for a mild form of the disease (Prod'homme et al., 2003).

Six mutations of the *RFX5* gene have been identified (Fig. 16.3) (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a). These include three deletions leading to a frameshift, two nonsense mutations, and one missense mutation. The missense mutation lies in the DBD and was identified in two related patients exhibiting an atypically mild form of MHCII deficiency (Nekrep et al., 2002). This mutation does not abolish DNA-binding activity completely and therefore allows residual expression of certain MHCII genes. The remaining mutations all lead to the synthesis of severely truncated RFX5 proteins lacking the DBD and/or the C-terminal moiety of the protein. A mutation within RFX5 has also been identified in G1B, which is an in vitro-generated MHCII regulatory mutant. The RFX5 gene in G1B contains a missense mutation situated just upstream of the DNA binding domain (Brickey et al., 1999).

Three different mutations affecting the *RFXAP* gene have been identified (Fig. 16.3) (reviewed in Krawczyk and Reith, 2006; Masternak et al., 2000a). These include two frameshift mutations resulting from an insertion and a deletion, and a nonsense mutation. All of these mutations lead to the synthesis of severely truncated proteins lacking a C-terminal glutamine-rich region, which is known to be essential for the function of RFXAP. Frameshift mutations resulting from the insertion of G nucleotides in the *RFXAP* gene were also identified in the in vitro-generated 6.1.6 cell line (Durand et al., 1997). One patient was recently found to carry a 75 bp insertion in the 5' untranslated region of the *RFXAP* gene (van Eggermond et al., 2008). This insertion constitutes a regulatory mutation that abrogates *RFXAP* expression by impairing the activity of its promoter.

STRATEGIES FOR DIAGNOSIS

Early diagnosis is critical because it increases the chances of successful hematopoietic stem cell transplantation (HSCT). Young children presenting with clinical and immunological features typical of MHCII deficiency should be referred by their physicians to specialized centers as soon as possible. The decisive criteria for the diagnosis of MHCII deficiency are the absence of MHCII expression on monocytes and B cells. These parameters should be tested in children having recurrent upper respiratory tract infections, diarrhea, and failure to thrive. Additional criteria warranting an investigation of MHCII expression include low $CD4^+$ T-cell counts, hypogammaglobulinemia, and profoundly impaired antigen-specific T- and B-cell–mediated immune responses.

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

MHCII deficiency is inherited as an autosomal recessive disease. Carriers are healthy and exhibit no known phenotype. Considering the rarity of the disease, carrier detection is of no interest unless a consanguineous union is envisaged despite genetic counseling. In this case it could be performed either by using polymorphic markers flanking the affected gene or by a direct search for known mutations. Given the severity of MHCII deficiency, prenatal diagnosis in affected families is a valid ethical option. Previously, prenatal diagnosis has been carried out safely between the 20th and 22nd week of amenorrhea by analyzing MHCII expression on fetal leukocytes obtained by means of an umbilical vein puncture guided by echography (Durandy et al., 1987). However, characterization of the mutations affecting the *CIITA*, *RFXANK*, *RFX5*, and *RFXAP* genes in families from complementation groups A, B, C, and D now offers a better option for prenatal diagnosis. The presence of these mutations could be assessed directly on trophoblasts obtained from a chorionic villi biopsy during the 11th week of amenorrhea.

TREATMENT AND PROGNOSIS

Treatment of infections and other complications can at best reduce the frequency and severity of the clinical problems associated with MHCII deficiency. The optimal symptomatic care available consists of the prophylactic use of antibiotics and administration of immunoglobulins. However, these means do not prevent progressive organ dysfunction and death. In the absence of curative treatment (HSCT), the prognosis is poor. As indicated in Table 16.4, the majority of patients who do not undergo HSCT die at a young age from various infections, with or without autoimmune manifestations. Only a minority of patients characterized by a less severe clinical picture survive beyond the age of 20 years. There is no obvious difference in prognosis for patients belonging to the four different genetic complementation groups. The leaky phenotype characteristic of atypical patients is associated with a better outcome (Hauber et al., 1995; Prod'homme et al., 2003; Wiszniewski et al., 2001; Wolf et al., 1995).

As for other combined immunodeficiency disorders, HSCT is currently the only available curative treatment for MHCII deficiency. The outcome of HSCT in patients with MHCII deficiency is summarized in Table 16.4. The success rate is relatively poor, since less than half of the patients were cured by the procedure (Klein et al., 1995). Results were much better in patients undergoing HSCT before the age of 2 years,

Table 16.4 OUTCOME WITH AND WITHOUT HEMATOPOIETIC STEM CELL TRANSPLANTATION (HSCT)

OUTCOME	*NO. PATIENTS*
Without HSCT	*21*
Pneumonia	20
Chronic diarrhea	19
Hepatitis, cholangitis	9
Sepsis	7
Meningoencephalitis	5
Autoimmunity	5
Alive, 1–31 years old (mean 10.5 years)	11
Death, 5 months to 16 years old (mean 5.7 years)	10
All HSCT	*39*
Alive 1–27 years after HSCT	16
Persistent immunodeficiency	1
Death after HSCT	23
HLA-Identical HSCT	*18*
Alive, 1–27 years after HSCT	10
Death, 46 to 384 days after HSCT	8

Data is from 60 patients treated at Hospital Necker-Enfants Malades between 1977 and 2009 (Renella et al. 2006; Picard, unpublished data).

probably because the viral burden and organ dysfunction are less intense (Klein et al., 1995). When an HLA-identical sibling is available, the chances of success are fairly good. Reduced survival after HLA-identical HSCT is caused by the high incidence of preexisting viral infections and is associated with the onset of severe acute graft-versus-host disease (Renella et al., 2006). The success rate is lower when HSCT is performed with matched unrelated donors or with partially HLA-compatible related donors. Although several patients have now been cured by HSCT with non–HLA-identical donors (Klein et al., 1995), the success rate remains lower than in other immunodeficiency syndromes. The two main obstacles are intractable persistent viral infections caused by a long-lasting T-cell immunodeficiency, and graft failure or rejection resulting from normal allogeneic responses in the patients.

Four conclusions can be drawn from our current experience with HSCT in MHCII deficiency (Klein et al., 1995; Renella et al., 2006). First, despite the lack of MHCII expression, the risk of graft-versus-host disease is similar to that observed in patients with other forms of immunodeficiency. Second, $CD4^+$ T-cell counts remain low (albeit functional) in long-term survivors because of defective MHCII expression by the thymic epithelial cells of the host. Third, the lack of MHCII expression in nonhematopoietic cells does not appear to be detrimental for patients who have undergone successful HSCT. Finally, given the invariably fatal course of typical MHCII deficiency and the poor outcome of HSCT performed after the age of 2 to 4 years, it is highly recommended that HSCT be performed in young children independently of whether or not an HLA-identical sibling is available.

Now that the four genes affected in MHCII deficiency have been identified, gene therapy has become a potential alternative to HSCT. Introduction of the wild-type *CIITA*, *RFXANK*, *RFX5*, or *RFXAP* genes into the hematopoietic stem cells of patients in complementation groups A, B, C, and D, respectively, would represent a logical therapeutic strategy. However, current gene therapy protocols remain hampered by the relative inefficiency of gene transfer into human hematopoietic stem cells, as well as by the risks entailed by vector insertion into the genome. Moreover, in normal individuals MHCII expression is tightly controlled in a cell-type–specific and inducible manner, and ectopic or nonphysiological levels of MHCII expression induced by the transgene should therefore be avoided. This should not represent a major problem for gene therapy with *RFX5*, *RFXANK*, and *RFXAP*, which are expressed ubiquitously at relatively constant levels in all cell types. Expression of CIITA is, on the other hand, tightly regulated. Correct expression of a *CIITA* transgene will be difficult to obtain unless the endogenous promoters of the *CIITA* gene are used.

MOUSE MODELS FOR MHCII DEFICIENCY

There are no spontaneous animal models for MHCII deficiency, but three mouse models have been constructed by gene targeting. The first model to become available was the MHCII knockout mouse, which reproduced many of the immunopathological features of the human disease, including hypogammaglobulinemia, decreased $CD4^+$ T-cell counts, and a deficiency in cellular and humoral immune responses to foreign antigens (reviewed in Dardell et al., 1994; Grusby and Glimcher, 1995). A more faithful model reproducing the molecular defect exhibited by patients in complementation group A was obtained by gene targeting of the mouse *CIIta* gene (Chang et al., 1996a; Itoh-Lindstrom et al., 1999; Williams et al., 1998). The phenotype exhibited by *CIIta* knockout mice is very similar to that of human MHCII-deficiency patients. Both constitutive and IFN-γ–induced MHCII expression is strongly reduced. There is also a drastic reduction in the number of $CD4^+$ T cells. $CD4^+$ T-cell–dependent immune responses are consequently severely compromised. A third model reproducing the molecular defect exhibited by patients in complementation group C was constructed by disruption of the mouse *Rfx5* gene (Clausen et al., 1998). The phenotype of *Rfx5* knockout mice is similar to that of *CIIta* knockout mice. Both constitutive and IFN-γ–inducible MHCII expression are lost, $CD4^+$ T-cell counts are strongly reduced, and adaptive immune responses are markedly impaired.

Both the *CIIta* and *Rfx5* knockout mice exhibit residual MHCII expression in certain tissues and cell types (reviewed in Reith and Mach, 2001), implying that there are RFX5- and/or CIITA-independent pathways for MHCII expression in specific cellular compartments. The precise pattern of residual expression differs between the two mice. $Rfx5^{-/-}$ mice retain MHCII expression in the thymic medulla and

significant, albeit weak, expression on a fraction of splenic and bone-marrow–derived dendritic cells, and on B cells activated in vitro with lipopolysaccharide (LPS) and/or IL-4 (Clausen et al., 1998). In contrast, residual MHCII expression in *CIIta*$^{-/-}$ mice concerns primarily dendritic cells in the lymph nodes, B cells in germinal centers, and a subset of thymic epithelial cells (Chang et al., 1996a; Williams et al., 1998). This difference in the pattern of residual MHCII expression is surprising because the human disease is phenotypically homogeneous. Leaky expression has been observed in cells from certain BLS patients, but no characteristic residual expression pattern distinguishing RFX-deficient patients from those with defects in CIITA has been described. This discrepancy could reflect species-specific differences in the respective roles of the MHCII regulatory factors. However, because of the rarity and severity of the disease, only relatively few patients from defined complementation groups have been studied in detail with respect to residual MHCII expression. Consequently, it is also possible that the phenotypic differences observed in the mouse system exist in the human disease as well but have escaped attention until now.

The development of CD4$^+$ T lymphocytes in the thymus requires positive selection driven by the expression of MHCII molecules on cortical thymic epithelial cells (Viret and Janeway, 1999). The fact that the CD4$^+$ T-cell population is almost completely absent in MHCII, *CIIta*, and *Rfx5* knockout mice is consistent with this (Chang et al., 1996a; Clausen et al., 1998; Dardell et al., 1994; Grusby and Glimcher, 1995). It is therefore quite surprising that CD4$^+$ T-cell counts are only mildly reduced in MHCII-deficiency patients (Griscelli et al., 1993; Klein et al., 1993). This discrepancy between MHCII deficiency and the existing mouse models for the human disease remains unresolved. One possible explanation is that mutations in the human *CIITA* or *RFX5* genes may permit a low residual level of MHCII expression on cortical epithelial cells of the thymus and that this residual expression is sufficient to drive positive selection of CD4$^+$ T thymocytes. In this context it may be relevant that residual MHCII expression in the thymus has indeed been described in certain patients (Griscelli et al., 1993; Schuurman et al., 1985). A subset of thymic epithelial cells retaining the ability to express MHCII molecules has also been described in *CIIta* knockout mice (Chang et al., 1996a) and in *Rfx5* knockout mice (Clausen et al., 1998). An alternative explanation could be that CD4$^+$ T-cell selection in humans can be driven by alternative mechanisms that differ from those most prominent in the mouse. Interestingly, an analysis of the CD4$^+$ T-cell repertoire in MHCII-deficiency patients has revealed subtle alterations suggesting that CD4$^+$ T cells in these patients may have escaped the normal thymic selection processes (Henwood et al., 1996). It should be mentioned, however, that the same alterations were not observed in another study (Rieux Laucat et al., 1993).

ACKNOWLEDGMENTS

The literature cited here represents only a small selection of all the contributions that have been made to the fields of MHCII gene regulation and the molecular basis of MHCII deficiency. We sincerely apologize to all colleagues whose work we have been unable to cite for reasons of lack of space. We thank all past and present members of our laboratories for helpful discussions and their contributions to the work reviewed here.

PEPTIDE TRANSPORTER DEFECTS IN HUMAN LEUKOCYTE ANTIGEN CLASS I DEFICIENCY

Henri de la Salle, Lionel Donato, and Daniel Hanau

Human leukocyte antigen (HLA) class I molecules present peptides, derived from proteins synthesized in the cell, to cytotoxic αβ $CD8^+$ T lymphocytes. In this way, they are involved in immune responses against intracellular pathogens and cancer cells. Although HLA class I molecules should a priori be essential to immune defense and thus to survival, a few cases have been described of children or adults who live with a low level of HLA class I cell surface expression. Notably, complete HLA class I deficiency has never been reported, which suggests that total deficiency would be lethal. The first case of HLA class I deficiency, or bare lymphocyte syndrome (BLS), was identified at a time when HLA class II typing techniques were unreliable. This case was later found to be an HLA class II deficiency associated with low expression of class I molecules (BLS type III) (Sabatier et al., 1996; Touraine et al., 1978), resulting from a defect in the RFXAP transcription factor (Durand et al., 1997). Two cases of class I deficiency (BLS type I) without immunodeficiency were subsequently described in a nonconsanguineous family (Payne et al., 1983). One was discovered when bone marrow transplantation was being considered to treat aplastic anemia, while the second was a younger brother who displayed the same defect of HLA class I expression but was healthy. Four other cases of BLS type I were identified in patients who had first-cousin parents and suffered from unexplained lung disease (de la Salle et al., 1994; Maeda et al., 1985; Sugiyama et al., 1989). Apart from one who experienced recurrent fever (Sugiyama et al., 1989), these patients did not seem to be abnormally susceptible to viral infections. Moreover, when complete clinical data were available, the patients often appeared to have been healthy during the first years of life. Thus, the pathology associated with BLS type I does not appear to be a direct consequence of the deficiency (i.e., an expected susceptibility to viral infections or cancer) but rather to result from secondary effects. Due to this absence of a direct link between clinical manifestations and deficiency, the discovery of the first cases of BLS type I was fortuitous, subsequent to serological HLA typing, by clinicians faced with a desperate situation. Since the first molecular genetic and clinical descriptions of two patients in 1994, other HLA class I-deficient individuals have been discovered among previous and new clinical cases.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Only 28 well-documented cases of HLA class I deficiency with normal expression of class II molecules have been published, 23 of them resulting from a defect in the peptide transporter associated with antigen processing (TAP). Contrary to BLS types II and III, which are characterized by decreased HLA class II expression and the early onset of severe combined immunodeficiency, HLA class I deficiencies do not lead to any particular pathological manifestations during the first years of life. Pathology of the gut (diarrhea) is not observed, unlike in BLS types II or III. The clinical course of the known cases (reviewed in Gadola et al., 2000 and summarized in Table 17.1) varies among individuals. Chronic inflammatory lung disease, developing generally in late childhood, is the most common, but not requisite, trait of TAP-deficient patients. It begins with infections with *Haemophilus influenzae* during the first decade of life, is confined to the respiratory tract, and extends from the upper to the lower airways. Other bacterial pathogens may also be found (*Streptoccocus pneumoniae*, *Klebsiella*, *Pseudomonas aeruginosa*). The high frequency of nasosinusal involvement and nasal polyposis, uncommon in children who do not have cystic fibrosis, is noteworthy.

Table 17.1 CHARACTERISTICS OF HLA CLASS I DEFICIENCIES CAUSED BY MUTATIONS IN TAP1 AND TAP2

SITE OF CLINICAL DISEASE	HLA HAPLOTYPE	MOLECULAR DEFECT	REFERENCE
RT	unknown	unknown	1
RT, skin	A*2402 B*4006 Cw*15 DRB1*08032 DPB1*0501 DQB1*0601	TAP1(260)	2

RT, skin	A*01 B*08 Cw*7 DR17 DR52 DQ2	TAP1(747)	16

RT, Respiratory tract disease including, depending on the case and the description, recurrent sinusitis, bronchitis, colonization with bacteria (*H. influenzae, P. aeruginosa*), obstructive impairment, bronchiectasis and emphysema. Skin: skin granulomas. Although uncharacterized, patient 1 displayed a typical TAP-deficient syndrome and was therefore included in the table. All the HLA haplotypes identified were homozygous.

Cases belonging to the same family are grouped; thus, 15 families, representing 23 confirmed TAP-deficient patients, have been described. Unrelated familial cases originating from the same geographical area and sharing the same HLA haplotypes are highlighted in gray. In the defect column, the positions of the mutated codons are given in parentheses.

References in which the mutations are described: 1, Sugiyama et al., 1989; 2, Azuma et al., 2001; de la Salle et al., 1999; Furukawa et al., 1999a, 1999b, 1999c, 2000; Maeda et al., 1985; Sugiyama et al., 1986; Watanabe et al., 1987; 3, de la Salle et al., 1994; Donato et al., 1995; Zimmer et al., 1998, 1999, 2007; 4, Moins-Teisserenc et al., 1999; 5, Caversaccio et al., 2008; 6, de la Salle et al., 1999; Plebani et al., 1996; 7, Willemsen et al., 1995; 8, Teisserenc et al., 1997; 9, Matamoros et al., 2001; 10, de la Salle et al., 2002; 11, Parissiadis et al., 2005; 12, Markel et al., 2004a, 2004b; 13, Dogu et al., 2006; 14, de la Salle et al., 2007a; 15, de la Salle et al., 2007b; 16, Villa-Forte et al., 2008.

The pathology inevitably evolves to a respiratory insufficiency resulting in bronchiectasis, emphysema, panbronchiolitis, or bronchial obstruction. In the early stages of the disease, computed tomography (CT) scans of the chest may show bronchiolectasis, which later leads to bronchiectasis (Fig. 17.1). Hypoxemia can occur during infectious exacerbation.

Skin lesions have been described in several patients and start with local inflammation, most often on the legs, developing into necrotizing granulomas. These lesions may be related to vasculitis, leading to an inappropriate diagnosis of Wegener's granulomatosis (Plebani et al., 1996; Teisserenc et al., 1997; Watanabe et al., 1987; Villa-Forte et al., 2008). In a number of cases, lesions occurring in the upper respiratory tract led to mutilation of the midface (Moins-Teisserenc et al., 1999). One of these patients did not display inflammation of the airways. Surprisingly, the defect may remain unnoticed for many years. Thus, two adults without inflammatory lung disease have been described, one totally asymptomatic and the other with minor skin lesions on one leg (de la Salle et al., 2002). These lesions generally heal only transiently and

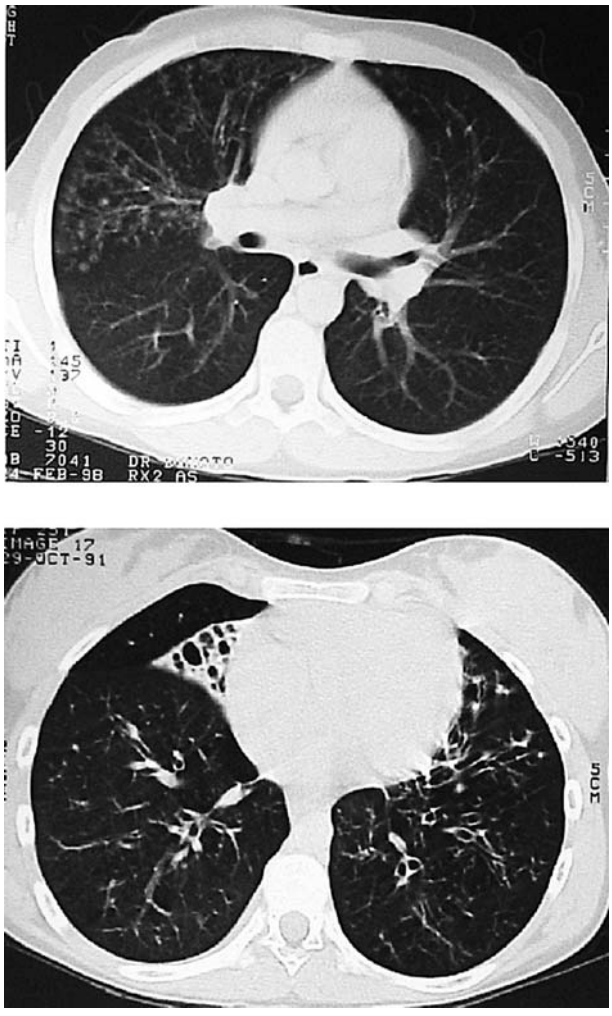

Figure 17.1 Chest CT scans. (Top) Bronchiolectasis in a 15-year-old TAP2-deficient patient. Patchy opacities spread out along the bronchovascular axes within the right middle lobe. (Bottom) Bilateral bronchiectasis in the patient's eldest sister, also TAP2 deficient. The lesions extend to the right middle lobe, lingula, and left lower lobe and represent a later stage of disease.

relapse, so they are difficult to treat and represent a major as yet unsolved dermatological problem.

Susceptibility to intracellular pathogens would be expected; accordingly, toxoplasmosis has been documented in TAP-deficient patients. In a 15-year-old patient, ocular toxoplasmosis resulted in necrotizing retinochoroiditis, which, despite anti-Toxoplasma therapy and subsequent surgery, led to the loss of one eye (Parissiadis et al., 2005). Another patient was treated for pulmonary toxoplasmosis; the clinical history revealed that there had been loss of vision in one eye for unknown reasons a few months before, which suggests that the toxoplasmosis might have initiated with an ocular infection (Dogu et al., 2006). Finally, poorly controlled pulmonary tuberculosis could be observed in a TAP-deficient child in Portugal having the same mutation than that of a Brasilian patient (unpublished observations, Villa-Forte et al., 2008).

An absence of efficient HLA class I restricted immune responses might finally lead to susceptibility to cancer. One case has been documented do date, a recent observation of skin carcinoma initiating within a skin lesion (España et al., 2010). This is interesting in that it raises the question as to whether the cancer resulted from an infection with a pathogen such as Merkel polyomavirus, which could not be investigated due to a lack of material.

The two HLA class I-deficient brothers described by Payne et al. were free of lung and upper airway disease, although respiratory involvement could not be excluded because the patients were young, no ear-nose-throat or pulmonary investigations had been carried out, and long-term data were lacking. One of these children suffered from unexplained anemia but recovered under prolonged corticosteroid treatment. Another case has since been discovered in France (de la Salle, unpublished data). As shown in the next section, this type of deficiency is not caused by a TAP defect.

Finally, a moderate HLA class I deficiency resulting from a defect in tapasin (TAP-associated glycoprotein) has been characterized. The patient did not display any of the symptoms associated with TAP deficiency but suffered from chronic primary glomerulonephritis (Yabe et al., 2002).

MOLECULAR BASIS OF TAP DEFICIENCY

MECHANISMS OF ANTIGEN PRESENTATION BY HLA CLASS I MOLECULES

Classical HLA class I molecules are composed of a polymorphic membrane-associated heavy chain, encoded by HLA-A, HLA-B, and HLA-C genes, associated with β2-microglobulin (β2m), a soluble subunit. After assembly in the endoplasmic reticulum, the heavy chain/β2m complexes associate with calreticulin, TAP, tapasin, and ERp57, forming altogether the "peptide loading complex" (PLC, see Fig. 17.2) (Wearsch and Cresswell, 2008). Calreticulin is a chaperone that controls the quality of proteins assembled in the endoplasmic reticulum, here newly synthesized heavy chain/β2m heterodimers. Within the PLC, TAP imports into the lumen of the endoplasmic reticulum peptides resulting from the cytosolic degradation of proteins, mediated in general by the proteasome or in rare cases by tripeptidyl peptidase II (Kloetzel, 2004). TAP is composed of two subunits, TAP1 and TAP2, and belongs to the ATP binding cassette (ABC) family of transporters. The cytoplasmic region of these transporters includes two ATP binding cassettes (Walker sites A and B) necessary for their activity (Schneider and Hunke, 1998). However, in the case of TAP, the ATP binding site of TAP1 is dispensable (Karttunen et al., 2001). The first four and three transmembrane domains of TAP1 and TAP2, respectively, bind tapasin and are dispensable for the peptide transporter activity of TAP. The six other transmembrane segments and the C-terminal cytoplasmic domains of each subunit constitute the core domains necessary and sufficient for the assembly of TAP and its peptide transport activity (Koch et al., 2004). Tapasin mediates a physical link between TAP and the heavy chain/β2m heterodimer and favors the binding of optimal peptides. The function of

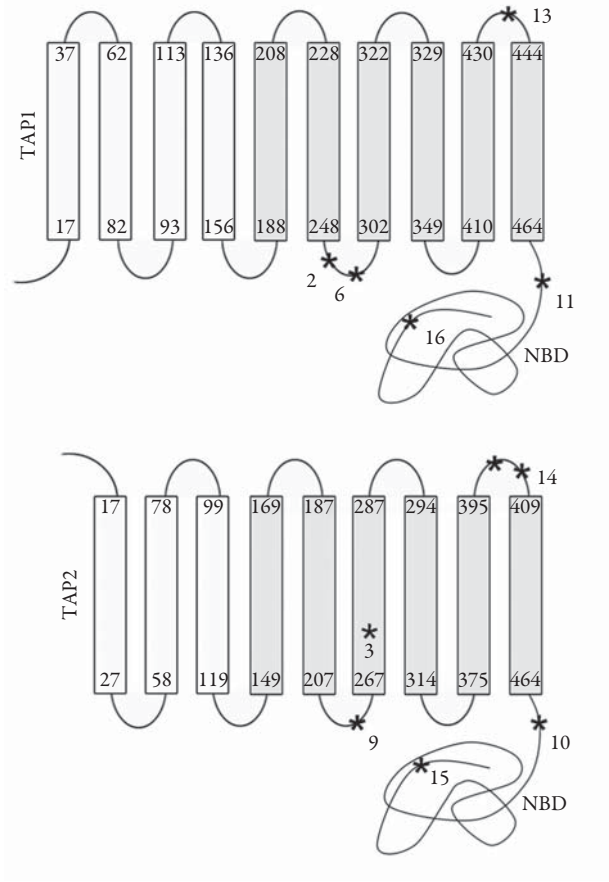

Figure 17.2 Structure of the TAP1 and TAP2 proteins and positions of the amino acids that have been found mutated in patients. The white and gray rectangles represent transmembrane domains respectively participating in interaction with tapasin, or constitutive to the transporter function. The numbers in the rectangles correspond to the amino acid coordinates of the N- and C-terminal ends of the domains (Koch et al., 2004). The mutations are numbered according to Table 17.1. NBD, nucleotide binding domain.

tapasin is controlled by ERp57, which associates with tapasin via a disulfide bridge. ERp57 increases the stability of the PLC and thereby facilitates the binding of optimal peptides by the heavy chain/β2m complex. ERp57 does not need to interact with calnexin or calreticulin to promote the assembly of class I histocompatibility molecules, and it enhances peptide loading independently of its redox activity (Zhang et al., 2009). Finally, the imported peptides may be too long to bind to HLA class I molecules, and hence the N-terminal ends of antigenic peptides may need to be processed by endoplasmic reticulum aminopeptidases associated with antigen processing (ERAP1 and ERAP2) (Wearsch and Cresswell, 2008).

Studies in tumor and mutant cell lines have shown that defective HLA class I expression may arise from downregulation of HLA class I or TAP genes, or from mutations in β2m, TAP, or tapasin genes. In TAP-deficient cell lines, most HLA class I molecules remain blocked between the endoplasmic reticulum and the cis-Golgi compartment and therefore stay endoglycosidase H sensitive and unsialylated. The HLA class I heavy chain/β2m complexes are peptide-free and unstable at 37°C, resulting in poor expression of HLA class I molecules on the cell surface. In the absence of TAP, the presentation of most peptides of intracellular origin is blocked, although TAP-independent presentation of some antigens can occur. The genes encoding the TAP subunits are located in the HLA class II genetic locus on chromosome 6 and are polymorphic; up to six TAP1 and four TAP2 human alleles have been described to date (Robinson et al., 2003). Calnexin is not essential for normal expression of HLA class I molecules (Scott and Dawson, 1995). In contrast, the processing of these molecules is altered in the tapasin-defective 721.220 cell line, in a manner similar to that in TAP-deficient cells, although the effect of the mutation depends on the biophysical characteristics of the HLA variants (Greenwood et al., 1994). Disruption of the ERp57 gene in mouse B lymphocytes affects the assembly of the PLC, leading to a moderate to weak decrease in plasma membrane MHC class I molecules, depending on the isoform, and a reduction of antigen presentation (Garbi et al., 2006). In the mouse, targeted disruption of the gene encoding the endoplasmic reticulum aminopeptidase had only a moderate effect on MHC class I expression on the plasma membrane, although antigen presentation could be significantly affected (Yan et al., 2006).

MOLECULAR BASIS OF HLA CLASS I DEFICIENCIES

Up until now, three kinds of HLA class I deficiency have been encountered. In two individuals (Payne et al., 1983), genetic analyses demonstrated that HLA class I genes were constitutively poorly expressed in lymphocytes (Sullivan et al., 1985). This deficiency was probably not linked to chromosome 6, as the two brothers had inherited different HLA haplotypes, but the causative genetic defect has not yet been elucidated. A second type of HLA class I deficiency arose from a tapasin defect. Only one patient has been described, born to consanguineous parents, HLA homozygous and bearing a homozygous mutation in the tapasin gene, located in the HLA region. The expression of HLA class I molecules was ten-fold reduced (Yabe et al., 2002), but no further biochemical or immunological investigations have been reported.

The third type is apparently the most common, probably because it generally leads to typical clinical manifestations. In all but one report, the patients were born to consanguineous parents, and when HLA typing could be performed, the individuals were always found to be HLA homozygous. In agreement with the location of TAP genes in the HLA class II genetic region, a homozygous mutation in one of the TAP genes was found in all characterized cases (Table 17.1). Biochemical studies of cell lines derived from these patients showed that their HLA class I heavy chains remained unsialylated (de la Salle et al., 1994, 1999; Maeda et al., 1985). Most of the heavy chains remained endoglycosidase H sensitive, while HLA class I molecules were unstable at 37°C (de la Salle et al., 1994, 1999, 2002; Teisserenc et al., 1997). Five mutations have been characterized in the TAP1 and six in the TAP2 gene; the MIM (Mendelian Inheritance in Man) numbers for

these deficiencies are 170260 and 170261, respectively. The main clinical features and the HLA haplotypes of the different patients are provided in Table 17.1. Identical HLA haplotypes were observed in different families, who appeared to originate from the same geographical areas. All the mutations generate subunits truncated in one of the transmembrane helices or in the cytoplasmic domain. Mutation in TAP1 may lead to instability of the TAP2 protein (Furukawa et al., 1999a; Moins-Teisserenc et al., 1999).

FUNCTIONAL ASPECTS

EXPRESSION OF HLA CLASS I MOLECULES

The expression of HLA class I molecules can be quantified by flow cytometry after staining of the cells with a pan-anti-HLA class I monoclonal antibody such as W6/32. On peripheral blood mononuclear cells (PBMCs) of the two individuals described by Payne et al., the expression of HLA class I molecules was reduced ten-fold, whereas this expression was normal on platelets (Sullivan et al., 1985). The latter observation would appear to contradict the fact that HLA typing could not be performed on platelets (Payne et al., 1983). Epstein-Barr virus-transformed B (EBV B) cell lines derived from the patients progressively expressed higher levels of HLA class I molecules after a few weeks of culture. In an analogous case, we observed that the PBMCs of a 2-year-old child displayed low HLA class I expression while an EBV B-cell line gradually expressed higher levels of these molecules, although still only 10 percent that of class I on normal EBV B cells. Additional experiments demonstrated that HLA class I genes could be induced in activated T cells, their expression being upregulated by tumor necrosis factor-α (TNF-α) and interferon-α (IFN-α) or IFN-γ (de la Salle, unpublished observations). Thus, in this type of deficiency, HLA class I genes can be induced by inflammatory cytokines. As a result, HLA class I-mediated immune responses can be increased when necessary and, for this reason, the defect may be qualified as "conditional." Although the HLA class I expression in other tissues of these individuals was not documented, it is noteworthy that the expression of HLA class II molecules was normal.

On the surface of cells from TAP-deficient patients, the expression of HLA class I molecules is reduced 100-fold (de la Salle et al., 1994, 1999; Teisserenc et al., 1997) and the same level of reduction is found on lymphocytes, monocytes, neutrophils, and skin fibroblasts. This expression increased slightly on lymphocytes and fibroblasts after treatment with IFN-α or IFN-γ, whereas TNF-α induced weak upregulation on fibroblasts only. However, these observations reflected merely the capacity of these cytokines to upregulate HLA class I genes. A similar effect was noted when the PBMCs of another patient were incubated with phytohemagglutinin (PHA) and IFN-γ (Plebani et al., 1996). Two adults with a TAP2 deficiency were described who surprisingly expressed five times more HLA class I molecules than other TAP-deficient patients (de la Salle et al., 2002). This discrepancy was found to result from a moderate TAP-independent cell-surface expression of HLA-B7 molecules, which was 20 percent of that on normal HLA-B7 cells.

HLA class I molecules were found to be absent from the skin of TAP-deficient patients (Hanau et al., 1994). Immunohistochemical studies of skin from two other patients showed that these molecules were not expressed in healthy skin biopsies but were present in skin lesions. In one case, HLA class I expression was lower than in skin from normal individuals (Watanabe et al., 1987), while in the other the location of these molecules within cells or at the cell surface was uncertain (Plebani et al., 1996).

Soluble HLA class I molecules circulate in plasma. TAP-deficient patients and the child described above who displayed a low but inducible HLA class I expression on lymphocytes had very reduced plasma levels of soluble HLA class I molecules of 0.15 and 0.31 μg/mL, respectively (normal values, 160 ng to 3 μg/mL) (unpublished data).

EXPRESSION OF NONCLASSICAL HLA CLASS I MOLECULES

Nonclassical HLA class I molecules are composed of nonpolymorphic heavy chains associated with β2m and, unlike the ubiquitous classical HLA class I molecules, are expressed only on specialized cells. In particular, CD1 molecules are expressed on dendritic cells, including epidermal Langerhans cells. In two TAP-deficient patients, immunocytochemical staining of skin biopsies showed HLA class I molecules to be undetectable but CD1a antigens to be normally expressed on Langerhans cells. Flow cytometry further demonstrated that CD1 antigens were present at normal levels on dendritic cells derived in vitro from monocytes (Hanau et al., 1994). In another case, CD1a molecules were likewise normally expressed on epidermal Langerhans cells in biopsies taken from nonlesional skin but were not detectable in biopsies taken from ulcers (Plebani et al., 1996). This absence of CD1a from lesion biopsies might nevertheless result only from the local inflammation and not be linked to the genetic defect.

Another important HLA class I-like molecule is HLA-E, which presents, in a TAP-dependent manner, peptides derived from the signal peptides of classical HLA class I molecules. This protein interacts with the NKG-2A/CD94 inhibitory receptor expressed on natural killer (NK) cells and a subset of T cells and thereby acts as a sensor in the biosynthetic pathway of HLA class I molecules. HLA-E/NKG-2A/CD94 interactions suppress the cytolytic responses of NK and T cells and their cytokine release. Surprisingly, immunofluorescence studies showed HLA-E to be expressed on the PHA-induced T-cell blasts but not on the EBV B cells of a TAP-deficient patient (Furukawa et al., 1999b). However, in another study, HLA-E molecules were nearly undetectable on the surface of PBMCs and EBV B cells (Matamoros et al., 2001).

HUMORAL IMMUNE RESPONSE

The effects of HLA class I deficiency on the levels of immunoglobulin (Ig) classes and subclasses have been reported in a few

studies. Hypergammaglobulinemia with low levels of IgG2 and an absence of IgG4 was observed in one case (Plebani et al., 1996) and IgG2 deficiency in another (Matamoros et al., 2001).

Titration of antibodies in the sera of two TAP2-deficient patients showed them to have been infected by most common viruses: measles, mumps, herpes, cytomegalovirus, influenza, varicella, and EBV (Donato et al., 1995). Since these viral infections did not lead to an exaggerated pathology or require special care, the TAP-independent immune responses of these individuals must be to some extent efficient. This contrasts with the pathologies of herpes, cytomegalovirus, and EBV observed in patients lacking NK cells (Biron et al., 1989) or with diminished NK-cell activity (Caligiuri et al., 1987). The fact that TAP-deficient patients can have high titers of antibodies against measles, mumps, herpes, cytomegalovirus, or varicella suggests that antibodies are important in their defense against these viruses. High levels of antiviral antibodies have not, however, been reported in all patients. Moreover, the titers of antibodies against EBV, respiratory syncytial virus, and influenza were normal (Donato et al., 1995, and unpublished data), which would suggest that cell-mediated immune responses may be effective against viruses. In contrast, vaccinations failed to induce antibody responses to polysaccharides (Matamoros et al., 2001). Antibodies against herpes and EBV were detected in serum from one case of "conditional" HLA class I deficiency (unpublished observations).

BACTERICIDAL/PERMEABILITY INCREASING (BPI) PROTEIN-MEDIATED RESPONSES

BPI is a protein expressed by neutrophils and to lesser extent by eosinophils, epithelia, and fibroblasts (Schultz, 2007). This protein protects the organism from gram-negative bacteria through an antibiotic activity and through endotoxin detoxification. In a number of chronic bacterial infections, in particular in TAP-deficient patients with chronic bacterial colonization of the lung, anti-BPI antibodies develop (antineutrophil cytoplasmic autoantibodies, or ANCA). These antibodies neutralize the activity of BPI and may exacerbate the inflammation of the respiratory tract (Schultz et al., 2003).

T-LYMPHOCYTE SUBPOPULATIONS

Experiments in transgenic mice have shown that the positive selection of $CD8^+$ $\alpha\beta$ T cells is dependent on interaction of their T-cell receptors with HLA class I molecules expressed on thymic epithelial cells. Consequently, MHC class I-deficient mice have very low numbers of $CD8^+$ T cells. Most analyses of T-cell subpopulations in BLS type I patients have been limited to determination of the ratio of $CD8^+$ to $CD4^+$ T cells. This ratio frequently appears to lie within normal values (Maeda et al., 1985; Moins-Teisserenc et al., 1999; Plebani et al., 1996; Sugiyama et al., 1989; Teisserenc et al., 1997), although the absolute number of T cells decreased progressively in one case (Plebani et al., 1996). No data are available on T-cell subsets in the patients described by Payne et al. In the apparently similar case identified in our laboratory, the numbers of $CD4^+$ and $CD8^+$ $\alpha\beta$ T lymphocytes were normal (unpublished observations).

T-cell subpopulations have been analyzed in PBMCs from few TAP-deficient patients (de la Salle et al., 1994, 2002; Moins-Teisserenc et al., 1999). The ratio of $CD8^+$ to $CD4^+$ T cells may appear to be somewhat diminished as compared to that in normal individuals, while expansion $\gamma\delta$ T cells is noticed. In one patient who was considered at the time to be healthy, the ratio of $CD8^+$ cells among $\alpha\beta$ T cells in PBMCs was very low (4 percent) whereas the number of $\gamma\delta$ T cells was normal (8 percent of T cells). He also developed lung pathology, and during the progression of the disease, an expansion of $\alpha\beta$ $CD8^+$ (16 percent of $\alpha\beta$ T cells) and $\gamma\delta$ T cells was observed (14 percent of T cells), suggesting that these two subsets can be recruited in immune responses (de la Salle et al., 1994, and unpublished observations). An expansion of $\gamma\delta$ T cells has been observed in several but not all cases (de la Salle et al., 1999; Matamoros et al., 2001; Moins-Teisserenc et al., 1999). Thus, in type I BLS patients a large proportion of $CD8^+$ cells may correspond to HLA-unrestricted $\gamma\delta$ T cells; consequently, a relevant assessment and interpretation of $CD8^+$ T-cell frequencies and $CD8^+$ to $CD4^+$ cell ratios is possible only by analyzing exclusively $\alpha\beta$ T cells. On this basis, numbers of $CD8^+$ $\alpha\beta$ T cells appear to be generally decreased in these patients, although they sometimes remain within lower normal limits. Finally, the repertoire of $CD8^+$ $\alpha\beta$ T cells is oligoclonal and quite similar to that of $CD4^+$ cells (de la Salle et al., 1997). This suggests that the deficiency has only a weak influence on the $CD8^+$ T-cell repertoire.

NK LYMPHOCYTE SUBPOPULATIONS

The number of NK cells seems to stay within normal ranges in HLA class I-deficient patients, varying from lower to higher values, depending on the individual (de la Salle et al., 1994, 2002; Furukawa et al., 1999a; Matamoros et al., 2001; Moins-Teisserenc et al., 1999). A study of the phenotype of NK cells in two TAP2-deficient patients showed that these cells express the type III receptor for IgG (CD16) and the CD56 adhesion molecule. In addition, 40 to 50 percent of NK cells were found to express high levels of CD56, compared to less than 10 percent in normal subjects (Zimmer et al., 2007). In TAP^+ individuals, these cells have to be activated by IL-2 to become cytotoxic.

The cytolytic activity of NK cells is controlled by a balance of activating and inhibitory receptors (Moretta et al., 2000), the latter receptors blocking the cytolytic process when they interact with HLA class I molecules on the target cells. Resting TAP-deficient NK cells display a normally diverse repertoire of inhibitory receptors (Furukawa et al., 1999c; Zimmer et al., 1998). The levels of expression of these receptors are similar to those on normal cells, except for the NKG-2A/CD94 and ILT2 receptors, which were found to be overexpressed on NK cells but not on T cells in three cases (Matamoros et al., 2001; Zimmer et al., 1998, 2007). This overexpression of NKG-2A/CD94 was not found in another study (Furukawa et al., 1999b), while in the two patients from the first study, it seemed to decrease with age or improvement of the clinical status (unpublished observations). The inhibitory receptors

negatively regulate the cytolytic activity of TAP$^-$ NK cells and are therefore functional.

In a more recent study (Markel et al., 2004b), the repertoire of inhibitory receptors on NK clones derived from three patients from the same family was compared to that on NK clones from an unaffected sister. The number of clones expressing higher levels of inhibitory receptors was increased among TAP$^-$ clones. Interestingly, whereas TAP$^+$ NK cells rarely express the inhibitory carcinoembryonic antigen-related cell adhesion molecule 1 (CEA-CAM1), most of the TAP$^-$ clones expressed this molecule. This work showed that the repertoire of inhibitory receptors on the activated NK cells of these patients is unique.

The repertoire of most activating receptors is also normal on peripheral TAP$^-$ NK cells (Vitale et al., 2002). Thus, these cells express receptors involved in the killing of tumor cells (NKp30, 40, and 46) or virally infected cells (NKG2-D). On polyclonal NK cell lines derived from TAP-deficient patients, the repertoire of activating receptors nevertheless displayed some abnormality, since the expression of NKp80 was low on many cells. Moreover, the same abnormality is observed at a clonal level. Triggering of these receptors induced normal cytolytic responses, except for 2B4 and NKp80, which were found to be functional only on a limited number of NK clones. Hence, the deficiency appears to have an observable effect on a restricted spectrum of NK receptors and only in some cells.

An interesting feature of NK cells from patients with chronic inflammation is the expression of CCR2. Bronchoalveolar fluids contain relatively large amounts of CCR2 ligand MCP1 and IL-2, which can activate recruited NK cells (Hanna et al., 2005). These observations support the hypothesis of a role of activated NK cells in the pathology of TAP-deficient patients (Moins-Teisserenc et al., 1999; Zimmer et al., 1998).

CELL-MEDIATED IMMUNE RESPONSES

The cytotoxicity of TAP-deficient NK and T cells has been investigated in several patients. Although resting NK cells did not appear to kill the HLA class I-negative K562 cells classically used in NK cytotoxicity assays, they were able to mediate a weak antibody-dependent cytotoxicity. After activation in vitro with IL-2 or IL-12, these NK cells killed K562 cells but not other HLA class I-negative cells such as Daudi or 721.221 cells (Furukawa et al., 1999c). When TAP-deficient NK cells were stimulated with EBV B cells and IL-2, they proliferated and developed cytotoxicity against several target cells in the same manner as NK cells from normal donors, although with less efficiency. More importantly, these activated TAP-deficient NK cells were cytotoxic to autologous EBV B cells and skin fibroblasts. Cytokines, which increase HLA class I expression and consequently protect normal fibroblasts from lysis by control activated autologous NK cells, did not protect against TAP-deficient cells (Zimmer et al., 1999). Reactivity to autologous EBV B cells and fibroblasts is mediated by an NK-cell subset expressing high levels of NKp46 (Vitale et al., 2002). Thus, it would appear that in vivo the NK cells of TAP-deficient patients can be activated by cytokines released during antiviral responses, and that their activated NKp46 bright NK cells can be aggressive to the surrounding uninfected cells.

In contrast, activated TAP$^-$ NK cells do not kill autologous T-cell blasts, whereas fewer than 10 percent of TAP$^+$ NK cell clones are unable to kill TAP$^-$ T-cell blasts. This tolerance to autologous T cells in TAP-deficient patients could be mediated by an inhibitory receptor expressed by all TAP$^-$ NK cells, but by no more than a few TAP$^+$ NK cells (Vitale et al., 2002). Support for this hypothesis was provided by the demonstration that CEA-CAM1 is expressed by most chronically activated TAP$^-$ NK cells and inhibits the lysis of autologous PHA T-cell blasts through homotypic interaction (Markel et al., 2004b). However, TAP$^-$ CEA-CAM1-negative T cells were also unable to kill autologous T-cell blasts, which indicates that other still undiscovered mechanisms are involved in the tolerance of activated NK cells to autologous T-cell blasts in these patients (Markel et al., 2004b, and unpublished observations).

Autoreactive $\gamma\delta$ T cells have also been described in TAP-deficient patients. Interestingly, biopsies of skin lesions revealed the presence of foci of activated NK cells and $\gamma\delta$ T cells in the dermis, suggesting a role of these cells in the development of skin lesions (Moins-Teisserenc et al., 1999).

TAP-independent anti-EBV $\alpha\beta$ T-cell responses have been demonstrated in two cases of TAP deficiency. In one study, a cytotoxic CD8$^+$ $\alpha\beta$ T-cell clone was characterized that recognized a peptide of latent membrane protein 2 (LMP2) presented by HLA-B molecules (de la Salle et al., 1997). The LMP2 antigen was also found to be presented by HLA-A2 on TAP-deficient cell lines (Lee et al., 1996). In other work, an anti-EBV T-cell clone recognizing the EBV transcription factor BMFR1 presented by HLA-B7 was isolated from another TAP-deficient patient (de la Salle et al., 2002). Therefore, CD8$^+$ $\alpha\beta$ T cells can contribute to immune responses against viruses in TAP-deficient patients through recognition of TAP-independent antigens presented by classical HLA class I molecules.

A MODEL FOR THE PATHOLOGY

At first glance, the absence of susceptibility to viruses and the predominance of pulmonary bacterial infections in TAP-deficient patients may appear surprising. Our analysis nevertheless demonstrates that cytotoxic CD8$^+$ $\alpha\beta$ T cells recognizing TAP-independent viral antigens can be stimulated in vivo and suggests that activated NK cells may also play a role in immune defense. These cell-mediated cytotoxic responses are less efficient than in normal individuals because (1) TAP-independent antigens are rarer and (2) activated TAP$^-$ NK cells are less cytotoxic than those from normal subjects. Although a higher production of antibodies may partly compensate for these weaker cell-mediated responses, the overall immune response is unlikely to be sufficient. Consequently, TAP deficiency should lead to a delayed clearance of viral infections, as observed in β2m-deficient animals (Raulet, 1994).

Several viruses, including respiratory syncytial virus, are known to induce synthesis of IL-8, a chemoattractant for neutrophils and for a subpopulation of T lymphocytes. Since the lungs are probably more subject to viral infections than other tissues, these organs would be attacked (1) by the viruses,

which are inefficiently cleared, and (2) by proteolytic enzymes released from neutrophils present in large numbers due to the sustained production of IL-8. In addition, the presence of MCP1 and IL-2 have been documented in the bronchoalveolar fluids of TAP-deficient patients with chronic inflammation (Hanna et al., 2005). Whether activated NK cells, and also cytotoxic $CD8^+$ αβ or γδ T cells, further kill uninfected HLA class I-deficient autologous lung cells, if no inhibiting receptors are engaged, remains to be clarified. On the other hand, expression of CEA-CAM1 counter-receptor, CEA1, on epithelial and endothelial cells (Obrink, 1997) might provide protection against activated CEA-CAM1$^+$ NK cells. If this pathway does exist, it could be antagonized by bacteria such as *H. influenzae*, which express CEA-CAM1 ligands (Virji, 2001). It should be noted that the concentration of soluble CEA-CAM1 in the blood of TAP-deficient patients is abnormally low (Markel et al., 2004a), which suggests that it is consumed in these chronically infected individuals.

Poor control of inflammatory cytotoxic responses may lead to destruction of ciliary cells and fibrosis of the lungs, with the result that bacteria and/or bacterial endotoxins are inefficiently eliminated, thereby increasing the chemotaxis of neutrophils and maintaining a state of chronic inflammation in the lungs. It has been shown that cystic fibrosis patients display inflammation of the lungs with an associated increased neutrophil count within the first weeks of life, several years before the appearance of pulmonary insufficiency (Khan et al., 1995). Similarly, the progressive degradation of lung tissues in TAP-deficient patients is probably mediated by neutrophils and may begin long before any observable pathology. As mentioned above, chronic bacterial colonization of the lungs can lead to the development of ANCA, which may exacerbate the pathology (Schultz, 2007).

One poorly understood aspect of the pathology is the development of skin lesions at any age and only in some patients. No pathogens could be detected in these lesions (Gadola et al., 2000). The activated NK and γδ T cells present in inflamed tissues, which kill autologous cells in TAP-deficient patients, may be involved, and histological studies support this hypothesis (Moins-Teisserenc et al., 1999).

STRATEGIES FOR DIAGNOSIS

Until recently, HLA class I deficiency was diagnosed by serological HLA typing. This technique is now rarely used and has been replaced by molecular typing, which, in this case, is partially informative. Thus, if molecular typing shows that the patient is HLA homozygous, this will be a strong indication that the defect is linked to HLA and might therefore be a tapasin or TAP deficiency. HLA typing is particularly relevant in the case of consanguineous families. However, although the situation has not yet been encountered, an absence of HLA homozygosity does not formally eliminate such a deficiency. In fact, an HLA homozygous TAP deficiency in a context of unrelated parents has been described (Parissiadis et al., 2005).

Flow cytometric analysis of PBMCs labeled with the anti-class I monomorphic monoclonal antibody W6/32 is a rapid and convenient way to confirm a suspicion of HLA class I deficiency. This test should also be carried out on PBMCs from other members of the family (parents and first-degree relatives). In this context, infection of a cell line derived from the patient with a recombinant vaccinia virus expressing TAP1, TAP2, or both subunits (Russ et al., 1995), followed by flow cytometry of cells stained with W6/32, will determine whether the deficiency results from a TAP defect and if so, which TAP gene is mutated. Somatic complementation, by fusing EBV B cells or T-cell blasts, from the patient with control $TAP1^-$- and $TAP2^-$-deficient lymphoblastoid cell lines also allows reliable identification of the deficiency (Markel et al., 2004b). The defect will then be characterized by RT-PCR analysis, followed by direct sequencing.

TREATMENT AND PROGNOSIS

Bronchiectasis and bacterial colonization of the respiratory tract lead to chronic respiratory failure and a profound reduction in life expectancy. As in cystic fibrosis and other inherited dysfunctions of the respiratory mucosa, the evolution of bronchiectasis is closely linked to the bacterial charge. Since no specific therapy can yet be proposed for HLA class I-deficient patients, the only way to limit the inflammatory process and hence the neutrophil-mediated lung damage is to aggressively treat and, if possible, prevent the episodes of bronchial infection. When the diagnosis is made in infancy, for instance, in the case of early detection in the family of a known patient, nurseries and other infant communities should be avoided to reduce the risk of early viral contamination. Immunizations against measles, pertussis, and influenza must be carefully controlled, and exposure to tobacco smoke in the home environment should be prohibited. Bacteriological examination of the sputum is mandatory to provide guidelines for antimicrobial therapy. *H. influenzae* and *S. pneumoniae* strains, which are commonly found in repeated sputum tests from such patients, can be treated with oral antibiotics (β-lactams with penicillinase inhibitors, macrolides), while intravenous treatment is advised in the event of a major bacterial inoculum (bronchorrhea). Some other types of gram-negative bacilli such as enterobacteria and nonmucoid *P. aeruginosa* strains may also be found in sputum and require intravenous administration of third-generation β-cephalosporins and aminoglycosides. Low doses of erythromycin were reported to improve and stabilize chronic inflammation of the respiratory tract in a patient treated for 19 years (Azuma et al., 2001; Furukawa et al., 2000). This antibiotic is also an inhibitor of neutrophil functions and is used in the treatment of diffuse panbronchiolitis in Far Eastern countries, which supports the hypothesis that the lung disease of TAP-deficient patients is mediated by neutrophils.

A long-term policy for antimicrobial therapy is difficult to define, as the bronchial colonization does not immediately endanger the survival of these HLA class I-deficient individuals. However, continuous or alternate use of oral antibiotics becomes necessary when bronchiectasis develops. Regular intravenous administration of high-dose antibiotics increases the patients' level of comfort and probably slows their progressive functional impairment.

Pulmonary function tests, which should be performed at regular intervals, will initially show bronchial obstruction unresponsive to inhaled bronchodilators. Inhaled corticosteroids have been tried at this stage, but without clear clinical benefit. Overdistention of the chest and chronic respiratory failure occur secondarily and lead to end-stage disease.

CT scans and 99m-Technetium pulmonary scintigraphies are useful tools for assessment of bronchiectasis. If localized lesions are suspected, preoperative bronchography and surgical lobectomy should be considered, although to our knowledge no HLA class I-deficient patient has to date undergone thoracic surgery. Since the mucosal injuries of type I BLS also involve the upper airways, nasal endoscopy and sinus CT scans can be proposed in the case of suspected sinusitis with nasosinusal polyps. The treatment of such lesions is surgical (polypectomy, ethmoidectomy) or medical (local washing, high-dose topical corticosteroids), or requires both types of intervention. Surgical treatment of chronic sinusitis was reported to accelerate the nasal disease in one case (Gadola et al., 2000) but not in another (Azuma et al., 2001). Chronic otitis media must be carefully checked on regular audiograms and tympanograms. Surgical operations should be performed only under high doses of intravenous antibiotics, and placement of tympanostomy tubes necessitates prolonged antibiotic therapy to avoid middle ear suppuration.

The skin ulcers and granulomas are difficult to cure and have dramatic, even tragic incidences on the life comfort and the sociability, especially in the cases of facial injuries. Trials with IFN-α or IFN-γ made the lesions worse, while skin grafting was followed by the reappearance of lesions at the same sites (Willemsen et al., 1995). Only basic antiseptic care can be recommended (Gadola et al., 2000), but relapse occurs fairly regularly.

One unexplained question is why some patients are moderately affected whereas others are severely ill. In two different families living in nearby areas, the patients had the same homozygous HLA haplotype (de la Salle et al., 2002; Markel et al., 2004b) and the same mutation (O. Mandelboim, personal communication). Nevertheless, in one family the two TAP-deficient adults had an excellent health status, while in the other family four children experienced severe lung lesions. Hence, environmental factors or polygenic traits must influence the clinical course of these patients.

Concerning the two patients followed in Strasbourg, their deficiency was diagnosed when they were 8 and 12. At this time the bacterial charge was of major concern for the eldest, requiring continuous oral antibiotics and intravenous treatment during infectious exacerbations. This policy did not induce any bacterial resistance and stabilized the bronchiectasis. The bronchorrhea gradually disappeared and antibiotics were withdrawn at the age of 20 with no further functional impairment, as is the usual pattern in bronchiectasis caused by non-cystic fibrosis. The younger patient has experienced a similar clinical course.

Bone marrow graft was attempted once in a patient with chronic skin ulcers, followed by clinical improvements (Khakoo et al., 2008). Nevertheless, since then, no definitive report has been published, questioning whether this therapy is appropriate.

ANIMAL MODELS

MHC class I-deficient transgenic mice have been generated by disrupting the genes encoding β2m (Koller et al., 1990; Zijlstra et al., 1990), the TAP1 subunit (Van Kaer et al., 1992), or tapasin (Grandea et al., 2000). The findings obtained with the first two models are discussed in detail in three reviews (Hoglund et al., 1997; Ljunggren et al., 1996; Raulet, 1994). These two deficient strains express low levels of MHC class I molecules on the plasma membranes and have very low absolute numbers of $CD8^+$ αβ T cells. In β2m-deficient mice, $CD8^+$ αβ T cells can reject allogeneic tumor cells and syngeneic tumor cells expressing minor antigens (Apasov and Sitkovsky, 1994). The mice can fight viral infections, but with lower efficiency than normal animals. Thus, attenuated influenza viruses are cleared more slowly and virulent strains inflict a higher rate of mortality, while β2m-deficient mice cannot eliminate Theiler's virus, although they survive early infection. The mechanisms of resistance to these and other viruses, such as Sendai virus, rotavirus, reovirus, and herpes simplex virus, appear to involve $CD4^+$ T cells and antibody production. The development of $CD8^+$ αβ T in TAP-deficient mice is impaired, but not as severely as in β2m-deficient mice (Ljunggren et al., 1996). In these animals, HSV glycoprotein B cytotoxic T cells specific to TAP-independent antigens were induced by immunization with a recombinant vaccinia virus or naked DNA, but not following HSV infection (Paliard et al., 2001). TAP-deficient animals were more susceptible to infection by the intracellular pathogen *Mycobacterium tuberculosis* (Behar et al., 1999), whereas they were not particularly susceptible to tumor formation (Johnsen et al., 2001).

The NK cells of β2m-deficient mice displayed reduced cytotoxicity but could be activated in vivo by viral infection (Su et al., 1994; Tay et al., 1995). The NK cells of these animals, like those of β2m-deficient mice, displayed reduced activity (Ljunggren et al., 1994). A study of MHC class I-deficient animals strongly suggested that their resting NK cells are self-tolerant due to reduced stimulation of inhibitory receptors (Joncker and Raulet, 2008).

FUTURE DIRECTIONS

Most known HLA class I deficiencies result from a defect in one of the two TAP subunits. HLA class I deficiency should be systematically investigated in cases of unexplained chronic inflammation of the respiratory tract leading to the development of nasal polyps, granulomatous lesions of the midface or legs, or bronchiectasis or chronic bacterial infection of the lungs, notably with *H. influenzae*. On the other hand, the fact that TAP-deficient adults can be healthy for decades indicates that TAP deficiency could come to the fore in atypical situations. It should be emphasized that in the course of our laboratory work, the first profiles of TAP-deficient patients (chronic inflammation of the respiratory tract, absence of phenotype, ocular toxoplasmosis) were identified after HLA typing had been requested on the basis of an inappropriate rationale. In the absence of clinical data on "conditional" HLA class I

deficiencies, the discovery of such defects is at present incidental. It will be necessary to collect data on the health status of these individuals and to elucidate the genetic defect(s) responsible for their deficiency.

The process of lung tissue degradation in HLA class I deficiency is likewise not yet fully understood, and efficient methods of treating the lung disease need to be developed, for example by testing drugs modulating neutrophil activity. The etiology of the skin lesions also requires investigation. The apparent absence of pathogens in the lesions needs to be reassessed, since over the past few years, thanks to the development of high-throughput sequencing techniques, several "new" viruses have been discovered. Effective care of the skin lesions remains a fundamental problem. Progress may result from the discovery of drugs targeting granuloma formation or survival. Interestingly, the lesions of one patient transiently regressed when she was pregnant (Furukawa et al., 2000), as has often been observed for other clinical manifestations of autoimmune diseases. This regression suggests that favorable anti-inflammatory responses are induced during pregnancy. Finally, the influence of HLA class I deficiency on the production of antibacterial antibodies requires clarification.

At a more fundamental level, as suggested by our own studies of anti-EBV T-cell responses in TAP-deficient patients, analysis of the antiviral responses mediated by $CD8^+$ $\alpha\beta$ T cells in these individuals might lead to the identification of a large number of viral proteins presented in a TAP-independent manner. Such observations could provide insight into the molecular bases and physiological relevance of these TAP-independent presentation pathways.

RETICULAR DYSGENESIS

Wilhelm Friedrich, Manfred Hoenig, Ulrich Pannicke, and Klaus Schwarz

HISTORY

Severe combined immunodeficiency (SCID) in association with congenital aleukocytosis was initially reported in 1959 by De Vaal and Seynhaeve in monozygotic prematurely born male twins who were noted at birth to completely lack white blood cells (WBC) (de Vaal and Seynhaeve, 1959). Histomorphologic findings in these infants, who both died as neonates from septic complications, revealed abnormalities consistent with SCID, with lack of lymphoid cells in lymphoid organs and with thymic dysplasia. In addition, bone marrow contained no myeloid cells and no lymphoid cells, while erythroid development was normal and megakaryocytes were present. The authors chose the term "reticular dysgenesis" (RD) based on the assumption that the disorder resulted from a defect of primitive multipotent "reticular" cells selectively failing to develop into myeloid and lymphoid precursor cells. Subsequently other cases with similar findings were reported, except that in some, WBCs were not completely absent and in the marrow, immature myeloid cells up to the promyelocyte stage were present (Alonso et al., 1972; Espanol et al., 1997; Gitlin et al., 1964; Haas et al., 1977; Ownby et al., 1976). An informative case study was published by Roper et al. using extensive cell-surface marker staining of marrow cells to dissect the various maturation stages (Roper et al., 1985). The authors found cells of all maturational stages of both lymphoid and myeloid development in the marrow, with a predominance of immature cells and almost complete depletion of myeloid cells beyond the promyelocyte stage, respectively of B cells beyond the pre-B-cell stage. Interestingly, also a substantial proportion of mature OKT3-positive T cells were observed in the marrow. These findings suggested to the authors that the defect in RD is an undefined abnormality interfering with late lymphoid and myeloid cell differentiation rather than an early stem-cell defect as proposed in the original description of the disorder. In 1983 the first successful treatment of a patient with RD by bone marrow transplantation (BMT) was reported, providing evidence that the disease is manifested within the stem cells and its progeny rather than in bone marrow microenvironmental elements (Levinsky and Tiedeman, 1983). It was also observed that in contrast to patients with other forms of inherited congenital neutropenias, treatment with G-CSF in RD was without any effect on granulopoiesis (Bujan et al., 1993). More recently, when more patients became evaluable after successful transplantation, primary sensorineural deafness was recognized as another hallmark of the disorder (Small et al., 1999). Very recently two groups independently described the molecular basis of the disorder to be a deficiency of adenylate kinase 2 (Lagresle-Peyrou et al., 2009; Pannicke et al., 2009).

CLINICAL AND LABORATORY PRESENTATION

There are a number of unusual clinical aspects that set patients with RD apart from patients with other forms of SCID (Table 18.1). Almost without exception patients come to medical attention during the neonatal period because of suspected neonatal infection and sepsis, findings of immaturity, or a combination of both. There is a high incidence of low birth weight, commonly due to both prematurity and intrauterine growth retardation, as based on a review of available data in 16 RD patients. Birth weights were below 2,500 g in 13 cases and even below 1,500 g in 5 cases. This is rather distinct from patients with other SCID variants, who are usually delivered at term and appear healthy without evidence of intrauterine growth retardation. Significant hepatomegaly

Table 18.1 **CLINICAL AND LABORATORY ABNORMALITIES IN RETICULAR DYSGENESIS DISTINCT FROM OTHER VARIANTS OF SEVERE COMBINED IMMUNODEFICIENCY**

- Low birth weight secondary to prematurity and/or intrauterine growth retardation
- Infectious complication during the neonatal period with high fatality rate
- Profound blood leukopenia and agranulocytosis
- Red cells normal/decreased
- Thrombocytes normal/decreased
- Marrow cellularity normal/decreased
- Maturation arrest of myeloid cells in bone marrow

and/or splenomegaly was noted in three cases, due in one case to cholestatic liver disease, in the others of unknown etiology. Abdominal symptoms secondary to intestinal stenosis were observed in two other cases requiring surgical intervention. In all patients surviving after transplantation, bilateral sensorineural deafness became evident (Small et al., 1999). Hearing assessment by brain stem-evoked response audiometry, applicable already in the small infant, has been useful to confirm the diagnosis of RD (Reubsaet et al., 2007).

Profound leukocytopenia and agranulocytosis represent the leading laboratory findings in RD. Automated WBC counting occasionally indicates a falsely higher leukocyte count when substantial numbers of nucleated red cell precursors are transiently present in the circulation. An analysis of hematological findings in 14 recently reported cases where the diagnosis of RD was confirmed by molecular analysis defines the range of hematological abnormalities in RD. WBC numbers have ranged from less than 100/uL to 1,600/uL (mean 630/uL). Granulocytes most commonly were completely absent, only exceptionally reaching at maximum 150/uL; monocytes were usually detected, mostly in lower-than-normal numbers. Of note, eight patients had neonatal anemia, with hemoglobin at birth as low as 3.7 g/dL and 5.4 g/dL, and in the others between 8 and 12 g/dL (normal 13.5 to 19 g/dL). Five patients showed marked thrombocytopenia, with platelet numbers below 50,000/uL in three cases in association with marked anemia. There was no apparent correlation of these hematological deficiencies with septic complications. Characterization of lymphocytes by surface marker analysis can reveal the presence of low numbers of CD3-positive T cells. In one study, six of six analyzed patients with RD were found to have very low numbers of T cells; in each case, these cells were noted to originate from an intrauterine maternofetal transfusion (Müller et al., 2001). This phenomenon of maternal T-cell engraftment is also found in other SCID patients but appears to be rather common in RD. In three of the six patients with maternal T cells, this engraftment was clinically inapparent, while three patients had manifestations of histologically proven graft-versus-host disease, involving in two cases the skin with mild transitory rashes and in one the liver with severe cholestatic liver disease at birth.

Examination of bone marrow aspirates and biopsies is helpful to confirm the diagnosis of RD; however, obtaining representative marrow samples in newborns, in particular in premature ones, may be difficult technically, and as a consequence adequate morphological assessment not always feasible. If available, the most prominent abnormality is the complete absence of mature myeloid cells. The marrow usually is normocellular and is dominated by immature myeloid cells up to the promyelocyte stage, with normally developing erythroid cells and with the presence of megakaryocytes. A representative marrow morphology is depicted in Figure 18.1.

MOLECULAR BIOLOGY OF RD

The defective gene in reticular dysgenesis, *adenylate kinase 2 (AK2)*, was discovered by homozygosity mapping and candidate gene sequencing (Lagresle-Peyrou et al., 2009; Pannicke et al., 2009).

The phylogenetically highly conserved *AK2* gene is located on chromosome 1p35.1 and encompasses about 24 kb. Two alternatively spliced mRNAs (isoform A and isoform B) are ubiquitously expressed (except for erythrocytes), albeit differing in relative expression. Surprisingly, AK2 protein was detected in the lumen of the capillaries and terminal blood vessels of the cochlear stria vascularis region in postnatal day 7 mice but not at birth, suggesting that AK2 may function as an ecto-enzyme (Lagresle-Peyrou et al., 2009). Isoform A encodes a protein of 239 amino acid length, while isoform B encodes 232 amino acids. Both isoforms differ only in a few residues at the C-terminal end.

AK2 is a nucleus encoded mitochondrial protein and is located in the intermembrane space of mitochondria. AK2 catalyses the reaction AMP + ATP $\leftrightarrow$ 2ADP. The ADP is transported into the mitochondrial matrix and serves as the phosphate acceptor of complex V of the electron transport chain during oxidative phosphorylation.

AK2 has an ATP and NMP binding domain as well as a LID domain. The extensive movement of its domains during catalysis has made AK2 a model for molecular dynamic studies (Schlauderer et al., 1996).

In addition, AK2 has been implicated in a novel apoptotic pathway through formation of a complex with FADD and caspase-10 (Lee et al., 2007).

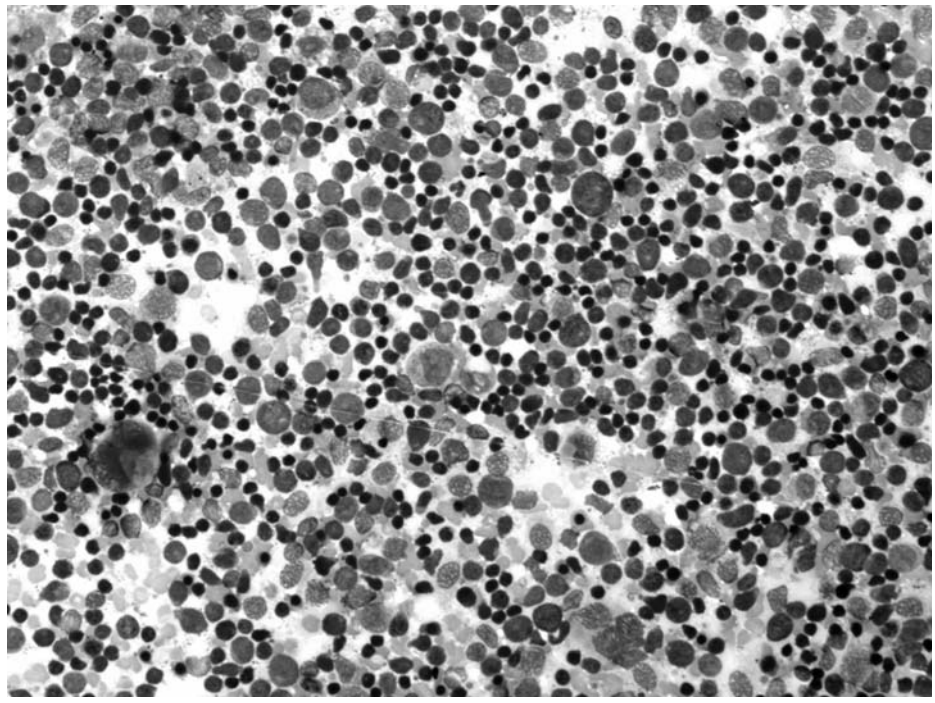

Figure 18.1 Representative bone marrow aspirate of a patient with reticular dysgenesis (May Grunwald/Giemsa staining, Olympus, ×1,000). (See Color Plate.)

MUTATION ANALYSIS OF RD PATIENTS

Pedigree analyses have confirmed that AK2 deficiency is an autosomal recessive genetic syndrome and affected children have failed to inherit normal alleles of the *AK2* gene. The genetic alterations are summarized in Table 18.2. The mutations are distributed over the complete gene. The spectrum of mutations includes small and large deletions, splice-site mutations, and missense as well as nonsense mutations. The majority of mutations are homozygously inherited in accordance with the consanguinity of the families. Each family bears its private mutation(s), excluding a founder effect. The mutations did not show any influence on AK2 steady-state RNA levels (Lagresle-Peyrou et al., 2009; Pannicke et al., 2009).

When tested, all of the identified mutations severely decrease the stability of the protein. The missense mutant p.Asp165Gly is expressed only in low levels (~10 percent) in an EBV line but not in fibroblasts of the patient, the missense mutant p.Arg103Trp shows residual expression (~10 percent) in fibroblasts, and all other mutants are null mutations.

One individual with all the clinical and cellular characteristics of RD exhibited no *AK2* mutations, suggesting that RD may be caused by genocopies (Pannicke et al., 2009).

The molecular pathophysiology of the AK2 deficiency is not clear at present either for the loss of leukocytes or for the sensorineuronal deafness. Nontransformed primary dermal fibroblasts of patients exhibit a higher propensity for apoptosis with increased reactive-oxygen levels and a lower mitochondrial membrane potential (Pannicke et al., 2009).

ANIMAL MODELS OF AK2 DEFICIENCY

In zebrafish, one of the human mutations (F3, Table 18.2) was mimicked by designing a splice-site morpholino. This led to aberrant splicing of the zebrafish *ak2* gene predicted to result in the translation of a nonfunctional protein. Interference with Ak2 function did not affect the overall development of embryos; likewise, neither immature hematopoietic cells nor erythropoiesis, as evidenced by the presence of circulating red blood cells, were affected in morphants. In contrast, developing lymphocytes (best revealed by the appearance of T cells in the thymus anlage) were absent in the Ak2 morphants. This indicates that the phenotype has a high degree of specificity and that Ak2 has an evolutionarily conserved function in leukocyte development (Pannicke et al., 2009).

The effects of an *Ak2* gene knockout on the phenotype of Ak2 mutants were examined using P-element technology in drosophila (Fujisawa et al., 2009). Although homozygous Ak2 mutated embryos developed without any visible defects, their growth ceased and they died before reaching the third instar larval stage. Maternally provided AK2 mRNA was detected in fertilized eggs, and weak AK2 activity was observed in first and second instar larvae of the homozygous AK2 mutants, suggesting that maternally provided AK2 is sufficient for embryonic development. Disappearance of AK2 activity during larval stages resulted in growth arrest and eventual death. Final conclusions regarding the distinct phenotypes of the diverse animal models and humans awaits more sophisticated modeling in mice, most using conditional alleles.

TREATMENT

Since the first report in 1983 of successful treatment of RD by hematopoietic stem cell transplantation (HSCT) (Levinsky and Tiedman, 1983), this therapy has been explored in a number of patients (Antoine et al., 2003; Bertrand et al., 2002; de Santes et al., 1996; Friedrich et al., 1985; Heltzer et al., 2007; Reubsaet et al., 2007). Because of the rare availability of HLA-identical siblings as donors, most patients were transplanted from HLA-haploidentical family donors or from HLA-matched unrelated donors. In the initial report, the donor was an HLA-identical sibling and the patient had received no preparative conditioning prior to transplantation. After transplantation significant graft-versus-host disease developed, complicated by marrow failure, but subsequently normal hematological and immunological functions developed, with evidence that all blood cells were of donor origin. Contrasting to this experience, it became evident that patients with RD undergoing transplantation in the absence of myeloablative conditioning are prone to fail reconstitution of myeloid functions, with persistence of agranulocytosis, presumably because colonization by donor stem cells requires prior depletion of stem-cell niches in the marrow. Although the need for myeloablative conditioning adds to its risks, HSCT needs to be implemented in RD patients as soon as possible because of the extremely high risk of the rapid development of fatal infectious complications. Meanwhile, a number of patients are long-term survivors, clearly attesting to the potential of this therapy to permanently reconstitute a normal blood cell and immune system and to cure the disorder (Antoine et al., 2003; Heltzer et al., 2007).

CD8 DEFICIENCY

Teresa Español and Esther Mancebo

CD8 serves as a co-receptor for T-cell receptor (TCR) recognition of MHC class I-associated peptides (Gao et al., 2000; Zamoyska et al., 1998), which in turn leads to cytotoxic αβ T lymphocyte (CTL) activation and lysis of the target cell. This mechanism enables CTLs to recognize and eliminate infected cells, tumor cells, and allogeneic cells. TCR complex signaling activates CD8 adhesion molecule function, resulting in a CD8 interaction with MHC-I that is sufficient to maintain firm T-cell adhesion (Varghese et al., 2008). The kinetics of CD8 and MHC interaction at the cell membrane has been measured (Huang et al., 2007), and crystal structure studies have defined the binding mode of CD8αβ to MHC-I (Shore et al., 2008).

CD8 molecules are expressed on the cell surface as either αα homodimers or αβ heterodimers. Surface expression of CD8β is dependent on expression of CD8α, as CD8β polypeptides in the absence of CD8α are retained in the endoplasmic reticulum and degraded. Both chains (α and β) are composed of a single extracellular immunoglobulin-like domain, a membrane-proximal hinge region, a transmembrane domain, and a cytoplasmic tail. CD8 associates with β_2m and the α2 and α3 domains of MHC class Ia molecules. This association increases the adhesion/avidity of the TCR to its class I target, and in addition, CD8 associates with the *scr* tyrosine protein kinase $p56^{lck}$, leading to rapid activation of the cytotoxic T lymphocyte via internal signaling events (Chapupny et al., 1998). Expression of CD8 is characteristic of CTLs and is critical for their progression through the process of positive selection during differentiation in the thymus (Zamoyska et al., 1998).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Only two unrelated familial cases with CD8 deficiency are described in the literature; both families are consanguineous and of Spanish Gypsy origin. The main clinical manifestations are recurrent infections of the respiratory tract. The first case reported (de la Calle et al., 2001) was a 25-year-old man admitted with respiratory distress, weight loss, and general malaise. He had suffered repeated bouts of bronchitis and otitis media from childhood. Chest X-ray and CT scan revealed disseminated bronchiectases. Sputum culture was positive for *Haemophilus influenzae*. Functional respiratory tests revealed severe mixed ventilatory disturbance. His clinical status improved after intravenous antibiotic therapy. He required further admissions because of respiratory reinfections of his extensive bronchiectases (*Pseudomonas aeruginosa* was detected in sputum on several occasions). By age 33, his ventilatory function had deteriorated to the point where he became wheelchair-bound and dependent on oxygen. The patient died before being able to undergo lung transplantation. This patient was the fourth of nine siblings of first-cousin parents. The remaining family members, including two sisters with CD8 deficiency (Fig. 19.1), do not have clinical disease.

The second case reported (Mancebo et al., 2008) was an 18-year-old woman, the first of three siblings of second-cousin parents. She suffered from recurrent respiratory infections starting at 1 month of age, including bronchiolitis, pneumonia, and otitis. On separate occasions, serologies were positive for RSV and parainfluenza 3 viruses. She required repeated hospitalizations. At the age of 4 years, she was diagnosed with asthma, otitis, sinusitis, and lung atelectasis. At 7 years

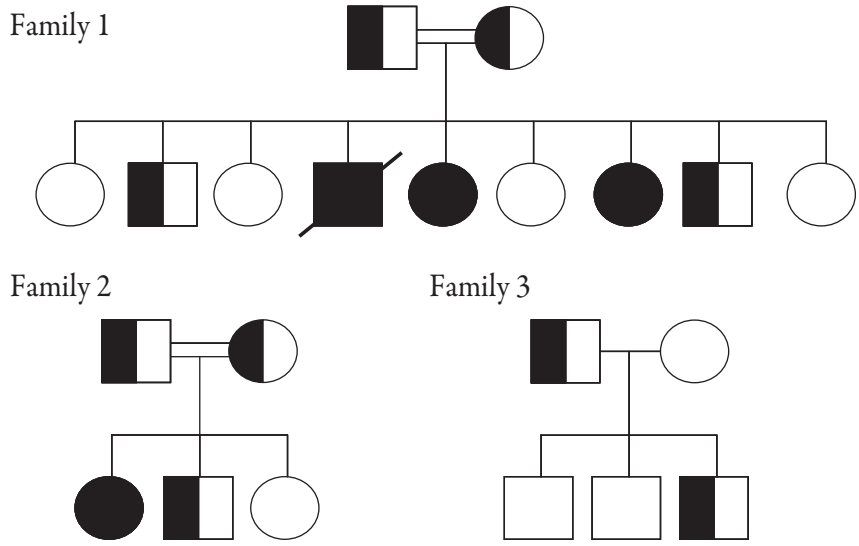

Figure 19.1 Pedigrees of families 1, 2, and 3.

of age, the patient was referred to an endocrinologist for failure to thrive. She had received all routine vaccinations, tests for allergy were negative, and serum immunoglobulin levels were normal. Although her infections resolved with antibiotic treatment, at 15 years of age she suffered two episodes of pneumonia together with several respiratory infections, with high temperature and productive cough.

LABORATORY FINDINGS

The main laboratory findings are shown in Table 19.1.

Total IgG and IgG subclasses were normal. Serologies were positive for tetanus, toxoplasma, *Mycoplasma pneumoniae*, CMV, herpes zoster, herpes simplex, and rubella in patient 1 and for CMV, EBV, and rubella in patient 2. Serologies were negative for HIV, EBV, *Legionella pneumophila*, aspergillus, and brucella in patient 1 and for HIV, hepatitis (A, B and C), syphilis, and toxoplasma in patient 2. Autoantibodies were negative in both patients.

Lymphocyte proliferation and subpopulations were normal in both patients, except that CD8 surface expression was not detected on either $CD3^+$ or $CD3^-$ cells (Table 19.1). Double-negative (DN) T cells ($TCR\alpha\beta$ + $CD4^-$ $CD8^-$) were increased (16 percent in patient 1 and 10 percent in patient 2; reference range = 0.1 to 2 percent). The predominant immunophenotype found in these α/β DN T cells of patient 1 was $CD3^{hi}$ $CD5^+$ $CD2^+$ $CD45RA^+$ $CD57^+$ $CD11b^+$ $CD28^-$, with a large Vβ repertoire. A more extended study in patient 2 and in a CD8-deficient sister of patient 1 revealed that DN T cells exhibit mostly an effector-memory or effector phenotype, respectively, whereas naïve T cells are underrepresented. Although, DN T cells from both patients show low TRECs levels and a skewed Vβ repertoire (Bernardo et al., 2011).

Upon stimulation, the DN T cells of the sister of patient 1 were positive for intracellular interferon-γ (IFN-γ), but not for interleukin (IL)-2 or IL-4. The percentage of TCR γδ T cells was normal, and weak CD8β expression was detected by Western blot in peripheral blood mononuclear cells (PBMCs); however, CD8β membrane expression was absent.

FAMILY STUDIES

Whole blood samples from the patients and their relatives were stained with an extensive panel of anti-CD8α monoclonal antibodies. Two asymptomatic younger sisters of patient 1 also lacked surface $CD8^+$ (α or β) expression and showed weak intracellular CD8β and high numbers of DN αβ T cells (10 percent and 4 percent, respectively). Mean fluorescence intensity of CD8α expression on cell surface and soluble CD8 (by ELISA test) were decreased in the parents and two brothers (II-2 and II-8) of patient 1 and in the parents and one brother (II-2) of patient 2 (all heterozygous carriers of the mutation, see below). These results indicated a good phenotype–genotype correlation.

MOLECULAR BASIS

Both patients shared a homozygous autosomal recessive missense mutation (c.331G>A) in exon 2 of the *CD8A* gene. This mutation predicts the substitution of a glycine by a serine at codon 111 (p.Gly111Ser) of the CD8α protein. Wild-type and mutated CD8, as well as chimeric CD8 molecules (CD8 MUT/WT and WT/MUT), were expressed after transfection by an expression vector (de la Calle-Martin et al., 2001), demonstrating that the presence of serine or another amino acid at position 111 precluded CD8 expression, thereby suggesting that the evolutionarily conserved glycine at this position may be important for appropriate folding of the protein. However, the lack of CD8 surface expression did not prevent development of a peripheral DN T-cell lineage with functional features resembling $CD8^+$ T cells, such as IFN-γ synthesis. Similar results have been reported in mice (Goldrath et al., 1997).

Table 19.1 Immunological Profile of CD8-Deficient Patients

	PATIENT 1	PATIENT 2
Age at diagnosis (y)	25	16
Sex	M	F
Present status	Died	Respiratory infections

Tetanus toxoid	Normal	-
Allogenic cells	Normal	-
NK cell function: (K562 cell lysis)	Normal	-

FUNCTIONAL ASPECTS

CD8 deficiency is compatible with life and results in a less aggressive primary immunodeficiency than deficiency of HLA class I. We believe that the absence of classical $CD8^+$ CTL may be partially compensated for by the presence of αβ DN T cells in our patients, and by the cytolytic function of NK cells (Brown et al., 2001). In vitro, at high effector–target ratios, the cytotoxic capacity of patient DN T cells was similar to control CTLs. However, at low ratios, the cytotoxicity was significantly diminished in patients, which suggests that, in limiting conditions, cytotoxicity is less efficient in the absence of CD8 . A fraction of the $CD3^+CD4^-$ T cells from the patients were found to be positive for CMV-pentamer staining. These results show that CMV specific T cells could be generated in the absence of CD8, although in a lower grade compared with healthy individuals (Bernardo et al, 2011). Also, DN T cells present a phenotype associated with effector and memory effector cytotoxic cells. The high antibody titers to many viral infections in patients demonstrated that they had been in contact with these viruses and were immunocompetent enough to overcome these infections. Although the last infections in patient 1 were bacterial, viral infections suffered at an early age might have been responsible for the bronchial lesions that later became superinfected, as has been reported in TAP-deficient adult patients (de la Salle et al., 1999).

MUTATION ANALYSIS

Messenger RNAs for CD8α and β were detected by RT-PCR at similar levels in the CD8-negative individuals, their relatives, and normal controls. Genetic studies of CD8α were conducted in view of the above-mentioned results. For mutational analysis of patient 1, primers were chosen to generate a product covering the entire coding region and the 5′ and 3′ UTRs for CD8α by RT-PCR. PCR products were subcloned and sequenced. For patient 2, primers were designed to amplify and sequence the six *CD8A* exons surrounding genomic sequences. These analyses revealed a G-to-A transition at nucleotide 331 in exon 2 (c.331G>A) of *CD8A* in both patients. This mutation predicts the substitution of a glycine by a serine at codon 111 (p.Gly111Ser) of the CD8α protein. The glycine residue is located in the immunoglobulin domain of the CD8α chain and is conserved in all reported species through evolution, and also in the corresponding region of the closely related molecules CD8β and CD7 (Hansen et al., 2000).

Intrafamilial segregation of the mutant allele confirmed its role in the CD8 deficiency. Genetic analysis of relatives was performed by direct sequencing of genomic PCR products. In family 1, the three CD8-deficient siblings were indeed homozygous for the mutated allele ($CD8^{ser111}$). The parents and two brothers found to have low CD8 expression were heterozygous, whereas three sisters with normal CD8 levels were homozygous for the wild-type alleles (de la Calle et al., 2001). In family 2, the mutation was heterozygous in both parents and a healthy brother of the patient.

Interestingly, the only two familial cases of CD8 deficiency described have the same mutation in *CD8A* gene and are of Spanish Gypsy origin, suggesting a founder mutation. The mutation creates an additional restriction site for the enzyme *Alu*I. We took advantage of this to develop a screening test specific for the mutation, which we applied to 734 unrelated healthy subjects representing different European Gypsy populations: 242 from Spain; 394 from Bulgaria, representing 8 sub-isolates; and 98 from Romania, Hungary, and the Czech Republic. We also tested 393 unrelated Spanish non-Gypsy individuals. The c.331G>A mutation was found in heterozygosity in only 1 of the 242 Spanish Gypsy subjects, and not in non-Gypsy populations or Gypsy groups outside Spain (Mancebo et al, 2008). The three Gypsy families carrying the mutation did not share a geographical origin in Spain, and available genealogical data revealed no relationship between them; however, their common ethnicity makes it likely that a founder was the source of the mutation. Further, the three families shared a core haplotype associated with the mutation (Table 19.2).

Table 19.2 **HAPLOTYPES OF GYPSY ORIGIN ASSOCIATED WITH THE C.331G>A MUTATION IN THE *CD8A* GENE**

	FAMILY 1 AND FAMILY 2	FAMILY 3	GENOTYPE FOR CEPH INDIVIDUAL 134702	HETEROZYGOSITY (%)	ALLELE FREQUENCY IN GYPSY CONTROLS (N = 58)
D2S2232	208	210	210/218	83	208: 14%, 210: 20%

D2S2181	181	181	181/181	70	181: 46%

Relative order and physical distances are as follows: D2S2232-60 kb-D2S388-936 kb-D2S417-23 kb-*CD8A*:c.331G>A-3 kb-STSCD8A-40 kb-STSCD8B-1464 kb-D2S2216-81 kb-D2S2181. The marker of heterozygosity and allele frequencies were calculated from a sample group of 58 Spanish Gypsies. To allow other laboratories to compare their data with those reported in this work, we provide allele sizes for individual 134702, available from CEPH (Dib et al., 1996).

STRATEGIES FOR DIAGNOSIS

CD8 deficiency is diagnosed when either a male or female patient lacks surface expression in mature T and NK lymphocytes and has high TCRαβ + $CD4^-$ $CD8^-$ T-cell numbers and mutation in *CD8A*. The main clinical manifestations are recurrent respiratory tract infections.

CD8 deficiency should be suspected in young Spanish Gypsy patients suffering repeated and/or severe respiratory infections, and a lymphophenotype should be ordered to confirm or rule out the absence of $CD8^+$ T cells. Specific recommendations for vaccination and smoking avoidance may be proposed to affected individuals. Detection of the c.331G>A mutation by the PCR-RFLP screening test permits rapid and inexpensive diagnosis in individuals known to be at risk, permitting genetic counseling regarding this Mendelian disorder. CD8 deficiency must be differentiated from other deficiencies with low CD8 cells, such as ZAP-70 and TAP.

TREATMENT AND PROGNOSIS

Antibiotic therapy was applied according to bacterial isolates, and prophylactic antibiotics were recommended. No curative therapy (such as by bone marrow transplant) was performed in these patients. Gene therapy could, theoretically, be a therapeutic protocol. The prognosis of this immunological defect appears variable, ranging from fatal pulmonary insufficiency to mild or even asymptomatic phenotype.

CONCLUDING REMARKS

Manifestation of CD8 deficiency in humans appears less severe than in mouse models. This syndrome, like TAP1 and TAP2 deficiencies, is compatible with life and less aggressive than HLA class I deficiencies. Affected individuals have increased peripheral αβ DN T cells committed to the CTL lineage that correspond to what "should be" the $CD8^+$ population if CD8 were expressed. CD8 chains are first expressed and used by T cells early during their intrathymic development to increase the likelihood of being rescued in the event that their TCR has low affinity for MHC class I. CD8α is also expressed by human monocytes and enhances FcγR-dependent responses (Gibbings et al., 2007). However, in CD8 deficiency, T-cell clones that fulfill the functional requirements for intrathymic survival display aberrant phenotypes in periphery (DN T cells) but seem to be at least partially functional.

The diagnosis of primary immunodeficiency in adults is being increasingly reported, and it remains to be seen whether the CD8-deficient sisters of patient 1 will develop symptoms in the future. Examples of poor correlation between genotype and phenotype in other primary immunodeficiencies are described (de la Salle et al., 1994; Kornfeld et al., 1997; Sneller et al., 1997), and either modifying genes (Foster et al., 1998) or epigenetic changes (Jirtle et al., 2007) could help to explain different clinical manifestations in patients with the same genetic defect in CD8.

CRAC CHANNELOPATHIES DUE TO MUTATIONS IN ORAI1 AND STIM1

Stefan Feske

INTRODUCTION

Ca^{2+} signals contribute to the function of many immune cells, including T and B cells, natural killer (NK) cells, mast cells, dendritic cells, and macrophages. These signals control diverse functions ranging from differentiation, proliferation, gene expression, and cell motility to secretion of vesicles containing cytokines, cytotoxic, or proinflammatory proteins (Feske, 2007). The main mechanism controlling Ca^{2+} influx in lymphocytes is store-operated Ca^{2+} entry (SOCE) through the so-called calcium release activated calcium (CRAC) channel. The importance of Ca^{2+} influx through CRAC channels for immunity is highlighted by the existence of patients with a combined immunodeficiency due to a defect in SOCE, CRAC channel function, and T-cell activation (Feske et al., 1996, 2006; Le Deist et al., 1995; McCarl et al., 2009; Partiseti et al., 1994; Picard et al., 2009).

In lymphocytes, Ca^{2+} influx is initiated by engagement of immunoreceptors such as the TCR, BCR, or Fc receptors, resulting in the activation of signaling cascades (Fig. 20.1). Importantly, inositol 1,4,5-triphosphate ($InsP_3$) mediates the release of Ca^{2+} ions from the endoplasmic reticulum (ER) and activation of stromal interaction molecule (STIM) 1. Multimerization of STIM1 in the membrane of the ER leads to the opening of the store-operated CRAC channel protein ORAI1 in the plasma membrane and sustained Ca^{2+} influx from the extracellular space. The term "store-operated Ca^{2+} entry" refers to the fact that the filling state of the ER Ca^{2+} store controls the opening of calcium channels in the plasma membrane. The CRAC channel is defined by its unique functional properties, measured by patch clamping, an electrophysiological method to measure ion channel currents. Both SOCE and CRAC channels represent a universal Ca^{2+} influx mechanism employed by lymphocytes and many other cell types. Besides CRAC channels, other ion channels are indirectly involved in the regulation of Ca^{2+} influx in lymphocytes. These include the nonselective cation channel TRPM4 and the potassium channels KCNN4 and KCNA3, which together control the plasma membrane potential; a negative membrane potential is required to promote passive influx of Ca^{2+} ions through open CRAC channels and along the electrochemical gradient. Thus, theoretically mutations in a number of genes may affect Ca^{2+} levels in lymphocytes, including molecules operating proximal to $InsP_3$ production and ER store depletion as well as those affecting SOCE more directly, such as STIM1, ORAI1, potassium, and TRPM channels.

ORAI1 DEFICIENCY

BIOLOGY OF ORAI1

The CRAC channel gene *ORAI1* (or *CRACM1*, *TMEM142a*) on human chromosome 12q24 is the founding member of a new class of ion channels structurally related to *ORAI2* (*CRACM2*, *TMEM142b*) and *ORAI3* (*CRACM3*, *TMEM142c*). *ORAI1* has only two exons and encodes a highly conserved 301 amino acid protein with a tetra-spanning plasma membrane topology. ORAI1 is the pore-forming subunit of the CRAC channel. A negatively charged glutamate residue, E106, in its first transmembrane domain functions as a Ca^{2+} binding site in the ion channel pore (Prakriya et al., 2006; Vig et al., 2006a; Yeromin et al., 2006). CRAC channels are thought to be tetramers, with each ORAI1 subunit contributing a glutamate residue for coordinated Ca^{2+} binding in the CRAC channel pore. ORAI2 and ORAI3, which share the predicted tetra-spanning membrane topology with ORAI1, can form Ca^{2+} channels when ectopically expressed in vitro, and it is possible

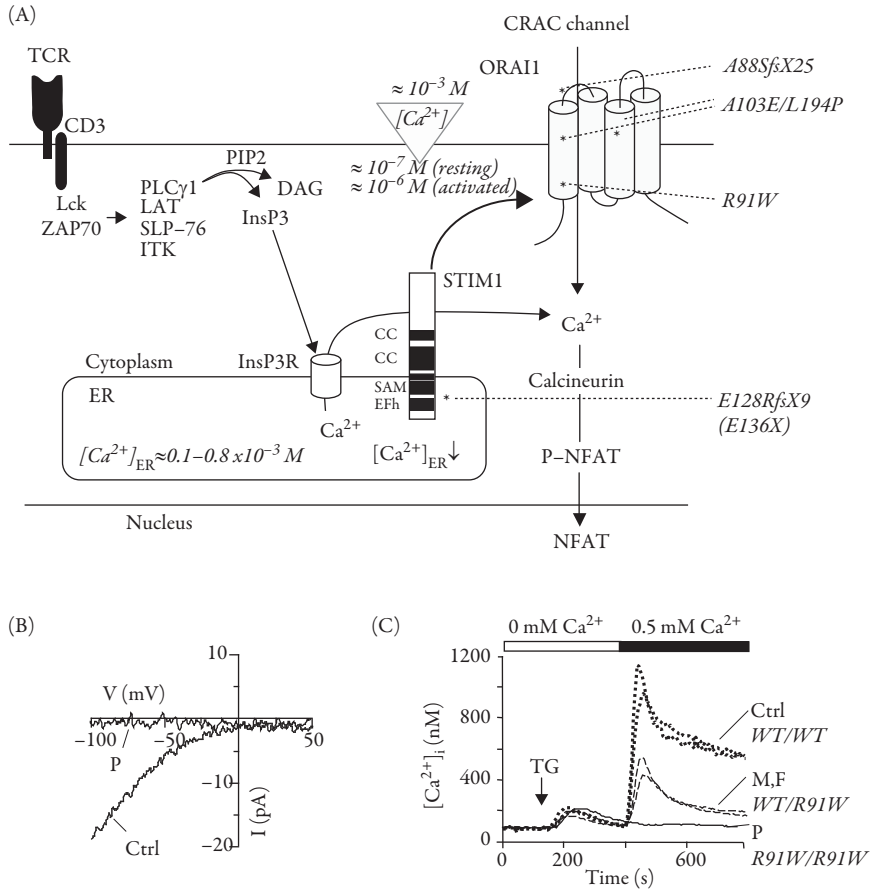

Figure 20.1 Store-operated Ca^{2+} entry (SOCE) through ORAI1 and STIM1 in T cells. (A) Following T-cell receptor (TCR) stimulation, the intracellular Ca^{2+} concentration $[Ca^{2+}]_i$ rises from ~50–100 nM at rest to ~1 μM. This increase in $[Ca^{2+}]_i$ following the activation of tyrosine kinases Lck and ZAP-70 (ζ-chain-associated protein kinase of 70 kDa), phosphorylation of adaptor proteins such as SLP76 (SH2-domain-containing leukocyte protein of 76 kDa) and LAT (linker for activation of T cells), and activation of phospholipase (PLC) γ1. PLCγ1 hydrolyses phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P_2) in the plasma membrane to inositol-1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG). $InsP_3$ binds to and opens $InsP_3$ receptors ($InsP_3Rs$) in the endoplasmic reticulum (ER), resulting in transient efflux of Ca^{2+}. Lower ER Ca^{2+} sensed by stromal interaction molecule 1 (STIM1) leads to the opening of calcium-release activated calcium (CRAC) channels in the plasma membrane, which are composed of ORAI1 subunits. Sustained Ca^{2+} influx through CRAC channels activates calcineurin and the transcription factor nuclear factor of activated T cells (NFAT). Known deleterious mutations in *ORAI1* and *STIM1* are indicated. STIIM1 domains: EFh, EF hand; SAM, sterile alpha motif; CC, coiled-coil. (B) Absent CRAC channel current I_{CRAC} in T cells of an ORAI1 deficient patient (P, with mutation R91W) compared to those of a control (Ctrl), measured in whole-cell patch-clamp recordings (Feske et al, 2005). Cells in which ER Ca^{2+} stores had been passively depleted were subjected to voltage ramps from –100 to +50 mV. (C) Impaired SOCE in ORAI1-R91W homozygous mutant (P) vs. heterozygous parental (M, F) or control (Ctrl) T cells. Single-cell ionized calcium concentration, $[Ca^{2+}]_i$, was measured by time-lapse microscopy after T-cell loading with the Ca^{2+} indicator dye Fura-2 and stimulation with thapsigargin (TG, *arrow*) to passively deplete ER Ca^{2+} in the absence of extracellular Ca^{2+} (*open bar*). After re-addition of Ca^{2+} (*black bar*), SOCE was undetectable in patient T cells and markedly reduced in heterozygous T cells.

that endogenous ORAI2 and ORAI3 play a role in CRAC channel function and SOCE in immune cells.

MOLECULAR BASIS OF ORAI1 DEFICIENCY

Discovery of ORAI1 by Modified Linkage Analysis and RNAi Screens

ORAI1 was discovered in three independent genome-wide RNAi screens of drosophila S2 cells for regulators of Ca^{2+} signaling and activation of the transcription factor NFAT (Feske et al., 2006; Vig et al., 2006b; Zhang et al., 2006) and by positional cloning (Feske et al., 2006). The latter approach relied on a strategy of genome-wide linkage analysis in a pedigree with only two patients by (1) identifying potential heterozygous disease carriers through functional tests in vitro (i.e., magnitude of Ca^{2+} influx) and (2) combining two independent modes of haplotype analysis. Twelve of 21 relatives of the patients showed ~50 percent reduced Ca^{2+} influx in their T cells compared to controls, suggesting that they were heterozygous carriers of the gene defect (Fig. 20.1C). Their DNA was used for microarray-based genome-wide single-nucleotide-polymorphism (SNP) mapping followed by evaluation of SNP data in two independent linkage analyses for an autosomal recessive and dominant disease trait, respectively (Feske et al., 2006). Together, both linkage analyses yielded a combined LOD score of 5.7, defining a 6.5 Mb interval on chromosome 12q24 containing ~74 genes. The hypothetical gene locus FLJ14466 located in the candidate region was sequenced because its drosophila homolog olf-186F was among

the positive hits in a RNAi screen for NFAT activating genes (Feske et al., 2006). FLJ14466 and olf-186F were renamed ORAI1 and dOrai, respectively, after the Orai (hours) Eunomia (Harmony), Dyke (Justice), and Eirene (Peace), the keepers of heaven's gate in Greek mythology (Stewart, 2005).

Mutations in ORAI1

To date, three families with six patients have been reported to lack CRAC channel function and SOCE due to mutations in ORAI1 (Fig. 20.1A, Table 20.1). An *R91W* missense mutation in exon1 of ORAI1 was identified in two patients from the first family whose T cells lacked SOCE and I_{CRAC} (Fig. 20.1B, C). Both patients were homozygous for a C→T transition at position 271 of the ORAI1 coding sequence (NM_032790), substituting highly conserved arginine residue 91 with tryptophan at the beginning of the first transmembrane domain of ORAI1(Feske et al., 2006). Hydrophobicity of the mutant tryptophan at position 91 is essential to abolish channel function; replacement of R91 with lipophilic leucine,

Table 20.1 **PHENOTYPES OF ORAI1 AND STIM1 DEFICIENCY**

	ORAI1	STIM1
Chromosome	**12q24**	**11q15**
Gene defects (all autosomal recessive)	**R91W, A88EfsX25, A103E/L194P**	**E128RfsX9**
# of patients (families)	**6 (3)**	**3 (1)**
Clinical Symptoms		
Immunodeficiency	**Viral, bacterial, fungal infections**	**Viral, bacterial, fungal infections**
Autoimmunity	**Neutropenia (1 patient)**	**Autoimmune hemolytic anemia, thrombocytopenia, lymphoadenopathy, hepatosplenomegaly**
Congenital myopathy	**Global muscular hypotonia, atrophic type II muscle fibers (R91W), respiratory insufficiency (R91W, A103E/L194P)**	**Global muscular hypotonia**
Ectodermal dysplasia	**Enamel dentition defect: Amelogenesis imperfecta type III (R91W), anhydrosis**	**Enamel dentition defect**
Other	**Idiopathic encephalopathy Facial dysmorphy**	**Nephrotic syndrome (1 patient)**
Outcome	**Death (in first yr): 4/6 Survival after HSCT: 2/6**	**Death (1.5–9 yrs): 2/3 Survival after HSCT: 1/3**
Laboratory Findings—Immunological		
Lymphocyte counts	**Normal**	**Normal**
T, B, NK cell subsets	**Normal**	**Normal, except $CD4^+$ $CD25^+$ $Foxp3^+$ Treg ↓**
T cell activation (in vitro)	**Proliferation ↓↓ Cytokines (IL-2, IL-4, IFN-γ) ↓↓**	**Proliferation ↓-↓↓**
Immunoglobulins	**Normal—↑ Ig levels, no seroconversion**	**Normal Ig levels, no seroconversion**
Laboratory Findings—Signaling		
Protein expression	**Yes (R91W), no (A88EfsX25), no (A103E/L194P)**	**No**
SOCE/I_{CRAC}	**Absent/absent**	**Absent/not tested**

ORAI1 and STIM1 deficiency is characterized by a defect in T-cell activation resulting in immunodeficiency, congenital myopathy, and anhydrotic ectodermal dysplasia. Lack of STIM1 expression in addition is associated with hepatosplenomegaly and autoimmunity due to greatly reduced numbers of T_{reg} cells. For details see text.

HSCT, hematopoietic stem cell transplantation; I_{CRAC}, Ca^{2+} release activated Ca^{2+} (CRAC) channel current; SOCE, store-operated Ca^{2+} entry.

Data from Feske, 1996, 2000, 2006; Le Deist, 1995; McCarl, 2009; Partiseti, 1994; Picard, 2009; Schlesier, 1993.

phenylalanine, or valine, but not with charged or neutral amino acids, impaired CRAC channel function (Derler et al., 2009; McCarl et al., 2009).

A patient from a second family (Fig. 20.1A), born to consanguineous parents, lacked SOCE and CRAC channel activity (Partiseti et al., 1994) and was homozygous for insertion of a single adenine between nucleotides 258 and 259 (258insA) of the *ORAI1* coding sequence (McCarl et al., 2009). This mutation at the end of the first transmembrane domain caused a frameshift at amino acid 88 and a premature termination codon at position 112 (*ORAI1 A88EfsX25*) (Fig. 20.1A). The lack of ORAI1 mRNA and protein in this patient is consistent with nonsense-mediated mRNA decay.

Two missense mutations in *ORAI1* exon 2, A103E and L194P, were identified in an affected patient from a third family (Le Deist et al., 1995; McCarl et al., 2009) (Fig. 20.1A). Both mutations interfered with stable protein expression as no ORAI1 protein was detected in the patient's fibroblasts or in HEK293 cells ectopically expressing these ORAI1 mutants. SOCE could be reconstituted in T cells and fibroblasts from all ORAI1-deficient patients by retroviral transduction with expression vectors encoding wild-type ORAI1 (Feske et al., 2006; McCarl et al., 2009).

CLINICAL AND IMMUNOLOGICAL PHENOTYPE OF ORAI1 DEFICIENCY

The dominant clinical phenotype in all patients was immunodeficiency, with severe infections early in life, but they also had congenital myopathy and ectodermal dysplasia. Recurrent severe infections were due to viral, bacterial, mycobacterial, and fungal pathogens causing pneumonia, meningitis, enteritis, gastrointestinal candidiasis, and sepsis in the various patients (Table 20.1) (Feske et al., 1996, 2000; Le Deist et al., 1995; McCarl et al., 2009; Partiseti et al., 1994). Antibiotics and intravenous immunoglobulin (IVIg) only inefficiently controlled infections, necessitating hematopoietic stem cell transplantation (HSCT). Two of six patients were treated successfully by HSCT, but the remaining four patients died in their first year of life. ORAI1-deficient patients resembled patients with severe combined immunodeficiency (SCID), although lymphocyte counts and numbers of $CD4^+$ and $CD8^+$ T cells and of B cells were normal. T-cell activation was severely compromised, with impaired proliferation and cytokine production in response to TCR-dependent and independent stimuli in vitro and absent skin delayed-type hypersensitivity reactions in vivo (Table 20.1) (Feske et al., 1996, 2000; Le Deist et al., 1995; Partiseti et al., 1994; Schlesier et al., 1993). Despite the activation defect in vitro, increased numbers of T cells with an activated ($CD3^+$ $HLA\text{-}DR^+$) and memory ($CD4^+CD45RO^+$, $CD4^+$ $CD29^+$) phenotype were observed in the peripheral blood of all patients analyzed for these markers.

ORAI1-deficient patients also developed early global muscular hypotonia with decreased head control, delayed ambulation, and reduced muscle strength and endurance (McCarl et al., 2009). The two surviving patients after HSCT had hypotonia of respiratory muscles, chronic pulmonary disease, superinfections, and bronchiectasis by the time of adolescence. Histologically, the myopathy was characterized by a variation in muscle fiber size, with a predominance of type I fibers and atrophic type II fibers (Plate 20.1). Other structural abnormalities commonly found in congenital myopathies were not observed.

Ectodermal dysplasia with anhydrosis (EDA), impaired sweat production, and a defect in dental enamel formation occurred in both surviving ORAI1-deficient patients (Plate 20.1). Dry skin and heat intolerance led to recurrent fevers. Hypocalcified dental enamel matrix led to use-dependent loss of the soft enamel and painful exposure of underlying dentin, consistent with the diagnosis amelogenesis imperfecta type III (Plate 20.1). Scalp hair and eyebrows, often sparse or missing in other forms of EDA, were normal in ORAI1-deficient patients.

Encephalopathy observed in a patient with a ORAI1 A88EfsX25 nonsense mutation and his unaffected brother was judged unlikely to be due to ORAI1 deficiency because it occurred in only one of three families with ORAI1 defects (Partiseti et al., 1994).

STIM1 DEFICIENCY

BIOLOGY OF STIM1

The human *STIM1* gene on chromosome 11p15 consists of 12 exons. STIM1 is a single-pass transmembrane protein of 685 amino acids localized predominantly in the membrane of the ER, where it functions as a sensor of ER Ca^{2+} concentrations and activator of ORAI1/CRAC channels (Liou et al., 2005; Roos et al., 2005). STIM1 contains a pair of low-affinity EF hand calcium-binding domains, a sterile alpha motif (SAM), and two coiled-coil protein–protein interaction domains. Depletion of Ca^{2+} from the ER results in dissociation of Ca^{2+} from the N-terminal EF hand domains of STIM1, unfolding of the EF-SAM domain, and multimerization of STIM1, ultimately leading to the assembly of STIM1 in large ER membrane clusters called puncta (Liou et al., 2007; Stathopulos et al., 2008). The formation of STIM1 puncta causes aggregation of ORAI1 in the plasma membrane and localized Ca^{2+} influx (Liou et al., 2005, 2007; Luik et al., 2006, Wu et al., 2006). STIM2, a closely related paralog of STIM1, is also located in the ER, is able to heterodimerize with STIM1, and acts as a positive regulator of SOCE (Manji et al., 2000; Williams et al., 2001). STIM2 activates Ca^{2+} influx upon smaller decreases in ER Ca^{2+} concentrations than STIM1 and was shown to regulate basal cytosolic Ca^{2+} concentrations (Brandman et al., 2007).

MOLECULAR BASIS OF STIM1 DEFICIENCY

To date, three patients from one family have been reported to lack SOCE due to mutations in STIM1 (Picard et al., 2009). Patient fibroblasts showed a pronounced defect in SOCE in response to thapsigargin, an inhibitor of the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA), which induces passive

depletion of intracellular Ca^{2+} stores. Born to consanguineous parents, the proband and her younger brother were homozygous for insertion of an adenine in exon 3 of *STIM1*, resulting in a frameshift beginning at codon 128 and a premature termination codon at position 136 (E128RfsX9). Consequently, STIM1 mRNA and protein were greatly reduced or absent in the patients' cells. SOCE was restored by retroviral transduction with wild-type STIM1 while partial reconstitution was achieved by expression of STIM2, suggesting that the genes have overlapping functions. Endogenous expression levels of STIM2 were not, however, sufficient to compensate for the lack of STIM1 in the patients.

CLINICAL AND IMMUNOLOGICAL PHENOTYPE OF STIM1 DEFICIENCY

Lack of STIM1 is characterized by immunodeficiency, congenital myopathy, and ectodermal dysplasia reminiscent of ORAI1-deficient patients but in addition results in autoimmune disease (Table 20.1) (Picard et al., 2009). Patients had recurrent bacterial and viral infections such as urinary tract infections, bacterial sepsis, otitis media, and pneumonia caused by a spectrum of pathogens, including *S. pneumoniae*, *E. coli,* cytomegalovirus, and varicella zoster virus. Lymphocyte counts were slightly reduced or normal. The proband had an age-appropriate distribution of lymphocyte subpopulations and normal TCR repertoire but decreased proportions of naïve $CD4^+$ T cells and $CD4^+CD45RA^+CD31^+$ T cells (recent emigrants from the thymus). T-cell proliferation in response to stimulation with phytohemagglutinin, phorbol 12-myristate 13-acetate plus ionomycin, or anti-CD3 antibody was markedly impaired, with even less response to recall antigens.

Immunodeficiency in the STIM1-deficient patients was complicated by hepatosplenomegaly and autoimmune disease (Picard et al., 2009). Two patients had lymphadenopathy and hepatosplenomegaly, but Fas-induced T-cell apoptosis measured in one was normal. All had thrombocytopenia and two had autoimmune hemolytic anemia. A likely cause for autoimmunity in STIM1-deficient patients is their reduced number of $CD4^+$ $CD25^+$ $FoxP3^+$ regulatory T cells (T_{reg}). Mice lacking expression of STIM1 and STIM2 also show T_{reg} cell defects (Oh-Hora et al., 2008). Lack of SOCE and reduced TCR signal strength in developing T cells may cause abnormal persistence of self-reactive T cells during thymic development, leading to the autoimmunity in human patients and mice. Despite reduced numbers of T_{reg} cells, STIM1-deficient patients did not resemble patients with X-linked immune dysregulation, polyendocrinopathy, enteropathy (IPEX) syndrome (Ochs et al., 2007), presumably because of impaired antigen-specific activation of effector T cells in the absence of STIM1 and SOCE.

Like ORAI1-deficient patients, those lacking STIM1 also suffered from ectodermal dysplasia and congenital myopathy as well as partial iris hypoplasia. The myopathy is consistent with the role of STIM1 in myoblast differentiation and the defect in skeletal muscle development and function found in *Stim1*-deficient mice (Darbellay et al., 2008; Lyfenko and Dirksen, 2008; Stiber et al., 2008).

ANIMAL MODELS

Gene-targeted mice lacking *Orai1* and *Stim1* expression have been generated by homologous recombination and insertional mutagenesis. In contrast to ORAI1- and STIM1-deficient patients (Feske et al., 2006; Picard et al., 2009), mice generally die in the first days postpartum, most likely due to hypotonia. Surviving $Orai1^{-/-}$ and $Stim1^{-/-}$ mice are severely runted but may catch up with their littermates in the first weeks of life, depending on genetic background. $Stim1^{-/-}$ mice show morphological abnormalities in skeletal muscle and defects in myoblast function.

Immune function is compromised in $Orai1^{-/-}$ and $Stim1^{-/-}$ mice due to severely impaired CRAC channel function and SOCE in $CD4^+$ and $CD8^+$ T cells, B cells, mast cells, and macrophages (Baba et al., 2008; Gwack et al., 2008; Oh-Hora et al., 2008), although one study found only mild impairment of Ca^{2+} influx in *Orai1*-deficient T cells (Vig et al., 2008). As a consequence, expression of cytokines interleukin (IL)-2, interferon (IFN)-γ, IL-4, and IL-10 was substantially reduced in T cells from $Orai1^{-/-}$ and $Stim1^{-/-}$ mice (Gwack et al., 2008; Oh-Hora et al., 2008), similar to ORAI1-deficient human patients (Feske et al., 2000). By contrast, T-cell proliferation in response to TCR stimulation and T-cell-dependent antibody responses were preserved in $Orai1^{-/-}$ (Gwack et al., 2008) and $Stim1^{-/-}$ mice (Beyersdorf et al., 2009). By contrast, B cells from $Orai1^{-/-}$ mice proliferated poorly in response to BCR stimulation (Gwack et al., 2008), and mast cells from both $Orai1^{-/-}$ and $Stim1^{-/-}$ mice showed reduced cytokine secretion and degranulation in vitro and attenuated passive cutaneous anaphylaxis in vivo (Baba et al., 2008; Vig et al., 2008). Finally, macrophages lacking *Stim1* expression had severely compromised FcRγII/III-mediated Ca^{2+} influx (Braun et al., 2008) and were protected from disease in in vivo models of autoantibody-mediated thrombocytopenia and anemia. These findings suggested a role for SOCE in phagocytosis in mice (Braun et al., 2008), in contrast to autoimmune hemolytic anemia and thrombocytopenia in STIM1-deficient patients (Picard et al., 2009).

Autoimmunity, lymphadenopathy, and splenomegaly observed in STIM1-deficient patients was recapitulated in mice with conditional, T-cell-specific deletion of both *Stim1* and *Stim2* ($Stim1^{f/f}$, $Stim2^{f/f}$ *CD4-Cre*). These mice had reduced numbers and impaired function of T_{reg} cells (Oh-Hora et al., 2008). In addition, double-deficient mice showed leukocytic organ infiltration, colitis, dermatitis, and blepharitis. A potential cause for the paucity of T_{reg} cells is the failed Ca^{2+}-dependent activation of NFAT, which interacts with binding sites in the promoter and enhancer of FoxP3, the lineage-determining transcription factor of T_{reg} cells (Tone et al., 2008).

Myeloid- and lymphoid-cell development in the bone marrow and thymus was unperturbed in *Orai1-, Stim1-*, and *Stim1/Stim2*-deficient mice, consistent with the normal leukocyte numbers in ORAI1- and STIM1-deficient patients (Beyersdorf et al., 2009; Feske et al., 1996; Gwack et al., 2008; Le Deist et al., 1995; McCarl et al., 2009; Oh-Hora et al., 2008; Partiseti et al., 1994; Picard et al., 2009). Ca^{2+} signals are widely considered necessary for differentiation and

selection of T cells in the thymus, but T-cell development was normal in *Stim1*-deficient mice (*Stim1$^{f/f}$ CMV-Cre*) despite a complete lack of detectable SOCE (M. Oh-Hora, A. Rao, SF unpublished); these data suggest that STIM1 and ORAI1 may be dispensable for lymphocyte development, with the notable exception of T_{reg} cells.

PROGNOSIS AND TREATMENT

Despite normal lymphocyte development in patients lacking functional ORAI1 or STIM1, the immunodeficiency is similar in scope and severity, especially in ORAI1-deficient patients, to that of SCID patients. Four of six ORAI1-deficient patients died in their first year of life due to recurrent, severe infections, and two STIM1-deficient patients died at 1.5 and 9 years of life of encephalitis and complications of HSCT, respectively. HSCT resulted in successful immune reconstitution in two ORAI1-deficient patients and one STIM1-deficient patient. The two now-adolescent ORAI1-deficient patients, however, suffer from secondary complications of muscular hypotonia and chronic pulmonary disease. In addition, one developed a monoclonal EBV-associated polymorphic B-cell lymphoma of host origin at 8 years of age. No signs of autoimmunity were observed in the surviving STIM1-deficient patient after HSCT.

CONCLUDING REMARKS

The clinical phenotypes of ORAI1 and STIM1 deficiency largely overlap, suggesting that the developmental and functional defects are not protein-specific but rather pathway-specific—that is, that they result from the absence of SOCE and CRAC channel function. The immunodeficiency in both diseases is caused by a severe defect in T-cell activation but not T-cell development. However, STIM1, but not ORAI1, seems required for the development of $CD4^+$ $Foxp3^+$ regulatory T cells, evidenced by the reduced numbers of T_{reg} cells in the peripheral blood of one STIM1-deficient patient and autoimmune lymphoproliferative disease in all three patients (Picard et al., 2009). While numbers of T_{reg} cells could not be evaluated in ORAI1-deficient patients, symptoms of autoimmunity were apparent in only one of the patients, who had neutropenia and thrombocytopenia at 7 months of age (McCarl et al., 2009). As ORAI1-deficient patients either died in their first year of life and or were treated by HSCT, it can be speculated that a defect in T_{reg} development and subsequent autoimmunity did not have enough time to manifest in these patients. Alternatively, residual SOCE in immature T cells in ORAI1-deficient (in contrast to STIM1-deficient) patients may permit T_{reg} development. Given the expression of ORAI2 in naïve CD4+ T cells, it is conceivable that other ORAI isoforms such as ORAI2 or ORAI3 play a role in SOCE in immature T cells and that mutations in these genes may be associated with defects in T-cell development or function.

Finally, the novel strategy used to positionally clone the ORAI1 gene described in this chapter may be useful for the identification of gene defects underlying other rare autosomal recessive diseases in which traditional linkage analysis cannot yield high enough LOD scores due to the small number of affected patients. Successful application of this approach relies on (1) a reliable test to identify heterozygous carriers and (2) a large enough number of relatives who can be tested.

21.

DEFICIENCY OF FOXN1

Claudio Pignata, Anna Fusco, and Stefania Amorosi

FOXN1 (NUDE) DEFICIENCY

In 1996, a novel form of severe combined immunodeficiency (SCID) (MIM 601705; Pignata Gguarino syndrome) was described and proposed as the human equivalent of the well-known murine phenotype defined as Nude/SCID (Pignata et al., 1996). This syndrome represents the first example of SCID not primarily related to an abnormality of the hematopoietic cell, but rather to an intrinsic alteration of the thymic epithelial cell (reviewed in Pignata, 2002). The hallmark of the Nude/SCID mouse is congenital alopecia associated with a profound T-cell defect (Flanagan, 1966).

Human Nude/SCID was identified in two sisters who had congenital alopecia of the scalp, eyebrows, and eyelashes; nail dystrophy; and a severe T-cell immune defect, inherited as an autosomal recessive disorder (Fig. 21.1) (Pignata et al., 1996). The older sister presented at the age of 2 months with erythroderma, persistent diarrhea, failure to thrive, lymph node enlargement, and hepatosplenomegaly. Hypereosinophilia and prominent functional abnormalities of T cells but not of B cells were observed. Despite therapy the patient died of bronchopneumonia at the age of 12 months. The younger sister, evaluated at 1 month of age, showed major immunological abnormalities leading to severe respiratory infections. At 5 months, she received an allogeneic HLA-matched bone marrow transplant (BMT). Of note, 1 year following the transplant, the patient still had alopecia and nail dystrophy. Due to the similarities between the human clinical features and the mouse Nude/SCID phenotype, known to be due to a *Foxn1* defect, molecular analysis of human *FOXN1* in these girls was performed and revealed a cDNA homozygous mutation 792C>T, producing the nonsense mutation R255X in exon 5 and complete absence of a functional protein (Frank et al., 1999).

Since the first description of these Nude/SCID patients, others with a similar phenotype have been diagnosed. A Portuguese newborn with alopecia, nail dystrophy, and severe infections had the same homozygous R255X mutation as the Italian patients (M. Markert and A. E. Souza, as reported at the XIIth Meeting of the European Society for Immunodeficiencies, Budapest, 2006). Another patient born to unrelated parents of mixed French/African origin had a homozygous cDNA 987C>T (R320W) missense mutation in exon 6 of *FOXN1* (Markert et al., 2011).

CLINICAL SPECTRUM OF THE NUDE/SCID PHENOTYPE

Pathological examination of two human fetuses carrying the R255X mutation in homozygosity, identified in the geographical area where the first patients originated, revealed the lack of a thymus, confirming that Foxn1 is essential for thymic development in humans. Defects in human fetal development could explain the high rate of mortality in utero observed in kindreds of this region. Fetal skin was tighter than usual and showed basal hyperplasia and dysmaturity, suggesting impaired differentiation. (Amorosi et al., 2008). One fetus also had neural tube defects, including anencephaly and spina bifida, consistent with evidence that the mouse *Foxn1* gene is expressed in epithelial cells of the developing choroids plexus (Amorosi et al., 2008).

The T-cell defect in human Nude/SCID includes a lack of proliferative responses associated with a severe differentiation blockage of T cells (Table 21.1) (Pignata et al., 1996). A prominent decrease of $CD3^+$, $CD4^+$, $CD8^+$ cells and $CD4^+$ $CD45RA^+$ naïve lymphocytes but normal B- and NK-cell compartments are found. From immunological

Figure 21.1 Alopecia of the scalp, eyebrows, and eyelashes, characterizing the human Nude/SCID phenotype. (From Pignata et al. *Am J Med Genet* 65:167–170, 1996, with permission.)

studies performed in a patient who underwent unmanipulated BMT, also containing mature T cells, it was documented that, despite an increase in $CD3^+$, $CD4^+$, and $CD8^+$ cells of donor origin, the $CD4^+$ $CD45RA^+$ naïve cells were not regenerated. Conversely, naïve $CD8^+$ cells increased, suggesting an extrathymic site of maturation for this subset (Pignata et al., 2001).

Heterozygous carriers of the R255X mutation frequently show congenital nail dystrophy, most specifically leukonychia, a typical arch pattern resembling a half-moon in the proximal part of the nail plate. However, the most frequent nail alteration is koilonychia ("spoon nail"), a concave surface and raised edges of the nail plate, associated with thinning of the plate itself. Canaliform dystrophy and a transverse groove of the nail plate (Beau line) may also be present (Fig. 21.2) (Auricchio et al., 2005). *FOXN1* is expressed in the nail matrix where the nail plate originates, confirming its involvement in the maturation of nails and suggesting nail dystrophy

Table 21.1 CLINICAL AND IMMUNOLOGICAL FEATURES OF HUMAN NUDE/SCID PHENOTYPE

FEATURES	NUDE/SCID
Clinical	
Athymia	Constant
Alopecia	Constant
Nail dystrophy	Constant
Failure to thrive	Frequent
Erythroderma	Frequent
Infections*	Constant
Age at presentation of infections	<6 months
Brain anomalies	Uncertain, but present in one fetus
Immunological	
Absolute lymphocyte count	Normal
$CD3^+$ cells	Markedly reduced (range: 0–25%)
$CD3^+$ $CD4^+$ cells	Absent to markedly reduced (range: 0–20%)
$CD3^+$ $CD8^+$ cells	Reduced (range: 0–11%)
$CD16^+$ $CD56^+$ cells	Normal
$CD19^+$ cells	Normal to elevated (range: 37–75%)
Naïve T lymphocytes	Extremely low (range: 0–3.1%)
Proliferative response to mitogens	Absent to markedly reduced
Specific antibody production	Absent to very low
Serum immunoglobulin levels	Normal to reduced

*Includes conjunctivitis (birth), pyogenic infections (2 mo), diarrhea (2–4 mo); BCG lymphadenitis (3 mo), *Mycobacterium bovis* infection (5 mo); severe herpesvirus 6 infection (4 mo); bronchiolitis, bronchopneumonia, interstitial pneumonitis (2–12 mo).

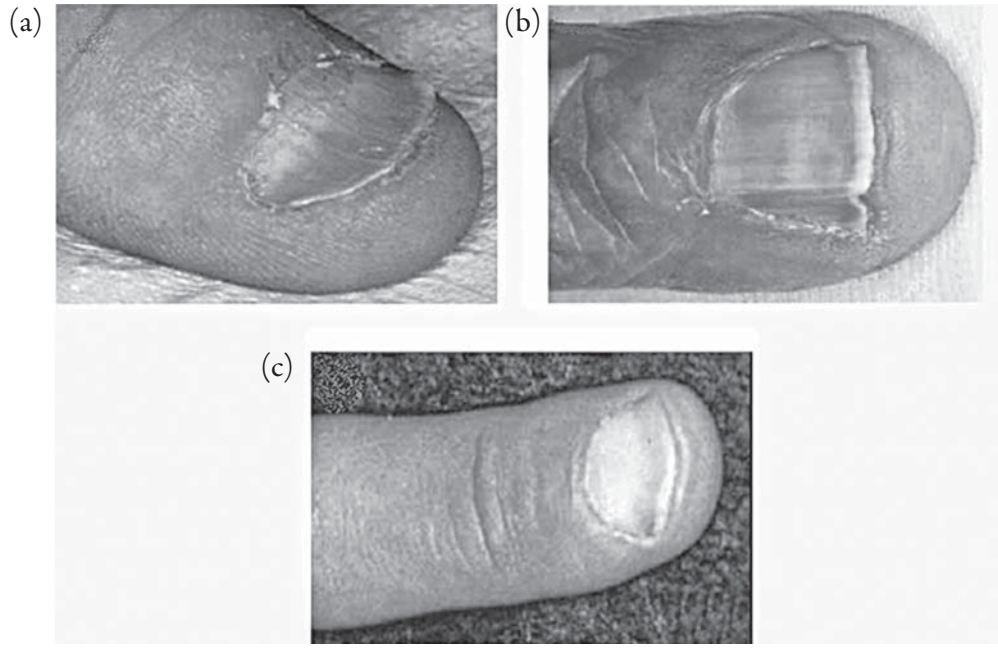

Figure 21.2 Nail dystrophy patterns associated with heterozygous *FOXN1* mutation: (A) koilonychia, (B) canaliform dystrophy, (C) leukonychia. (From Auricchio et al. *Arch Dermatol* 141:647–648, 2005, with permission.)

as a sign of heterozygosity for *FOXN1* mutation (Auricchio et al., 2005).

THE MURINE NUDE PHENOTYPE

In 1966, S. P. Flanagan identified a mouse phenotype that spontaneously appeared in the Virus Laboratory of Ruchill Hospital of Glasgow. The mouse had hair fibers with abnormal keratinization and a follicular infundibulum unable to enter the epidermis (Flanagan, 1966). Affected mice also showed dysgenesis of the thymus (Pantelouris et al., 1970; Takahashi et al., 1992), resulting in a compromised immune system lacking T cells. The analysis of serial histological sections of the area where a normal thymus would be found revealed absence of thymic epithelial cells, Hassall's corpuscles, or thymocytes. However, occasionally in the anterior mediastinum an irregularly shaped, minute mass containing normal and brown fat was present. Lymph nodes and Peyer's patches revealed a dramatic lymphoid depletion of the paracortical areas. A marked depletion of cells was also found in the periarteriolar region (the presumed thymic-dependent area) of the spleen.

Nude mice have a severe T-cell deficiency and an overall severely impaired immune response. Lymphocytes are unable to respond to T-cell mitogens or antigens. IgM levels are elevated, IgG1 and IgG2 mildly depressed, and IgA are undetectable (Amman et al., 1971; Bankhurst et al., 1975). Nude mice possess T-cell precursors, and cell-mediated immunity can be partially restored by either thymic extracts or thymus transplantation (Gershwin et al., 1975; Loor et al., 1973). It should be mentioned that studies performed in Nude/SCID mice gave a great contribution to the knowledge of cell-mediated immunity. For a long time, the DiGeorge syndrome (DGS) was erroneously considered the human counterpart of the murine Nude/SCID phenotype, although the immunological impairment profoundly differs between DGS and mouse Nude/SCID.

The molecular nature of the nude defect was characterized and attributed to deficiency of the transcription factor Foxn1, also called Whn or Hfh11 (Byrd, 1993; Nehls et al., 1994; Takahashi et al., 1992). Spontaneous mutations in Foxn1 also occur in rats (Nehls et al., 1994) and result in a comparable phenotype (Cash et al., 1993).

The Nude mouse epidermis shows failure in differentiation and reduced number of tonofilaments in spinous, granular, and basal layers (Köpf-Maier et al., 1990). The nude *Foxn1* gene doesn't affect the growth of hair follicles, but rather the epidermal differentiation process, regulating the balance between proliferation and differentiation of keratinocytes in the hair follicle (Brissette et al., 1996; Lee et al., 1999). Alterations of digits and nails were also reported in a few strains of Nude mice, probably due to an abnormal production of filaggrin protein in the nail matrix and nail plate, subsequent to a loss of keratin 1 protein. Increased fetal loss may be due to a change in the hormonal status, as demonstrated by altered serum levels of estradiol, progesterone, and thyroxine (Köpf-Maier et al., 1990).

FOXN1 AND ITS ROLE IN THYMUS AND SKIN

Foxn1 is a highly conserved transcription factor. It belongs to the forkhead gene family that comprises a diverse group of "winged-helix" transcription factors that are involved in

development, metabolism, cancer, and aging. These factors are developmentally regulated and direct tissue-specific transcription and cell-fate decisions (Lai et al., 1993). Foxn1 expression is regulated by wingless (Wnt) proteins (Balciunaite et al., 2002) and bone morphogenetic proteins (BMPs) (Tsai et al., 2003) in both autocrine and paracrine fashions (reviewed in Jonsson et al., 2005), and its expression is restricted to epithelial cells in the skin and thymus (Brissette et al., 1996). During embryogenesis in mice Foxn1 is expressed in several mesenchymal and epithelial cells, including those of the liver, lung, intestine, kidney, and urinary tract as well as skin and thymus. In adult life its expression is limited to epithelial cells of the intestine, spermatocytes, and thymus (Ye et al., 1997). In particular, on the basis of the observation that Nude mouse keratinocytes do not differentiate in a normal fashion, Foxn1 could be considered as a key regulator of the balance between keratinocyte growth and differentiation, through its ability to suppress involucrin and locrin, both components of the cornified envelope, and profilaggrin, involved in the aggregation of the intermediate filaments.

The expression of Foxn1 begins in the mouse thymus anlage at about E11.5. Within a normal thymus, mature T lymphocytes derive from the interaction between the thymic epithelial cell, representing the main component of the stroma, and the T-cell precursors (thymocytes) (reviewed in Blackburn et al., 2002, and Manley, 2003). Thymic epithelial cells are involved in both thymus organogenesis and most of the maturation stages of thymocyte development.

Of note, there are remarkable similarities between thymic epithelial cells, keratinocytes, and skin fibroblasts that led to consideration of the skin as a nonhematopoietic tissue able to support the development of functional human T cells. Foxn1 is expressed in human skin cell/hematopoietic progenitor cell (HPC) cultures, where the full process of human T-cell development can be modeled (Clark et al., 2005). Although thymus and skin are different in three-dimensional structure, experiments performed with keratinocytes and fibroblasts of the skin and HPCs obtained from bone marrow, reconfigured in a different three-dimensional arrangement, demonstrate the capacity to generate T cells with the hallmarks of recent thymic emigrants, such as the presence of T-cell surface markers including the CD3/T-cell receptor (TCR) complex (Douek et al., 1998) and TCR excision circles, which derive from the recombination of TCR genes. These cells also possess a diverse TCR repertoire and can be considered mature and functional because they have full capacity to proliferate, express the activation antigen CD69, and produce cytokines in response to TCR/CD3 stimulation. Therefore, skin and bone marrow elements might be used to generate de novo functional and diverse T-cell populations, thus opening new windows for innovative therapeutic approaches to immunological disease (Clark et al., 2005).

CHRONIC MUCOCUTANEOUS CANDIDIASIS AND SUSCEPTIBILITY TO FUNGAL INFECTIONS DUE TO DEFECTS IN CARD9 AND DECTIN-1

Bodo Grimbacher

Chronic mucocutaneous candidiasis (CMC) comprises a wide range of disorders characterized by persistent and recurrent infections of the skin, nails, and mucosa with predominantly *Candida albicans*. CMC is a heterogeneous disease and may be complicated by endocrinopathies such as hypoparathyroidism, hypoadrenalism, and ovarian failure as well as autoinflammatory disorders including autoimmune hepatitis, vitiligo, and alopecia (Kirkpatrick, 2001; Lilic, 2002). Additionally, CMC patients may be susceptible to infections with pathogens other than *C. albicans*. Bacterial infections of the respiratory tract, urogenital tract, and skin have also been described (Kirkpatrick, 2001) as well as invasive fungal infections with *Histoplasma capsulatum* or *Cryptococcus neoformans*; CNS infections due to *Candida* or *Cryptococcus* are rare but have been reported (Kauffman and Shead, 1981; Kirkpatrick, 2001; van 't Wout et al., 1988). CMC patients may also present with dermatophyte infections of the skin and nails, often resulting in disfigurements (Kirkpatrick, 2001; Shama and Kirkpatrick, 1980). The majority of CMC patients present in childhood with stubborn and persistent *Candida* infection of the mouth, known as thrush, and the diaper area. The infection is usually localized but may spread and affect nails and other skin areas. In adults with late onset, a thymoma with or without thymoma-associated diseases such as myasthenia gravis may be present (Kirkpatrick, 2001; Kirkpatrick and Windhorst, 1979; Lilic, 2002).

CMC is a primary immunodeficiency that must be distinguished from APECED (autoimmune polyendocrinopathy candidiasis ectodermal dysplasia), also known as APS1 (autoimmune polyglandular syndrome type 1), caused by mutations in the *AIRE* (autoimmune regulator) gene and in which candidiasis is a clinical hallmark (see Chapter 31) (Finnish-German APECED Consortium, 1997; Nagamine et al., 1997). Other primary immunodeficiencies such as severe combined immunodeficiency (SCID) (Chapter 9), DiGeorge syndrome (Chapter 45), or hyper-IgE syndrome (Chapter 38) must be considered, as well as secondary immunodeficiency due to underlying diseases including iron deficiency, HIV infection, diabetes mellitus, or denture stomatitis (Kirkpatrick, 2001). The long-term use of immunosuppressive drugs, in particular inhaled steroids, is also associated with oral candidiasis.

Increased susceptibility to mucosal and cutaneous *Candida* and other fungi is often attributed to an impaired cellular immune response and may be observed in patients with congenital or acquired T-cell defects. A wide range of different immunological abnormalities in T cells of CMC patients has been described (de Moraes-Vasconcelos et al, 2001; Eyerich et al., 2007, 2008; Kirkpatrick, 2001; Lilic et al., 2003). A critical factor for the pathogenesis may be the impaired ability of T cells to release certain cytokines, with a shift from typical Th1 cytokines such as interleukin (IL)-12 to IL-10, but impaired maturation of dendritic cells may also contribute to the disease in CMC patients with or without APECED/APS1 (Ryan et al., 2008).

A subset of T cells, IL-17 and IL-22 producing helper T cells, is required for adaptive antifungal immunity. These Th17 cells play a crucial role in the host defense against *Candida* in mice, and these cells are reduced in number in patients with CMC (Conti et al., 2009; Eyerich et al., 2008; Glocker et al., 2009; LeibundGut-Landmann et al., 2007). The majority of CMC patients have normal serum immunoglobulin levels and high titers of anti-*Candida* antibodies. In patients with CMC and additional severe bacterial infections such as pneumonia, a careful examination of their immune status should be carried out to clarify the extent of immunodeficiency. Most cases of CMC are sporadic, but families with both autosomal dominant and recessive inheritance have been reported (Atkinson et al., 2001; Loeys et al., 1999; Sams et al., 1979; Wells et al.,

19972). Genetic studies found linkage of a dominant candidiasis/thyroiditis syndrome to chromosome 2 and candidiasis associated with low ICAM-1 expression to chromosome 11, but no causative genes have been identified (Atkinson et al., 2001; Mangino et al., 2003).

Genetic and functional studies in a large consanguineous five-generation family identified four CMC patients carrying a homozygous loss-of-function mutation in the gene *CARD9* encoding the caspase recruitment domain-containing protein 9 (Glocker et al., 2009). The gene, located on chromosome 9, encodes a protein of 536 amino acids. Like other CARD proteins, CARD9 has an N-terminal CARD domain that mediates binding to other CARD-domain containing molecules, and a C-terminal coiled-coil domain enabling protein oligomerization. The null mutation detected in the patients results in a premature termination codon at amino acid 295 (Q295X) (Glocker et al., 2009).

CARD9 plays a central role in human antifungal defense by triggering proinflammatory responses (Fig. 22.1). The transmembrane pattern recognition receptor Dectin-1 senses 1–3 and 1–6 linked β-glucans, fungal pathogen associated molecular patterns, and signals via an immunoreceptor tyrosine-based activation (ITAM) motif that becomes phosphorylated by sarcoma (Src) kinases (Gross et al., 2006; Ruland, 2008; Taylor et al., 2007). The phosphorylated ITAM recruits and activates the SH2 domain containing spleen tyrosine kinase (SYK). The Dectin-1/SYK complex can then engage CARD9, which associates with B-cell leukemia/lymphoma 10 (BCL10) and mucosa-associated lymphoid tissue 1 (MALT1) to form an intracellular signaling structure that relays the fungal recognition signal. The downstream elements in this pathway include the transcription factor nuclear factor kappa B (NF-κB), as well as p38 mitogen activated protein kinase (MAPK) and JNK kinase (Fig. 22.1). This signaling pathway is operative in myeloid cells and triggers the production of key cytokines such as TNF-α, IL-1β, IL-6, and IL-23 (LeibundGut-Landmann et al., 2007; Ruland, 2008), which are required for innate antifungal immunity and the generation of Th17 cells (Fig. 22.2). In addition to Dectin-1, Dectin-2 and Mincle may also recognize fungi, engage the ITAM adaptor FcRγ for SYK activation, and signal via the CARD9 pathway (Sato et al., 2006; Yamasaki et al., 2008).

By using an in vivo model based on cells from Card9$^{-/-}$ mice, it was demonstrated that the human wild-type CARD9 protein, but not the truncated CARD9 protein of patients carrying the Q295X mutation, reconstituted Dectin-1 mediated signaling in murine Card9$^{-/-}$ macrophages (Glocker et al., 2009). In parallel to *Card9*$^{-/-}$ mice, all patients with mutated CARD9 had reduced numbers of Th17 cells, compounding their increased susceptibility to fungal infections. This supports the observations that (1) CARD9-mediated signaling contributes to Th17 cell differentiation and (2) Th17 cells play a critical role in the defense against *Candida* in CMC patients (Conti et al., 2009; Eyerich et al., 2008).

The importance of Dectin-1 as pathogen recognition receptor (PRR) has been demonstrated not only in dectin-1–deficient mice, which are susceptible to infections with *C. albicans*, but also in human patients with a single point mutation in Dectin-1 leading to a premature stop codon, defective surface expression, and a reduced production of TNF, IL-6, and IL-17 (Ferwerda et al., 2009; Taylor et al., 2007). These patients suffered from recurrent vulvovaginal candidiasis and onychomycosis. Remarkably, there was no impact on fungal phagocytosis and intracellular killing (Ferwerda et al., 2009).

Thus, these rare human genetic deficiencies of Dectin-1- and CARD9 with susceptibility to fungal infections emphasize the need for intact Dectin-1/CARD9 signaling to maintain adequate antifungal defenses. Since candidiasis is relatively common, genetic defects impairing the Dectin-1/CARD9 signaling pathway may underlie susceptibility to fungal infection more frequently than previously appreciated.

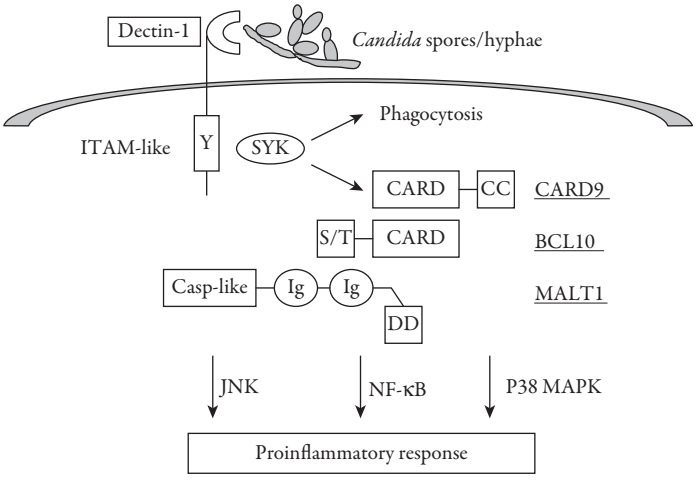

Figure 22.1 Summary of Dectin-1/CARD9 signaling pathway (modified after J. Ruland). CC, coiled-coil domain; S/T, serine/threonine-rich region; Ig, immunoglobulin repeat; DD, death domain.

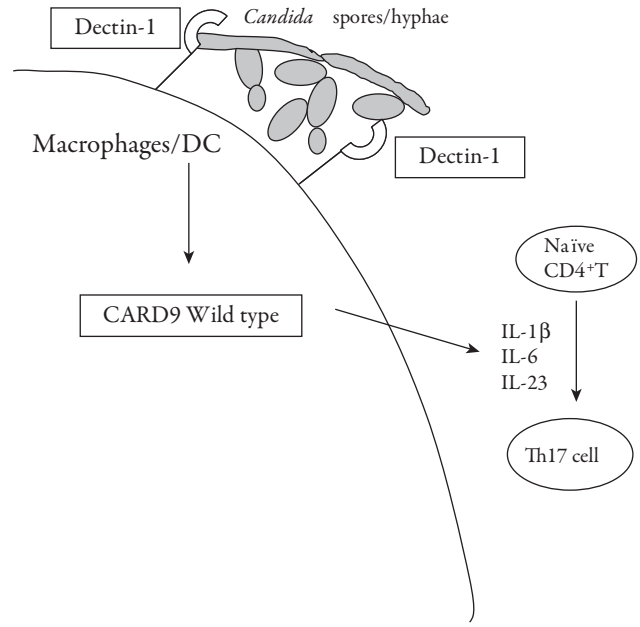

Figure 22.2 Generation of cytokines required for differentiation of naïve T cells toward Th17 cells. DC, dendritic cells.

SEVERE COMBINED IMMUNODEFICIENCY DUE TO ABSENT CORONIN-1A

Lawrence R. Shiow, Kenneth Paris, and Jennifer M. Puck

INTRODUCTION

The actin regulator Coronin-1 (also known as tryptophan-aspartate containing coat protein or TACO, ClipinA, or p57) is a cytoplasmic actin-binding protein predominantly expressed in hematopoietic cells (Su et al., 2004). Coronin-1A also binds to and inhibits the actin nucleating complex Arp2/3, which is critical for actin cytoskeleton branching. Normal T lineage cells express Coronin-1A, but lack other coronin family proteins with redundant function. Thus Coronin-1A deficient T-cells in both human and mouse are unable to remodel their actin cytoskeleton and consequently have impaired survival, signaling, and migration. B and natural killer (NK) cells are largely spared. Coronin-1A deficiency in humans (MIM #6050000) causes T lymphocyte impairment that may result in moderate combined immunodeficiency (CID) to severe combined immunodeficiency (SCID) similar to the murine ortholog (Shiow et al., 2008, 2009; Moshous et al., 2013).

CORONIN-1A STRUCTURE AND MOLECULAR FUNCTION

The *CORO1A* gene contains 11 exons and is located on human chromosome 16p11.2, a locus enriched with segmental duplications and prone to copy number variation (Martin et al., 2004; Stankiewicz et al., 2002). Coronin-1A is a 57 kDa protein with WD repeat domains near the N-terminus and a C-terminal coiled-coil domain. There is 95 percent amino acid sequence homology between human and mouse (Altschul et al., 1990). Coronin-1A WD repeat domains form a seven-bladed beta-propeller (Appleton et al., 2006). A conserved arginine residue near the N-terminus, displayed on the surface of the propeller, is required for binding to filamentous (F)-actin (Cai et al., 2007). The coiled-coil domain is thought to mediate homo-oligomerization of Coronin-1A (Oku et al., 2005). The molecular role of Coronin-1A in actin remodeling is similar to that of closely related and more ubiquitously expressed Coronin-1B. Both Coronin-1A and Coronin-1B share a conserved N-terminal phosphorylation site that regulates Arp2/3 binding (Cai et al., 2005, 2008; Foger et al., 2006).

Coronin-1A was co-purified with *phox* proteins responsible for generating reactive superoxides for phagosomes (Grogan et al., 1997). In *Mycobacterium bovis*-infected human macrophages, Coronin-1A was associated with F-actin at early phagosomes (Schuller et al., 2001). In a human leukemic T cells and mouse lymphocytes and macrophages, it co-localized with F-actin near the leading edge during cell migration and clustered with cross-linked T-cell receptor complexes (Combaluzier et al., 2009; Ferrari et al., 1999; Foger et al., 2006; Haraldsson et al., 2008; Jayachandran et al., 2007; Mueller et al., 2008; Mugnier et al., 2008; Nal et al., 2004; Shiow et al., 2008).

CLINICAL, IMMUNOLOGICAL, AND MOLECULAR FINDINGS

The first human with Coronin-1A deficiency was a girl who suffered from recurrent infections in her first year of life and had severe varicella following immunization with live attenuated varicella vaccine at age 13 months (Table 23.1) (Shiow et al., 2008, 2009). A chest CT scan showed a normal-sized thymus, unusual for SCID and similar to patients with interleukin-2 receptor alpha deficiency (Roifman, 2000), suggesting that the defect primarily affects thymocytes after the double-positive developmental stage. Indeed, this feature was also consistent with mouse models of Coronin-1A deficiency. The patient had reduced T-cell but normal B- and

Table 23.1 CLINICAL AND IMMUNOLOGICAL FEATURES OF CORONIN-1A DEFICIENCY

Growth and Development	Failure to thrive (Speech and motor delay, behavioral difficulties in one patient with concomitant interstitial deletion of chromosome 16p.11.2.)
Infections	Severe post-vaccination varicella Severe rotaviral diarrhea Recurrent otitis media Chronic pansinusitis Chronic pneumonia Oral thrush
Thymus	Present, normal in size
Lymphocyte Phenotype	Reduced CD3 T-cell number, B and NK cells present
Mitogenic Challenge	Reduced responses
Immunoglobulins	Normal total IgM and IgG Poor antibody responses to immunizations Poor primary and secondary responses to ΦX-174

NK-cell numbers. Proliferative responses to mitogens were low. While total serum immunoglobulin levels were normal, specific antibody responses to tetanus and pneumococcal antigens were poor. The patient also had a poor primary response and almost no secondary response when challenged with bacteriophage ΦX-174. Later in childhood she also had low-average to average cognitive functioning and attention-deficit/hyperactivity disorder (ADHD) that responded to stimulant medication.

Sequencing of genomic DNA revealed the patient had inherited from her father a 2 bp deletion in *CORO1A* at cDNA 248–249 (Shiow et al., 2008). This frameshift mutation resulted in a premature stop codon within the beta-propeller, predicted either to produce unstable mRNA or to destabilize protein folding. Coronin-1A protein was absent when assayed by Western blot and flow cytometric analysis. Maternal DNA showed a normal *CORO1A* sequence, but a genomic copy number microarray analysis (see Chapter 57; Fig. 57.2) determined that the patient had a de novo 600 kb deletion of her maternal chromosome 16p11.2, making her hemizygous for *CORO1A* (Shiow et al., 2009). The deleted interval, flanked by nearly identical segmental duplications, is known to be susceptible to copy number variation, with deletions and duplications associated with autism spectrum disorder and neurodevelopmental conditions, including ADHD (Kumar et al., 2008; Weiss et al., 2008).

Coronin-1A deficiency was also found by whole-exome sequencing in 3 siblings with intragenic mutations who exhibited similar immunodeficiency to that of the index case (Moshous et al., 2013).

TREATMENT

Despite medical management with antibiotics and intravenous immunoglobulin ,the original patient had failure to thrive with recurrent and progressive infections, particularly of the lungs. At 4 years of age she received a matched unrelated cord blood transplant resulting in full myeloid and lymphoid donor chimerism and complete immune reconstitution. By 6.5 years of age, she exhibited accelerated growth and resolution of pulmonary infiltrates. The three consanguimrous siblings all had T cell lymphopenia. While the oldest survived after treatment at 1 year of age for acular EBV-related orbital lymphoma, the other siblings, who developed B cell lympho Proliferation at 7.5 and 14 months, died from complications of chemotheraphy and hematopoietic cell transplantation, respectively. These individuals had a hemozygous V134M missense mutation that deerwassed, but did not abregate Coronin-1A activity.

MOUSE MODELS

Targeted disruption or hypomorphic mutations of Coronin-1A in mice result in T lymphocytopenia with sparing of B and NK cells (Foger et al., 2006; Haraldsson et al., 2008; Mueller et al., 2008; Mugnier et al., 2008; Shiow et al., 2008). In agreement with the thymus observed in the human patient, these mice have normal thymocyte numbers. Murine Coronin-1A deficiency results in late thymocyte developmental arrest at the mature single-positive stage (Foger et al., 2006) or impaired TCR signaling (Mueller et al., 2008; Mugnier et al., 2008). Thymocytes and T cells from Coronin-1A–defective mice also display impaired cellular migration to chemotactic cues (Foger et al., 2006; Shiow et al., 2008). The T cells display abnormal cellular protrusions when migrating in vitro and have impaired migration when tracked by two-photon microscopy of explanted lymph nodes (Shiow et al., 2008).

While Coronin-1A deficiency does reduce B-cell numbers, T-dependent antibody responses and germinal center formation are impaired (Combaluzier et al., 2009; Haraldsson et al., 2008; L. Shiow, unpublished observations). However, T-independent antibody production is not affected, suggesting that Coronin-1A is not critical for B-cell signaling. Redundancy with other coronin family members may explain why B, NK, and other leukocyte subsets do not require Coronin-1A for survival, signaling, and migration.

CONCLUSIONS AND FUTURE DIRECTION

Coronin-1A deficiency is the first SCID disease to be associated with actin cytoskeleton regulation. With its nonredundant and essential role in T-cell homeostasis and the *CORO1A* gene localization within a copy number variant locus, future cases of Coronin-1A deficient T^- B^+ NK^+ SCID are expected. Future studies of human T cells lacking Coronin-1A may shed light on how this molecule promotes cell survival. Further biochemical work on related coronins and studies in mouse models may further clarify mechanisms of actin cytoskeleton regulation. For example, Coronin-1A–deficient T cells

display varying degrees of TCR signaling abnormalities, failing to maximally flux calcium after exposure to anti-CD3 (Haraldsson et al., 2008; Mueller et al., 2008; Mugnier et al., 2008; Shiow et al., 2008). Analogously, in vitro studies with Coronin-1A–deficient B cells have demonstrated an antigen receptor-signaling defect that resolved with stronger co-stimulation (Combaluzier et al., 2009). Future work is needed to determine whether antibody defects reflect a primary role for Coronin-1A or are secondary to impaired T-cell help.

ACKNOWLEDGMENTS

The authors are grateful for the collaboration of Jason Cyster, Matthew Akana, and Ricardo Sorensen as well as the patient and her family; funding was obtained from UCSF Medical Scientist Training Program, Genentech Sandler Family Foundation, US Immunodeficiency Network, Jeffrey Modell Diagnostic Centers for Primary Immunodeficiency, and Howard Hughes Medical Institute.

24.

BRIEF INTRODUCTION TO B-LYMPHOCYTE DEFECTS

C. I. Edvard Smith

The B-cell lineage is affected in many forms of primary immunodeficiencies. Often this is due to a defect inherent to the B cell itself, but in an even greater number of disorders it is secondary to abnormal T lymphocytes, which cannot provide adequate signals for B lymphocytes to thrive. Thus, as a rule, altered B-cell populations accompany T-lymphocyte abnormalities.

The most classical B-lineage defect is X-linked agammaglobulinemia (XLA), which was first reported by Ogden C. Bruton in 1952 and was later shown to be caused by a differentiation defect, where patients essentially lack B lymphocytes and plasma cells (Chapter 25). In XLA the defect is inherent to the B-cell lineage. Because the disease gene is located on the X chromosome, XLA accounts for the majority of defects affecting pre-B-cell receptor (pre-BCR)/BCR signaling. These patients are highly susceptible to infections with pyogenic bacteria but also to enteroviruses, which in the healthy individual may be removed by circulating antibodies, but also following binding to immunoglobulins on the surface of B lymphocytes.

Over the past years, an increasing number of rare, autosomal recessive (AR) forms, currently affecting five different components of the pre-BCR/BCR, have been identified. These defects are described in Chapter 25 and are listed in Table 1.1 ("B. Deficiencies Predominantly Affecting Antibody Production"). Phenotypically they are often indistinguishable from the X-linked form but can be revealed through their different inheritance. A recently identified AR form of agammaglobulinemia is deficiency of the p85α subunit of PI3-kinase (Conley et al., 2012).

Mutations in the genes encoding the constant region of the heavy and kappa light chains, described in the 1980s, caused the first known immunodeficiencies specifically affecting the B-cell lineage. They are listed in sections B.2 and B.3, respectively, in Table 1.1. In contrast to patients lacking B lymphocytes, many individuals with heavy chain defects are healthy. The genetic abnormality is most often caused by gene deletions, and the absence of one gene product frequently seems to result in increased expression of other isotypes, likely having a compensatory effect. Because these defects only occasionally cause clinically manifest disease, they are not further described in any of the chapters.

The most common B-lineage defects are IgA deficiency and common variable immunodeficiency (CVID), described in Chapter 28. The underlying mechanisms remain elusive, although certain predisposing genes have been described. In particular, the *TACI* gene has been extensively studied in very large patient materials. Over the past few years, CVID-related diseases affecting genes encoding a B-cell–expressed CD (cluster of differentiation) marker have been described, namely those involving CD19, CD20, and CD81 (Chapter 28; see also Table 1.1, section B). A syndrome characterized by cold urticaria, and where 11 percent of patients also are diagnosed as having CVID, was recently reported (Ombrello et al., 2012) to originate from internal, in-frame deletions, resulting in a truncated, constitutively active form of phospholipase Cγ2 (Table 1.1; see the CVID section B.4). While it is likely that such mutations are rare, this points to the fact that highly unusual phenotypes may result from internal deletions also in other genes, considerably increasing the total number of immunodeficiencies. Complete inactivation of the *PLCG2* gene has not been reported to date, but the outcome, based on mouse studies, suggests that it may result in a phenotype severely affecting B-lymphocyte development. Similar to the effect of the internal deletion, it is likely that the phenotype is not restricted to the B-cell lineage (Faccio and Cremasco, 2010).

A reduced number of B cells expressing CD27, a "memory cell" marker, is a hallmark of patients with CVID, but the

underlying mechanism is not related to abnormalities in the *CD27* gene itself. Recently, however, patients with mutations in the gene for CD27 were found to suffer from severe Epstein-Barr virus (EBV) infections (van Montfrans et al., 2012). The defect does not seem to primarily impair B-lymphocyte function, but rather to affect the cellular immunity. For this reason CD27 deficiency is listed in Table 1.1 under the section "E.8 Familial hemophagocytic lymphohistiocytosis (FHL) and lymphoproliferative syndromes." These syndromes are also mentioned in Chapter 1, since they demonstrate that human beings are equipped with several genes to provide protection against otherwise lethal EBV infections.

Of great interest for B-cell biology are the defects of class-switch recombination and somatic hypermutation (Chapters 26 and 27). These disorders were initially named "dysgammaglobulinemia," with deficiency of 7S and elevated 19S gammaglobulins, and subsequently "hyper-IgM syndromes," because when first described in the early 1960s, the characteristic phenotype was one of increased serum IgM. However, while inefficient class-switching may cause this laboratory abnormality, the symptoms are secondary to the lack of IgA, IgG, and IgE, which cannot be expressed owing to the primary defect. Importantly, once the corresponding disease genes were cloned, it became immediately apparent that many affected patients present with hypogammaglobulinemia and normal or low serum IgM. So, even if the original name is still frequently being used, it should be replaced by the gene defect. Moreover, while all class-switch recombination abnormalities by definition affect B lymphocytes, the "classical" class-switch immunodeficiencies caused by mutated genes for the CD40 Ligand (CD40L) or CD40 primarily impair T-lymphocyte function. The affected patients are prone to develop opportunistic infections and malignancies, resulting in a more severe phenotype; they are listed in Table 1.1, section A.8. On the other hand, class-switch recombination syndromes affecting only B cells, exemplified by mutations in the AID and UNG genes, are generally milder and discussed in Chapter 27 (see section B.6 of Table 1.1).

X-LINKED AGAMMAGLOBULINEMIA AND AUTOSOMAL RECESSIVE AGAMMAGLOBULINEMIA

C. I. Edvard Smith and Mary Ellen Conley

X-linked agammaglobulinemiac (XLA) and the known forms of autosomal recessive agammaglobulinemia (ARA) are caused by a B-lymphocyte differentiation arrest. XLA was originally described in 1952 by the American physician Dr. (Colonel) Ogden C. Bruton (Bruton 1952). It is frequently recognized as the prototype primary immunodeficiency (Rosen et al., 1984); it was one of the first immunodeficiencies described and it was clearly the first for which a laboratory finding (absence of the gammaglobulin fraction on protein electrophoresis) dictated effective therapy (gammaglobulin). Both XLA and ARA are characterized by an increased susceptibility to extracellular bacterial infections (Conley et al., 2009; Lederman and Winkelstein, 1985; Lopez-Granados et al., 2002; Ochs and Smith, 1996; Sideras and Smith, 1995). Enteroviral infections also frequently run a severe course, often resist therapy, and may result in significant morbidity or death (Lederman and Winkelstein, 1985; Lopez-Granados et al., 2002; McKinney et al., 1987; Misbah et al., 1992; Ochs and Smith, 1996; Plebani et al., 2002, Winkelstein et al., 2006). Infections with mycoplasmas and giardia also occur more frequently (Franz et al., 1997; LoGalbo et al., 1982; Roifman et al., 1986).

Through different approaches, the gene affected in XLA, *BTK* (MIM 300300), was isolated simultaneously by two groups and found to encode a novel cytoplasmic tyrosine kinase designated *Bruton's agammaglobulinemia tyrosine kinase*, or BTK (Tsukada et al., 1993; Vetrie et al., 1993).

Mutations in the μ heavy chain gene (*IGHM*, MIM 147020), the first gene to be associated with ARA, were reported 3 years later (Yel et al., 1996) in seven patients who had a disorder very similar to XLA. Based on the hypothesis that mutations in other genes encoding components of the B-cell receptor (BCR) might cause agammaglobulinemia, mutations in the genes for λ5 (*IGLL1* MIM 146770), Igα (*CD79A* MIM 112205), and Igβ (*CD79B* MIM 147245) were sought and identified (Dobbs et al., 2007; Ferrari et al., 2007; Minegishi et al., 1998, 1999a). Mutations in the gene for the scaffold protein BLNK, which assembles signaling molecules downstream of the BCR, have also been associated with agammaglobulinemia (*BLNK* MIM 604515) (Minegishi et al., 1999c). On the whole, the different forms of ARA are phenocopies of XLA, although the patients with ARA tend to come to medical attention earlier and are more likely to have severe complications of agammaglobulinemia (Conley et al., 2005a; Lopez-Granados et al., 2002).

Bruton's initial report described an 8-year-old boy highly susceptible to bacterial infections, in particular *Streptococcus pneumoniae*, from the age of 4.5 years (Bruton, 1952a). As reviewed in greater detail (Sideras and Smith, 1995; Smith and Notarangelo, 1997), the electrophoretic analysis of serum, which had only recently been applied in a clinical setting, revealed the absence of detectable immunoglobulins (Ig). This finding prompted Bruton to coin the term *agammaglobulinemia*, a name that has been kept in spite of the observation that minute and sometimes even considerable amounts of Ig are detectable in some XLA patients. Bruton not only realized that there was a connection between the absence of Ig and the susceptibility to infections, he also initiated substitution treatment with subcutaneous γ-globulin and demonstrated its efficacy.

It has been noticed that the patient initially described by Bruton had some characteristics that are not typical for classical XLA (reviewed in Sideras and Smith, 1995). However, certain patients with XLA, as confirmed by mutation analysis, have a mild disease phenotype similar to, or even milder than, that of Bruton's case (Broides et al., 2006; Bykowsky et al., 1996; Jones et al., 1996; Hashimoto et al., 1999; Plebani et al., 2002; Saffran et al., 1994; Stewart et al., 2001; Vihinen et al., 1995a, 1996b, 2001; Wood et al., 2001). In a collaborative study, Bruton et al. reported on additional patients in whom the diagnosis of XLA seems indisputable (Bruton et al., 1952); more importantly,

the original report inspired a great number of investigators to look for patients with antibody deficiency. As a result, within a few years, many patients were identified worldwide not only with XLA but also with many other forms of Ig abnormality (reviewed in Good et al., 1962; Sideras and Smith, 1995). The recognition of different forms of antibody deficiency disease was a gradual process, and it was not until the late 1960s and early 1970s, when B cells were first recognized to express cell-surface Ig, that a classification as we know it today was generally accepted (Cooper et al., 1973; Naor et al., 1969).

Both XLA and ARA are characterized by an increased susceptibility to infections, with onset most often during the first year of life, when transferred maternal Ig has been catabolized. Analysis of serum demonstrates a pronounced decrease in Ig levels of all isotypes; IgA is usually undetectable. There is a virtual absence of humoral response to recall antigens. B-lymphocyte and plasma-cell numbers are markedly decreased, whereas other cell lineages are usually normal in number and phenotype. The defects in XLA and ARA cause a differentiation arrest confined to the B-cell lineage (Fig. 25.1), distinguishing XLA and ARA from several other Ig deficiencies. Collectively these mutations dampen or extinguish signaling from the pre-BCR/BCR resulting in similar phenotypes. B-lineage cells in all organs are affected, resulting in a reduced size of lymph nodes and tonsils. Approximately 85 percent of patients with lack of B lymphocytes and low, or absent, levels of Ig have mutations in the *BTK* gene (Conley et al., 1998). Another 5 percent have mutations in μ heavy chain, 4 to 5 percent have defects in λ5, Igα, Igβ, or BLNK, and the nature of the gene defect remains unknown in about 5 percent of patients (Conley et al., 2005b).

The defective gene in XLA encodes a cytoplasmic tyrosine kinase designated BTK in humans (and Btk in mice). The genes causing ARA, when mutated, are presented in Chapter 1, Table 1.1, Section B: Deficiencies Predominantly Affecting Antibody Production. Mutation analysis will confirm the diagnosis and may be used to identify healthy carriers. Treatment consists of antibiotics to combat ongoing infections and prevent infections and γ-globulin substitution as prophylaxis.

CLINICAL MANIFESTATIONS

INCIDENCE

The incidence of XLA has been investigated in several ethnic populations (Sideras and Smith, 1995; Toth et al., 2009; Winkelstein et al., 2006). In the United States the calculated frequency is at least 1/379,000 (Winkelstein et al., 2006). The possibility that there are ethnic differences in the incidence of XLA has been considered. In a Japanese survey by Hayakawa et al. (1981) only 56 XLA cases were reported. Low numbers were also found in Malaysia (Noh et al., 1995), in black populations in the United States and South Africa, as well as in an Eastern and Central European population (Toth et al., 2009). However, lethal X-linked traits are believed to occur by de novo mutations in approximately one third of the cases (Chase and Murphy, 1973; Haldane, 1935), a finding arguing against variations in mutation frequency among different ethnic populations. Rather, underreporting is more likely. In support of this notion, the number of Japanese patients with verified mutations in the *BTK* gene has increased considerably (Kanegane et al., 2001). However, delayed diagnosis in non-Caucasians has been reported (Conley and Howard, 2002) and may be due to reduced access to medical care and/or modifying genetic factors that influence the clinical phenotype. The incidence of all forms of ARA combined is approximately 5 in 10^7, although for the individual genes the number is considerably lower, with μ heavy chain gene mutations forming the largest group (Lopez-Granados et al., 2002), with a suggested incidence of 2.5 in 10^7. The various forms of ARA have been reported in all populations, but they occur more frequently in populations with a high index of consanguinity.

ONSET OF SYMPTOMS AND AGE AT DIAGNOSIS

In both XLA and ARA the onset of symptoms, mainly manifested as respiratory and/or gastrointestinal tract infections, is normally within the first year of life, after the disappearance of maternal IgG transported across the placenta. Among the 175 patients with XLA analyzed by Winkelstein et al. (2006), about 50 percent had symptoms during the first year. In a British study, which included 44 patients with XLA, 60 percent of affected boys had symptoms during their first year of life and 20 percent remained asymptomatic until the age of 3 to 5 years (Hermaszewski and Webster, 1993). In an Italian study of 73 patients with mutation-verified XLA, the mean age at onset of symptoms was 2 years (Plebani et al., 2002). The typical sites of infections in XLA are presented in Table 25.1. In reports from recent years there seems to be a tendency toward later onset of symptoms. This phenomenon

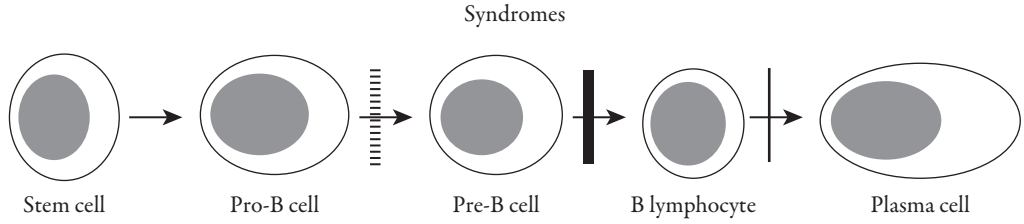

Figure 25.1 Schematic representation of B-lymphocyte development and the differentiation block/growth arrest in XLA. The broken line represents a partial block and the filled line an almost total block in B-lineage differentiation in XLA (modified from Mattsson et al., 1996). The thin broken line demonstrates the second block affecting B-cell differentiation as detected in mice with a targeted deletion of the *Btk* gene (Hendriks et al., 1996).

may be caused by a generous contemporary usage of more efficient antibiotics.

Winkelstein et al. (2006) reported a mean age at diagnosis of 2.6 years for patients with a family history of immunodeficiency and 5.4 years for those without. In patients with mutation-proven sporadic XLA, diagnosed between 1990 and 2001, Conley and Howard found that the mean age at diagnosis was 35 months but the median age was 26 months. They noted that the diagnosis of XLA in a patient without a family history of disease was usually made when the patient was hospitalized for a severe or unusual infection.

Although the mean age at the onset of symptoms has increased, the mean age at diagnosis of XLA has decreased in all populations (Hansel et al., 1987; Plebani et al., 2002). Moin et al. (2004) reported that the age at diagnosis in the Iranian population had decreased considerably over the past 30 years. This decrease can be attributed to increased awareness of the disease but also the availability of mutation detection with resulting carrier detection and early genetic analysis in families with a history of XLA.

A subset of patients with mutation-verified XLA is not recognized to have immunodeficiency until adulthood (Conley and Howard, 2002; Conley et al., 2008; Hashimoto et al., 1999; Kornfeld et al., 1996; Morwood et al., 2004; Stewart et al., 2001; Vihinen et al., 1995, 1996b, 2001; Wood et al., 2001). In some cases this is because the patient did not have symptoms severe enough to elicit an evaluation; in others symptoms were present but not pursued. It is noteworthy that onset may also vary among individuals within the same family carrying the same mutation in the *BTK* gene (Bykowsky et al., 1996; Kornfeld et al., 1996; Saffran et al., 1994; Wedgewood and Ochs, 1980), demonstrating that other factors may influence this process.

In general, patients with all forms of ARA have the onset of symptoms and are recognized to have immunodeficiency at an earlier age than patients with XLA (Conley et al., 2005b; Lopez-Granados et al., 2002). This can be attributed, at least in part, to the fact that XLA is a leaky defect in B-cell differentiation (Conley et al., 1985; Nomura et al., 2000; Noordzij et al., 2002; Tedder et al., 1985), whereas the block in B-cell development is more severe in patients with ARA. The mean age at diagnosis in 16 patients with μ heavy chain deficiency was 11 months (Lopez-Granados et al., 2002). However, there are exceptions. In 1955 Waldenström et al. (Kulneff et al., 1955) described two brothers and a distant cousin with agammaglobulinemia who were born between 1945 and 1949. Two of these patients survived into adulthood despite what would be considered by current standards inadequate gammaglobulin replacement. Later studies showed that these patients had mutations in μ heavy chain (Lopez Granados et al., 2002).

SPECTRUM OF INFECTIONS

The types of infection seen in patients with agammaglobulinemia are influenced by whether the patient is receiving replacement Ig therapy, the age of the patient, and the types of exposure the patient experiences. Almost all patients with agammaglobulinemia have recurrent upper and/or respiratory problems, and many have gastrointestinal infections (Conley and Howard, 2002; Hermaszewski and Webster, 1993; Lederman and Winkelstein 1985; Ochs and Smith, 1996; Winkelstein et al., 2006). In a high proportion of patients, particularly patients without a family history of disease, an evaluation for immunodeficiency occurs when the patient is hospitalized for a severe, complicated, or prolonged infection (Conley and Howard, 2002). After the initiation of Ig therapy, acute, severe infections are much less common (Howard et al., 2006; Quartier et al., 1999). However, low-grade, chronic, insidious infections and complications of agammaglobulinemia may compromise the quality of life in affected patients. Although rare patients with agammaglobulinemia develop opportunistic infections, such as *Pneumocystis jirovecii* pneumonia (Alibrahim et al., 1998; Kanegane et al., 2009; Rao and Gelfand, 1983) or JCV-mediated leukoencephalopathy (Bezrodnik et al., 1998; Teramoto et al., 2003), the most typical infections are those caused by encapsulated bacteria and enteroviruses.

Bacterial Infections

Bacterial infections are the major complications in XLA and ARA as well as other antibody deficiencies (Hermaszewski and Webster, 1993; Lederman and Winkelstein, 1985; Ochs and Smith, 1996; Spicket et al., 1991; Stiehm et al., 1986; Winkelstein et al., 2006). The typical sites of infections are presented in Table 25.1. In a survey of patients with XLA, Lederman and Winkelstein (1985) reported a history of respiratory tract and/or gastrointestinal tract infections in 91 percent of patients at the time of diagnosis. Similar findings were obtained by Hermaszewski and Webster (1993).

The most frequently observed organisms seen in patients with agammaglobulinemia include *H. influenzae* and *S. pneumoniae*. These organisms may cause sepsis, meningitis, cellulitis, pneumonia, arthritis, otitis, sinusitis, and/or conjunctivitis. Since the availability of the conjugated *H. influenzae* vaccine in the late 1980s and early 1990s, serious infections with *H. influenzae* have almost disappeared in otherwise healthy children. Sepsis, meningitis, or cellulitis due to *H. influenzae* in a vaccinated child should elicit an evaluation for antibody deficiency. After the initiation of Ig therapy, the incidence of serious infections with *H. influenzae* and *S. pneumoniae* decreases, but the majority of patients continue to have problems with otitis, sinusitis, and/or conjunctivitis (Howard et al., 2006; Winkelstein et al., 2006).

Pseudomonas or staphylococcal sepsis is a relatively common presenting finding in patients with agammaglobulinemia. This association, first recognized as early as 1963 (Speirs et al., 1963), occurs more often in patients less than 1 year of age and almost exclusively in patients with neutropenia (Conley and Howard 2002; Farrar et al., 1996; Kanegane et al., 2005; Lopez-Granados et al., 2002). Neutropenia and sepsis are not usually seen in patients receiving adequate Ig therapy.

Infections with the nonsporulating gram-negative rod *Campylobacter jejuni* have been reported to cause sepsis, gastrointestinal disease, erysipelas-like skin lesions, pericarditis, and recurrent fever in patients with agammaglobulinemia (Kerstens et al., 1992; Rafi and Matz, 2002). The diarrhea may be of long duration, but in some cases patients are asymptomatic (Chusid et al., 1987; Hermaszewski and Webster, 1993; Melamed et al., 1983; Schuster et al., 1996; van der Meer et al., 1986). Excretion of *C. jejuni* in the stool, which in untreated nonimmunodeficient subjects normally persists for 2 to 3 weeks, may be prolonged.

Infection with fastidious organisms related to *C. jejuni,* such as *H. cinaedi* (previously known as *C. cinaedi*) or *Flexispira rapini*, has been reported in patients with XLA who are on therapeutic doses of Ig (Cuccherini et al., 2000; Gerrard et al., 2001; Simons et al., 2004, and personal observation). Patients often have the insidious onset of lower extremity swelling with woody induration and pigmentation in the affected areas. Thrombophlebitis and necrosing skin lesions can develop. Signs of infection are initially minimal with no fever and no warmth in the affected area. The erythrocyte sedimentation rate (ESR) is usually elevated and there is mild anemia of chronic disease. These organisms are very difficult to culture and require prolonged therapy, often with intravenous antibiotics.

Systemic *Ureaplasma urealyticum* infections or infections with other *Mycoplasma* species are also frequent and may primarily cause symptoms in the respiratory tract, joints, and urogenital tract (Gelfand, 1993; Hermaszewski and Webster, 1993; Lederman and Winkelstein, 1985; Roifman et al., 1986; Stuckey et al., 1978; Webster et al., 1978). These organisms are often difficult to identify, and the course of disease may be prolonged, with an insidious onset. Symptoms may be severe, with accompanying weight loss. Combined infections of *Mycoplasma* and other bacterial species may also contribute to disease severity. Urogenital tract infections can cause urethral strictures and result in epididymitis and prostatitis (Hermaszewski and Webster, 1993; Ochs and Smith, 1996).

Viral Infections

Most viral infections run a normal course in XLA and ARA (Conley et al., 2009; Janeway et al., 1953; Lederman and Winkelstein, 1985; Ochs and Smith, 1996). There is no evidence to suggest that the members of the herpes family, such as cytomegalovirus (CMV), varicella, or Epstein-Barr virus (EBV), cause unusual problems in patients with agammaglobulinemia. Patients with XLA who acquired hepatitis C from contaminated IVIG did not have an unusually severe course of disease, in contrast to many patients with CVID (Adams et al., 1997; Bjørø et al., 1994; Razvi et al., 2001). There may be a slight increase in the severity of some viral infections in the first few years of life; Conley and Howard (2002) found that a high percentage of patients with sporadic XLA had been hospitalized for a viral infection prior to diagnosis. However, these infections were not severe enough to elicit concern about immunodeficiency. The neutropenia with sepsis seen as presenting findings in patients with XLA or ARA may be due to a higher incidence of viral-induced bone marrow suppression in patients who lack natural antibodies. After the development of T-cell immunity, these infections are less troublesome. By contrast, infections with enteroviruses, including poliovirus, echoviruses, and coxsackievirus, can cause chronic meningoencephalitis and sometimes a dermatomyositis/fasciitis-like syndrome in a subset of patients with agammaglobulinemia (Lopez Granados, 2002; McKinney et al., 1987; Misbah et al., 1992; Wyatt, 1973).

The incidence of chronic enteroviral infection in the current era is markedly decreased compared to that seen 20 to 30 years ago. This is most likely due to our ability to provide normal concentrations of serum IgG with newer preparations of gammaglobulin. However, a few patients who have been treated with adequate doses of Ig have developed progressive encephalitis with documented enteroviral infection (Misbah et al., 1992; Quartier et al., 1999, 2000), and others have developed progressive neurological disease of unclear etiology (Ziegner et al., 2002) that may be caused by enterovirus. It is possible that these patients acquired the enteroviral infection before they were started on Ig therapy. Patients with immunodeficiency may harbor vaccine-associated poliovirus for many years before they develop symptoms (DeVries et al., 2011; MacLennan et al., 2004). The same may be true for echovirus, the most common cause of progressive enteroviral encephalitis in patients with agammaglobulinemia (McKinney et al., 1987).

The presentation of enteroviral encephalitis in patients with agammaglobulinemia is quite variable. Although some

patients have an acute onset of fever and headache, an insidious onset is more common. Patients may show behavior changes, declining cognitive skills, hearing loss, ataxia, paresthesias, or seizures (McKinney et al., 1987). Some but not all patients have an increased number of lymphocytes in the cerebral spinal fluid (CSF). The protein and glucose may be normal, but more often the protein is increased and the glucose is decreased. Early in the course of the disease imaging studies with magnetic resonance imaging (MRI) or computed tomography (CT) may be normal, but later studies show cerebral atrophy affecting both gray and white matter. PCR may identify enterovirus in CSF samples that are negative in viral cultures (Quartier et al., 2000; Rotbart et al., 1990); however, PCR may be negative, especially in patients being treated with adequate or high doses of Ig (personal observation).

Enteroviral infection may also present as a dermatomyositis-like syndrome associated with dissemination of enterovirus (McKinney et al., 1987; Thyss et al., 1990). This form of the disease is characterized by peripheral edema, erythematous rash, and evidence of inflammation in skin and muscle biopsy specimens. The infection in the central nervous system seems to occur prior to dissemination of the virus. Edema or myositis with fasciitis may be found as the only manifestation of viral dissemination. Enteroviral hepatitis resulting in hepatomegaly and an increase in liver enzymes such as alanine aminotransferase are frequently seen in affected patients, usually associated with erythematous rashes and fever.

Vaccine-associated polio can be the cause of paralysis and chronic progressive enteroviral encephalitis in patients with agammaglobulinemia; however, not all patients with agammaglobulinemia who receive live polio vaccine acquire symptomatic disease (Wyatt, 1973). During the period in which babies routinely received the live Sabin vaccine at 2, 4, 6, and 18 months of age, approximately 2 to 5 percent of patients with hypogammaglobulinemia showed clinical signs of disease. Wyatt estimated that this was similar to the percentage of otherwise healthy children who developed polio after exposure to wild-type virus. The factors that make some patients more vulnerable to enteroviral infection are unknown but are likely to include modifying genetic factors.

The clinical course of enteroviral encephalitis, including vaccine-induced polio, is quite variable. Some patients have rapidly progressive disease whereas others demonstrate a slow decline characterized by periodic exacerbations followed by periods of stable disease lasting as long as 20 years. At autopsy the histological appearance is sometimes consistent with that seen in an end-stage, severe encephalitic process of long duration (Fig 25.2). Some patients with polio, even wild-type polio, have spontaneous recovery. At least two adults with XLA had wild-type polio as children in the 1950s and were left with some residual weakness but recovered before they were recognized to have immunodeficiency (Conley and Howard, 2002; Sarpong et al., 2002).

Treatment for patients with chronic enteroviral encephalitis is inadequate. Most would agree that higher doses of therapeutic Ig are warranted in affected patients, but some patients progress despite this (Misbah et al., 1992). Intraventricular or intrathecal Ig has been used (Erlendsson et al., 1985; Johnson et al., 1985; Kondoh et al., 1987; Misbah et al., 1992; Quartier et al., 1999, 2000), but this therapy is associated with a high risk of bacterial contamination of the reservoir, and the evidence that it is effective is weak. Ribavirin, an antiviral drug, has been used but does not appear to clear the virus (MacLennan et al., 2004; Misbah et al., 1992; Thibaut et al., 2011). Some success has been reported with the use of an experimental antiviral drug, Pleconaril (Rotbart and Webster, 2001).

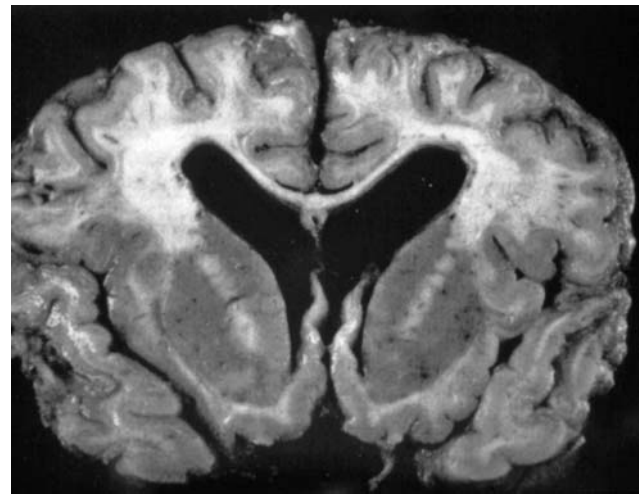

Figure 25.2 Whole-brain section of a patient with XLA having an enteroviral infection presumably contracted at 8 years of age. Autopsy performed at 17 years of age, after several years of progressing dementia, shows severe thinning of the cerebral cortex, reduced subcortical and deep white matter, and marked dilatation of the lateral ventricles. (Reproduced from Rudge et al., 1996).

CHRONIC AND RECURRENT DIARRHEA

Gastrointestinal infection caused by the flagellate *Giardia lamblia* has been found in many patients with XLA or ARA, although it appears to be more common in CVID (Hermaszewski and Webster, 1993; Lavilla et al., 1993; LoGalbo et al., 1982; Ochs et al., 1972). Winkelstein et al. (2006) reported that 12 of 46 XLA patients with chronic or recurrent diarrhea had a *G. lamblia* infection. In patients with XLA or ARA, giardia infection may not be associated with typical abdominal pain and diarrhea. Instead, malaise, fatigue, and an unexpectedly low concentration of serum IgG may be the early signs of infection. It is often very hard to eradicate giardia in these patients. Other causes of diarrhea in patients with agammaglobulinemia have included rotavirus, *Campylobacter fetus*, enterovirus, *Salmonella*, and cryptosporidia (Winkelstein et al., 2006, and personal observation).

ARTHRITIS

Arthritis was relatively common in patients with XLA in the 1960s and 1970s but is less common in the current era. Arthritis may be the presenting symptom and has been mistaken for chronic juvenile arthritis (Hansel et al., 1987). The arthritis is normally nonseptic and monoarthritic and affects the large joints, causing hydroarthritis with relatively little

pain (McLaughlin et al., 1972; Ochs and Smith, 1996). The arthritis frequently responds to gammaglobulin treatment (Plebani et al., 2002; Webster et al., 1976), and there is usually no apparent joint destruction. Residual IgG levels above 8 g/L were associated with improvement of clinical symptoms, whereas in patients with 5 to 8 g/L recurrences were seen (Quartier et al., 1999). The ESR is normal, as are the results of serological tests for rheumatoid factor and antinuclear antibodies. (Because these patients essentially lack immunoglobulins, autoantibody analysis is of no value.) Lederman and Winkelstein (1985) reported arthritis, including polyarthritis, in 20 percent of XLA patients. Less than half of the episodes were due to acute pyogenic infections. Conley and Howard (2002) reported pneumococcal arthritis in two patients diagnosed after 40 months of age. Enteroviruses or *Mycoplasma* species have also been identified in affected joints from some patients (Ackerson et al., 1987; Hermaszewski and Webster, 1993). An atypical case of rheumatoid arthritis with infiltrating CD8 cells and a case of psoriatic arthritis have been reported (Palazzi et al., 2003; Verbruggen et al., 2005).

AUTOIMMUNITY

In contrast to CVID (Cunningham-Rundles et al., 1987; Hermaszewski et al., 1991), XLA and ARA do not seem to predispose to most autoimmune disorders (Sideras and Smith, 1995). Type 1 diabetes has been reported in only a single patient with XLA, suggesting that humoral immunity is of great importance for the development of this form of autoimmunity (Martin et al., 2001). As mentioned in the section on arthritis above, cases of rheumatoid and psoriatic arthritis in XLA have also been reported (Palazzi et al., 2003;Verbruggen et al., 2005). However, inflammatory bowel disease (IBD) or a protein-losing enteropathy with features similar to IBD may be seen in 5 to 10 percent of patients with XLA or ARA (Cellier et al., 2000; Hermaszewski & Webster, 1993; Minegishi et al., 1999; Norman et al., 1975; Washington et al., 1996).

In some patients with agammaglobulinemia, classical signs of IBD may follow a documented infection with Giardia, enterovirus, or another pathogen. After the pathogen has been cleared, the patient may continue to have poor weight gain, abdominal pain, and low serum IgG despite adequate doses of therapeutic Ig. In other patients, no prior infection is identified. Aggressive immunosuppression, including high doses of steroids and an antimetabolite, is generally necessary to control the IBD. Concurrent therapy with antimicrobials may be helpful. Anti-TNF therapy does not appear to be useful in these patients.

ALLERGIC REACTIONS

Although one would expect patients with XLA or ARA to be free from typical allergies, patients occasionally develop seasonal allergies characterized by conjunctivitis and rhinorrhea; other patients have documented drug allergies. These patients have not had detectable serum IgE (personal observation). Kudva-Patel et al. (2002) described a patient with XLA who developed a diffuse, maculopapular rash with pruritus, hyperthermia, flushing, and lethargy after treatment with intravenous ceftriaxone; after drug challenge, the symptoms recurred. A skin biopsy showed the presence of infiltrating $CD4^+$, $CD45RO^+$ memory T cells in the absence of detectable IgE.

TUMORS

The question of whether there is an increased risk of malignancy in patients with XLA has not been resolved. Patients reported before 1993, when the gene responsible for XLA was identified, may have had one of the disorders that masquerades as XLA rather than XLA. Disorders associated with malignancy that can be similar to XLA include X-linked lymphoproliferative disease, CVID, and myelodysplasia.

There is some evidence for an increased incidence of gastrointestinal adenocarcinoma in patients with XLA. Van der Meer et al. (1993) described three patients with XLA and rectal adenocarcinoma. These patients, who were less than 40 years old, all had an extensive family history of XLA or a proven mutation in the *BTK* gene. Brosens et al. (2008) reported two cases of colonic adenocarcinoma in young men with mutations in *BTK*. Two young men with well-documented XLA and gastric carcinoma have been reported (Bachmeyer et al., 2000; Lavilla et al., 1993). We are aware of five additional XLA patients with adenocarcinoma of the gastrointestinal tract, all relatively young men. Some but not all of these men have had chronic gastrointestinal infection. Based on the observations that gastrointestinal adenocarcinoma is typically a malignancy of patients over 50 years of age, all of the reported XLA patients with this diagnosis have been less than 50 years old, and the relatively small number of patients with XLA who have reached adulthood, it is likely that there is an increased incidence of this cancer in patients with XLA. Adults with XLA, particularly those who have had chronic gastrointestinal infection, should be screened for colon cancer at a younger age than otherwise healthy individuals.

The basis of the increased risk of gastrointestinal cancer in patients with XLA is not clear. Chronic infection may lead to inflammation and dysplasia (van der Meer et al., 1993). There is likely to be altered gut flora in these patients due to their disease and antibiotic therapy. Glutathione-S-transferase activity has been found to significantly correlate with intestinal tumor incidence in humans, and decreased levels were identified in patients with XLA (Grubben et al., 2000). It is worth noting that human adenocarcinoma cell lines do not express BTK (Smith et al., 1994a).

A few XLA patients with other malignancies have been reported. Two patients with pituitary adenoma have been identified (Hermaszewski and Webster, 1993; Ochs and Smith, 1996). Von Recklinghausen disease was diagnosed at the age of 33 in one patient (Hirata et al., 2002). T-cell lymphomas were observed in two patients (Howard et al., 2006; Kanavaros et al., 2001). Squamous lung cancer has been reported in a 32-year-old patient with XLA (Echave-Sustaeta et al., 2001), and one patient with XLA has been diagnosed with osteosarcoma (personal observation).

No malignancies have been reported in ARA; however, the total number of patients identified is relatively small, and few of those patients have reached adulthood. If the malignancies in XLA are due to chronic inflammation, one would expect the incidence of tumors to be similar or greater in patients with ARA.

BTK has been implicated as tumor-inducing through an effect dependent on different splice variants induced by the fusion protein Bcr-Abl (Feldhahn et al., 2005a, 2005b). However, while the SH3 domain of BTK may serve as a substrate for the Abl cytoplasmic tyrosine kinase (Bäckesjö et al., 2002), a recent study found no evidence for a connection to tumors (MacPartlin et al., 2008).

Initial studies of patients with various forms of B-lymphoid tumors did not indicate any abnormal expression of BTK (Katz et al., 1994; Vorechovsky et al., 1994b). Furthermore, an increased frequency of chromosomal aberrations in the Xq22 region (in which the *BTK* gene is located) has to date not been reported in B-lineage tumors.

CAUSES OF DEATH

The causes of death in patients with XLA have changed over the years. Family studies suggest that patients who were born before 1960 often died suddenly at less than 5 years of age, most likely due to an acute bacterial infection. Although this still occurs, particularly in patients who are not yet receiving Ig replacement (Conley and Howard, 2002; Kanegane et al., 2005), it is uncommon in the current era. In surveys published before 1996 that included 170 patients with XLA, a total of 29 deaths were reported (Hermaszewski and Webster, 1993; Lederman and Winkelstein, 1985; Ochs and Smith, 1996). Twelve of these deaths were attributed to enteroviral infection, most often echovirus but also including coxsackievirus and vaccine-associated poliovirus. Chronic pulmonary disease was responsible for another nine deaths. Three patients died of hepatitis and the remaining patients died of other infections or inflammatory disease. Fatal adenocarcinoma of the gastrointestinal tract has been reported in patients with XLA (Bachmeyer et al., 2000; van der Meer, 1993).

In a more recent study that included 201 patients with XLA, Winkelstein et al. (2006) reported 17 deaths, 10 of which occurred after 1995. These more recent deaths included three patients with echovirus encephalitis and another young patient who died of myocarditis, perhaps due to coxsackievirus. Two patients died of chronic lung disease. Renal failure, hepatitis, adenoviral encephalitis, and complications of stem cell transplant were each responsible for one death. The causes of death were more diverse in a group of 10 adults reported by Howard et al. (2006). Only a single patient died of enteroviral encephalitis, and two died of chronic lung disease. Liver failure was the cause of death in four patients, three of whom had documented hepatitis C infection. The hepatitis C was acquired in the mid-1980s when several preparations of IVIG were contaminated with the virus. Although some patients with XLA or ARA may still have disease related to that contamination, one would expect the incidence of hepatitis C to decrease. One patient in that group died of T-cell lymphoma, one patient with inflammatory bowel disease died of a perforated bowel, and one died of a recreational drug overdose. As a higher proportion of patients with XLA are surviving into middle age and beyond, one would expect a greater proportion of patients with XLA to die of causes unrelated to their immunodeficiency.

Patients with ARA have died of enteroviral encephalitis and sepsis (Lopez-Granados et al., 2002, and personal observation). However, like the patients with XLA, many of those who were recognized to have immunodeficiency at an early age and who have been compliant with medical care have not had major problems.

LABORATORY FINDINGS

Patients with XLA and ARA generally have normal complete blood counts and serum chemistries. However, as noted above, profound neutropenia can be seen in patients who have not yet been started on adequate gammaglobulin replacement therapy (Buckley and Rowlands, 1973; Conley and Howard, 2002; Farrar et al., 1996). This neutropenia is unlikely to be caused by the absence of BTK in the myeloid lineage because neutropenia at presentation is more common in patients with ARA compared to those with XLA (Conley et al., 2005a), and most of the genes responsible for ARA are expressed exclusively in B-lineage cells. A low globulin fraction with normal serum albumin might alert the physician to the diagnosis of agammaglobulinemia.

The concentration of all serum Ig isotypes is markedly decreased in patients with agammaglobulinemia and the serum IgM and IgA are usually undetectable by a clinical laboratory (Table 25.2). Most patients with XLA have a small amount of measurable IgG and some patients have near-normal concentrations of IgG (Bykowsky et al., 1996; Conley and Puck, 1988; Plebani et al., 2002; Saffran et al., 1994, Wood et al., 2001). The serum IgM may be at the lower range of normal before gammaglobulin therapy is started, but it often decreases to less than 20 mg/dL after the initiation of treatment. Antibody to vaccine antigens is generally absent in patients with XLA and ARA, but there are rare exceptions (Conley et al., 2008; Wood et al., 2001).

The most characteristic laboratory finding in XLA and ARA is the marked reduction in the number and percentage of B cells (Table 25.2) in the peripheral circulation (Conley, 1985; Conley et al., 2005a; Cooper and Lawton, 1972; Naor et al., 1969; Sideras and Smith, 1995; Siegal et al., 1972; Yel et al., 1996). Most patients with XLA, particularly patients who are less than 10 years old, have a very small number of B cells in the blood (<1 percent of the total lymphocytes). These B cells have a distinctive phenotype characterized by increased expression of surface IgM and decreased expression of CD19 (Conley 1985; Dobbs et al., 2007). Most of these cells can be brightly stained for CD38 and CD24, which marks them as transitional B cells, B cells that have recently emigrated from the bone marrow (Cuss et al., 2006; Suryani et al., 2010).

Patients with XLA, ARA, or CVID with low numbers of B cells have reduced T-memory cells as detected by CD45RO

Table 25.2 CHARACTERISTIC LABORATORY FINDINGS IN PATIENTS WITH X-LINKED AGAMMAGLOBULINEMIA

SERUM IG LEVELS*	IGM	IGG	IGA
(g/L)	<0.1	<2	Often undetectable
Isohemagglutinins†	Undetectable		
Antibody responses to foreign antigens†	Undetectable or markedly reduced		
Peripheral blood‡	CD19	CD20	Surface Ig+
B-lymphocyte markers	<2%	<2%	<2%

*Normal values vary somewhat among different laboratories but are typically as follows: IgM: 0.5–2 g/L; IgG, 7–16 g/L; IgA: 0.5–3 g/L in adults. Normal values for IgA may vary extensively until adolescence. The IgG level is typically >4 g/L at all ages. In the newborn it is similar to what is seen in adults, as a consequence of placental transfer; it will thereafter decrease until about 6 months of age.

†Analysis is not obligatory for diagnosis, but it is recommended in patients having essentially normal Ig levels. For definitive diagnosis of XLA, mutation analysis has to be carried out.

‡Normal values vary somewhat among different laboratories, but are typically 5 to 20 percent, corresponding to $0.08–0.4 \cdot 10^9$ cells/L. As surface Ig determination may be influenced by Fc receptor binding, the inclusion of CD marker analysis is recommended.

(Martini et al., 2011); however, it is not clear that this has an effect on T-cell function. There are reports indicating that antigen-specific T memory is normal in XLA (Paroli et al., 2002; Plebani et al., 1997), but there are also studies indicating that T-cell memory to some antigens may be impaired (Morales-Aza et al., 2009).

B cells make up the major cell type in germinal follicles, and germinal follicles constitute much of the bulk of lymph nodes. In patients with ARA or XLA lymph nodes, tonsils and adenoids are very small and germinal follicles are absent on histological analysis (Good, 1954; Sideras and Smith, 1995). In the lamina propria of the gut, plasma cells are typically absent (Ament et al., 1973; Buckley and Rowlands, 1973; Ochs et al., 1972; Pan et al., 2002).

Analysis of bone marrow from patients with XLA or one of the known forms of ARA has revealed a maturation block between terminal deoxynucleotidyl transferase (TdT) Cμ-negative pro-B-cells and Cμ-positive pre-B-cells (Campana et al., 1990; Nomura et al., 2000; Noordzij et al., 2002a). The severity of the block in XLA is variable, and a few pre-B-cells are seen in most patients. The proliferative activity of these pre-B-cells is impaired (Campana et al., 1990; Noordzij et al., 2002a; Pearl et al., 1978). The block in B-cell differentiation is more severe in most patients with ARA (Ferrari et al., 2007; Minegishi et al., 1998, 1999; Yel et al., 1996).

MOLECULAR BASIS OF X-LINKED AGAMMAGLOBULINEMIA

THE GENE DEFECTIVE IN X-LINKED AGAMMAGLOBULINEMIA ENCODES A TYROSINE KINASE

The molecular basis of XLA was identified using two different modes of gene cloning: positional cloning by applying cDNA selection on yeast artificial chromosomes from the implicated region, and investigation of novel protein tyrosine kinases (PTKs) expressed in B lymphocytes (Tsukada et al., 1993; Vetrie et al., 1993). These studies demonstrated that a gene, *BTK*, encoding a novel cytoplasmic PTK was defective in XLA. PTKs are enzymes that catalyze the phosphorylation of tyrosine residues in proteins with ATP as phosphate donor and belong to the enzyme classification (EC) group EC 2.7.1.112. PTKs are subdivided into receptor PTKs, which are membrane-spanning proteins such as the receptor for platelet-derived growth factor (PDGF), and cytoplasmic or nonreceptor PTKs, exemplified by the cellular homolog of Rous sarcoma virus, c-Src (Manning et al., 2002). In humans there are 58 receptor and 32 nonreceptor PTKs.

When the *BTK* gene was isolated, it was the first time a cytoplasmic PTK was implicated in a hereditary human disease. Subsequently, mutations in the genes encoding ITK, JAK3, and ZAP-70 cytoplasmic kinases have been shown to cause primary immunodeficiency (see Chapters 1, 10, and 15, respectively).

BTK is composed of 659 amino acids with a total molecular weight of 77 kDa; the corresponding mRNA is normally found as a single species of 2.7 kb (Smith et al., 1994b; Tsukada et al., 1993; Vetrie et al., 1993). BTK carries three domains, which are also found in SRC. These are from the C-terminus, the kinase domain of about 280 amino acids, also referred to as *SRC homology 1* (SH1); a region of about 100 residues, which binds to phosphorylated tyrosine residues, designated SH2; and a domain of about 65 amino acids known to interact with proline-rich stretches, referred to as SH3 (Pawson, 1995).

In addition, BTK contains two regions in the N-terminus, designated *Pleckstrin homology* (PH), with 140 amino acids, and *Tec homology* (TH), containing approximately 80 residues. The PH domain is found in more than 100 proteins and is believed to have a membrane-targeting function (Rameh et al., 1997; Salim et al., 1996). The TH region is composed

of an extension of the PH domain, designated the *Btk motif* (27 residues), and a proline-rich stretch (Smith et al., 1994b; Vihinen et al., 1994b). The Btk motif in the TH region has been shown to bind a Zn^{2+} ion (Vihinen et al., 1997b). This region was named after TEC, which was the first member identified in the family of PTKs to which BTK belongs (Mano et al., 1990). The other family members are ITK (also called TSK and EMT) and BMX (also called ETK). The kinase TXK (also RLK) lacks the PH domain but is related to the TEC family of kinases.

Mutations in ITK have recently been reported in five members of two different families (Huck et al., 2009; Stepensky et al., 2011). All five patients developed severe immune dysregulation with B-cell proliferation or Hodgkin's lymphoma after EBV infection. Disease-causing, loss-of-function mutations have not been reported for any of the other TEC family members to date. For comprehensive reviews of the TEC family see Hussain et al., 2011; Smith et al., 2001, and Takesono et al., 2002.

CHROMOSOMAL REGION CONTAINING THE *BTK* GENE AND DELETIONS EXTENDING INTO THE *TIMM8A*, *TAF7L*, AND *DRP2* GENES

The human *BTK* gene is located on the long arm of the X chromosome in a region designated Xq22.1 (Fig. 25.3). It is transcribed in a telomere (→) centromere direction (Vorechovsky et al., 1994a) and encompasses 37.5 kb (Hagemann et al., 1994; Ohta et al., 1994; Rohrer et al., 1994; Sideras et al., 1994), as depicted in Figure 25.3. Use of cDNA selection technology enabled identification of several RNA species expressed from this region in B cells and in B-cell progenitors (Vorechovsky et al., 1994a). A deletion extending into the closest flanking gene, the centromerically located gene initially referred to as *DXS1274E*, was found in a family with XLA and sensorineural deafness (Vorechovsky et al., 1994a). Mutations in this gene, later renamed *DDP* (deafness dystonia protein) and subsequently officially renamed *TIMM8A* (Translocase of inner mitochondrial membrane 8 homolog A), because it encodes a conserved mitochondrial protein, were found to cause Mohr-Tranebjaerg syndrome (Jin et al., 1996). Subsequently, patients with various deletions extending from the *BTK* gene into the *DDP* gene have been reported (Richter et al., 2001; Sediva et al., 2007). Moreover, two families have been described with deletions encompassing four genes, *BTK*, *TIMM8A*, *TAF7L*, and *DRP2* (Jyonouchi et al., 2007; Sediva et al., 2007). The phenotype of the extended deletion does not differ from patients with BTK and TIMM8A deficiency; however, it is likely that spermatogenesis is impaired in patients with TAF7L deficiency. A map of this chromosomal region is depicted in Figure 25.3.

GENOMIC ORGANIZATION OF THE *BTK* GENE

BTK was the first member of the TEC family for which the genomic organization was established. The human *BTK* gene comprises 19 exons, including a 5′ untranslated region (exon 1) and a 3′ exon containing both the C-terminal coding and a 3′ untranslated part (Hagemann et al., 1994; Rohrer et al., 1994; Sideras et al., 1994), as depicted in Figure 25.3. The size of the exons varies from 55 to 560 bp, and the introns range from 164 bp to 9 kb. In the mouse, a similar genomic organization was observed (Sideras et al., 1994), the difference being mainly an increased size of introns 4 and 12. The number of exons is identical in humans and mice, as are the exon–intron boundaries. Furthermore, the human, mouse, and rat BTK proteins are highly conserved, being 98 to 99 percent identical at the amino acid level (Lindvall et al., 2005; Sideras et al., 1994).

The promoter region of the *BTK* gene was initially inferred from sequence motifs in the DNA stretch 5' of the start site (Sideras et al., 1994). Through functional analysis of this region, binding sites for members of four families of transcription factors have been identified, Sp1/3, Spi-B/PU.1, and OCT1/OBF1 and nuclear factor (NF)-κB, all of which have been shown to bind and activate transcription (Himmelmann et al., 1996; Müller et al., 1996, 1999; Yu et al., 2008). Tissue specificity seems to be provided by the Spi-1/PU. 1 factors, which are selectively expressed among hematopoietic cells. BTK is expressed in all hematopoietic cells with the exception of T cells and plasma cells. This indicates that the *BTK* gene is turned on early during differentiation, and of note is that BTK expression has been observed in cells carrying the early progenitor marker CD34 (Smith et al., 1994a).

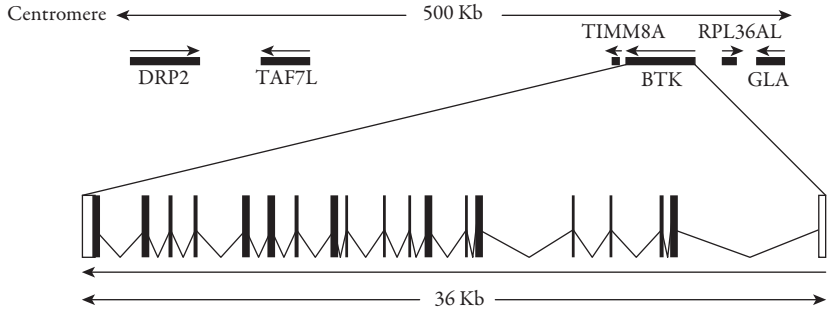

Figure 25.3 Physical map of the Xq22.1 region showing the *BTK* gene and adjacent genes (top) and how they are transcribed. Deletions encompassing the 3′ end of the *BTK* gene and extending into the *TIMM8A* gene cause XLA and Mohr-Tranebjaerg syndrome. Below is the organization of the *BTK* gene, showing the 19 exons. Filled squares represent translated exonic regions.

FUNCTIONAL ASPECTS OF PRE-BCR AND BCR AND OTHER FORMS OF RECEPTOR SIGNALING

MULTIPLE RECEPTORS CONNECT TO BTK IN B AND NON-B HEMATOPOIETIC CELL TYPES

During the development of the B-cell lineage immunoglobulin genes are rearranged, first giving rise to an expressed μ heavy chain, which together with VpreB and λ5 makes up the pre-B-cell receptor. Later, upon the successful generation of a light chain, the BCR is formed (reviewed in Kurosaki et al., 2010). None of these receptors carries an intracellular signaling domain, but instead they make use of accessory transmembrane signaling partners, namely Igα (CD79a) and Igβ (CD79b). Initial steps downstream of BCR activation include tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequences on Igα and Igβ by SRC family kinases. When the BCR gets activated, but also under "tonic signaling" (Monroe, 2006), a signalosome is formed containing BLNK (also known as SLP-65 or BASH), phospholipase Cγ2 (PLCγ2) and protein kinase C (PKC). Similarly, the pre-BCR generates a signaling complex (Guo et al., 2000). BTK's main role is to phosphorylate PLCγ2 on two tyrosine residues, resulting in the activation of this enzyme (Humphries et al., 2004). This generates inositol 1,4,5-trisphosphate (IP3) and diacyl glycerol (DAG). This in turn activates PKCβ in B lymphocytes and induces the release of Ca^{2+}, with subsequent activation of several downstream components, including NF-κB and other transcription factors. PKC plays a dual role by enhancing the downstream signaling while at the same time phosphorylating BTK, thereby inhibiting its activity (Yao et al., 1994). Another enzyme negatively regulating BTK through phosphorylated serines is the isomerase Pin1, which recognizes two separate serine residues in the PH (pleckstrin homology) domain (Yu et al., 2006). IP3 is formed after cleavage of phosphatidylinositol 3,4,5-trisphosphate (PIP3), and PIP3 is generated by phosphatidylinositol 3-kinase (PI3K). PIP3 is also of importance for BTK membrane tethering because the PH domain of BTK specifically binds to PIP3 (Rameh et al., 1997; Salim et al., 1996).

Apart from the pre-BCR and the BCR, many other receptors also activate BTK (Nore et al., 2000). One common denominator for many of these receptors may be PI3K. A variety of cytoplasmic molecules have been linked to BTK by physical or genetic means (reviewed in Mohamed et al., 2009).

ACTIVATION OF BTK BY RECEPTORS IN NON-B CELLS

BTK is broadly expressed among hematopoietic cell types, with the exception of T cells (Smith et al., 1994a). Important receptors, such as the Fcε receptor of mast cells, which mediates degranulation responses via IgE and allergen complex-induced binding, have been linked to BTK activation by genetic and biochemical criteria (Hata et al., 1998a; Kawakami et al., 1994). A different type of receptor activation is exemplified by the collagen-mediated activation of platelet aggregation via non-integrin glycoprotein receptors. Although XLA patients show no overt defect in blood clotting, BTK is clearly activated by this mechanism and may play an additive role with other Tec family kinases in mediating effective platelet activation (Quek et al., 1998). Toll-like receptor signaling has also been investigated in XLA non-B cells, but without any clinical implications (Marron et al., 2010; Sochorová et al., 2007).

ROLE OF BTK IN THE NUCLEUS

While BTK mainly resides in the cytoplasm, a potentially important BTK signaling event is to influence processes within the nucleus through the activation of transcriptional regulators. Evidence for BTK directly modifying transcription factors such as STAT5 (Mahajan et al., 2001) and TFII-I (Egloff and Desiderio, 2001; Novina et al., 1999) by tyrosine phosphorylation is one mode of control. The NF-κB transcription factor pathway has also been connected to BTK. BCR-induced activation of IKK and subsequent degradation of I-κB and activation of the NF-κB pathway is impaired in B cells lacking BTK, BLNK, or PLCγ2 (Bajpai et al., 2000; Petro et al., 2000; Petro and Khan, 2001; Tan et al., 2001). Interestingly, NF-κB also positively regulates the *BTK* promoter yielding a positive feedback loop (Yu et al., 2008). BTK was also found to shuttle between the cytoplasm and the nucleus (Mohamed et al., 2000). At least one transcription factor, Bright, is reported to bind directly to BTK (Webb et al., 2000) and relocalize as a complex within the nucleus. Bright also binds to lipid rafts (Schmidt et al., 2009). Recently an anchyrin-repeat-containing protein was found to regulate BTK shuttling by interacting with its SH3 domain (Gustafsson et al., 2012).

MUTATION ANALYSIS FOR *BTK*

BTK gene mutation detection is increasingly dependent on direct sequencing of exonic regions and splice sites, while previously most of the techniques used to identify mutations in BTK relied on PCR amplification, followed by a screening assay. Those were single-strand conformation polymorphism (SSCP) (Conley et al., 2004, Holinski-Feder et al., 1998; Vorechovsky et al., 1995a) or denaturing high-performance liquid chromotography (DHPLC) (Xiao and Oefner, 2001). Over 90 percent of mutations in BTK consist of single base pair substitutions or the loss or gain of less than 10 base pairs. The remaining mutations are more complex mutations, or deletions, insertions, or inversions (Conley et al., 2005b). Splice-site mutations are rather frequent. In rare cases, analysis of mRNA is needed to identify splice-site mutations because they occur in intronic regions far away from the regular consensus sites (Kralovicova et al., 2011).

In 1994 an international study group for XLA was formed with the aim of collecting all mutations into a common database (Vihinen et al., 1995). This database, designated BTKbase, is continuously updated and available through the Internet (http://bioinf.uta.fi/base_root/) (Väliaho et al., 2006). Investigators carrying out mutation analyses are

encouraged to contact the study group and report new information. Instructions are available at the BTKbase website or through one of the authors (C.I.E.S.). For further information on immunodeficiency disease mutation databases, including instructions for data submission, see Chapter 58.

The most recent edition of BTKbase, Version 8.53, last updated June 17, 2013 contains 1,254 public entries. Thus, the majority of affected families have mutations that are unique to their family. This observation can be explained, at least in part, by the fact that XLA is maintained in the population by new mutations. The high homology between human and murine BTK also suggests that very few alterations in the sequence are tolerated. No single mutation in the *BTK* gene accounts for more than 3 percent of patients (Conley et al., 2005a), and these represent CpG sites frequently affecting arginine codons (Väliaho et al., 2006).

Mutations in BTK are scattered throughout the gene, affecting every domain of the protein. Approximately 35 percent of mutations are single base pair substitutions resulting in amino acid substitutions. These missense mutations are not uniformly distributed but are preferentially found in the kinase domain, especially in the C-terminal portion of the kinase domain. A number of missense mutations also exist in the PH and SH2 domains, whereas the TH-SH3 region is much less affected (Lindvall et al., 2005).

Premature stop codons account for about 20 percent of families and single base pair substitutions resulting in splice defects are seen in an additional 15 to 20 percent of families. The insertion or deletion of 1 to 10 base pairs causes a frameshift mutation and a secondary premature stop codon in another 15 to 20 percent of families. A small number of in-frame deletions of 3 base pairs have been reported (Conley et al., 2005a; Väliaho et al., 2006). The premature stop codons, splice defects, and frameshift mutations are evenly distributed over the gene. A single mutation confined to the promoter region has been found (Holinski-Feder et al., 1998), but this type of mutation is very rare, typically corresponding to a few percent or less in *BTK* and other genes (Giannelli et al., 1996).

Certain DNA sequences are more vulnerable to mutations. For example, CpG sites are highly prone to mutagenic events. The 5-methylcytosine base frequently spontaneously deaminate to thymine, causing transitions (Duncan and Miller, 1980). These sites are also the major mutational hot spots for the sex-linked primary immunodeficiencies, including XLA (Conley et al., 2005a; Lindvall et al., 2005; Smith and Vihinen, 1996; Väliaho et al., 2006). Not all CpG sites in BTK are associated with disease, suggesting that selected sites might not be sensitive to replacement (Lindvall et al., 2005) or the DNA/chromatin structure may provide some protection to some sites.

Large deletions in the *BTK* gene, ranging in size from 2 kb to nearly 200 kb, are seen in about 5 percent of families with XLA. Some of these deletions extend into neighboring genes, including *TIMM8A*, *TAF7L*, and *DRP2*, as noted above (Richter et al., 2001; Rohrer et al., 1999; Sediva et al., 2007; van Zelm et al., 2008; Vetrie et al., 1993; Vorechovsky et al., 1994a). Deletions that include the 3' part of BTK almost invariably delete the gene *TIMM8A*, which is located less than 1 kb downstream of exon 19 of *BTK*. Of note, in some patients with XLA and deletions that include TIMM8A, deafness was initially attributed to chronic otitis or the use of toxic antibiotics. A small number of duplications of 2 or more exons in *BTK* and an inversion of at least 48 kb that disrupted *BTK* between exons 4 and 5 have been reported (Rohrer et al., 1999). Two unrelated patients with XLA have been shown to have two different retrotransposon insertions at exactly the same site immediately downstream of exon 9 of *BTK* (Conley et al., 2005b).

Initial studies suggested that there was no correlation between the specific mutation in *BTK* and the severity of disease (Holinski-Feder et al., 1998; Vihinen et al., 1996a). However, analysis of larger numbers of patients indicates that some mutations are more likely to result in an older age at diagnosis, a slightly higher concentration of serum immunoglobulins, and a few more B cells in the peripheral blood (Broides et al., 2006; Lopez-Granados et al., 2005; Noordzij et al., 2002b; Plebani et al., 2002). Amino acid substitutions, particularly amino acid substitutions that allow the production of some BTK protein, and splice defects that occur at sites in the splice consensus sequence that are conserved but not invariant are more likely to be associated with a milder phenotype. The genotype–phenotype correlation is weak, and patients from the same family with the same mutations may have striking differences in clinical findings (Buckley and Sidbury, 1968; Bykowsky et al., 1996; Goldblum et al., 1974; Kornfeld et al., 1996; Saffran et al., 1994; Wedgwood and Ochs, 1980). This suggests that there are modifying genetic or environmental factors that influence the severity of disease.

MUTATION ANALYSIS FOR ARA

Mutations in μ heavy chain account for the largest proportion of patients with ARA. The μ heavy chain locus is complex with 50 to 120 VH regions, half of which are pseudogenes (Cook et al., 1994; Matsuda et al., 1993), approximately 30 DH segments (Ichihara et al., 1988; Schroeder et al., 1988), and 6 JH regions upstream of the μ constant region. There are polymorphic variations in the number of VH, DH, and JH segments. The search for mutations in μ heavy chain has focused on the 6 exons that encode the constant region (CH) of μ heavy chain. The first 4 exons encode the individual CH domains and the last 2 exons encode the sequences required to produce a membrane form of μ heavy chain.

Twenty-six families with mutations in the constant region of μ heavy chain have been identified (Ferrari et al., 2007b; Lopez-Granados et al., 2002; Meffre et al., 2001; van Zelm et al., 2008; Yel et al., 1996; Zhang et al., 2010, and unpublished observation). The spectrum of mutations in μ heavy chain differs quite remarkably from that seen in BTK. Half of the mutations are large deletions, 71 to 732 kb in length, that remove all of the constant region exons and usually additional segments of the μ heavy chain locus, including some VH segments, DH segments, JH segments, and other constant region genes (Lopez-Granados et al.,

2002; van Zelm et al., 2008; Yel et al., 1996, and unpublished observations). Eight frameshift mutations, four deletions, three insertions, and one complex combination of insertion and deletion have been reported. Only four single base pair substitutions have been reported: one resulting in a premature stop codon in exon 3, two causing amino acid substitutions in exon 4, and one occurring at the −1 position of the alternative splice site in exon 4 (Lopez-Granados et al., 2002).

In contrast to XLA, in which no single mutation in BTK accounts for more than 3 percent of patients, several mutations in μ heavy chain have been seen in multiple families. The most common mutation is the single base pair substitution at the alternative splice site. This G-to-A substitution, which occurs at a CpG site, has been identified in eight unrelated families from all over the world (Ferrari et al., 2007; Lopez-Granados et al., 2002; Zhang et al., 2010). The mutation has been seen on least three different μ heavy chain haplotypes (Lopez-Granados et al., 2002). By contrast, shared descent is clearly responsible for a 2 bp deletion at codon 168 in exon 2. This mutation has been seen in four unrelated families, two of whom are Spanish and two of whom are Hispanic-American. This mutation occurred on the same uncommon haplotype of the μ heavy chain locus (Lopez-Granados et al., 2002, and unpublished observation). Two Turkish families with the same 72 kb deletion have also been reported (van Zelm et al., 2008). At this time there does not appear to be a genotype–phenotype correlation in patients with mutations in μ heavy chain. All of the reported defects result in a complete block in B-cell differentiation at the stage when the pre-BCR should be expressed on the cell surface.

Mutations in other components of the pre-BCR or BCR may also result in profound hypogammaglobulinemia and markedly reduced or absent B cells. As noted above, the pre-BCR is composed of μ heavy chain, the transmembrane signal transduction molecules Igα and Igβ, and the surrogate light chain (Melchers, 2005). The surrogate light chain is made up of two B-cell specific proteins, VpreB and λ5/14.1 (Kudo and Melchers, 1987; Melchers et al., 1993; Sakaguchi and Melchers, 1986), encoded within the lambda light chain locus on chromosome 22q11.2 (Bauer et al., 1993; Bossy et al., 1991; Erikson et al., 1981). These two proteins assemble to produce a complex that is very similar to a lambda light chain. The amino-terminal portion of VpreB has high homology to the variable region of an immunoglobulin molecule and the carboxyterminal portion of λ5/14.1 has homology to the J region and constant region of lambda light chain (Kudo and Melchers, 1987; Sakaguchi and Melchers, 1986). They are noncovalently linked to each other (Kerr et al., 1989; Minegishi et al., 1999) and covalently linked to the μ heavy chain via a cysteine residue in the carboxyterminal portion of λ5/14.1 (Kerr et al., 1989; Pillai and Baltimore, 1987). Together, VpreB and λ5/14.1 form a surrogate light chain that escorts the rearranged μ heavy chain to the cell surface prior to the rearrangement of the conventional light chain genes. This allows the B-cell precursor to test the integrity of the rearranged μ heavy chain before investing in extensive proliferation or additional gene rearrangements.

The genes for VpreB and λ5/14.1 are relatively small—2 exons and 3 exons, respectively. Because there are two λ5 pseudogenes that have over 95 percent homology with exons 2 and 3 of λ5/14.1, care must be taken to develop assays that are specific for the functional gene (Minegishi et al., 1998). Although no mutations in VpreB have been reported, two patients with defects in λ5/14.1 have been identified (Conley et al., 2009; Minegishi et al., 1998). The first patient was recognized to have immunodeficiency at 3 years of age when he developed meningitis and arthritis due to *H. influenzae*. Panhypogammaglobulinemia, absent titers to vaccine antigens, and a lack of peripheral blood B cells were seen and he was started on IVIG. At later evaluations he has had serum IgM and IgA that were less than 8 mg/dL and less than 0.02 percent $CD19^+$ cells in the blood. Mutation studies documented a premature stop codon in exon 1 at codon 22 on the maternal allele and 3 base pair substitutions in exon 3 at codons 131, 140, and 142 on the paternal allele. The first two substitutions would not be expected to alter the coding sequence; however, the C-to-T transition at nucleotide 425 would be predicted to replace the invariant proline at codon 142 with a leucine. Protein folding studies demonstrated that this alteration resulted in an inability of the λ5/14.1 protein to fold properly (Minegishi et al., 1998).

Of interest, the 3 base pair substitutions in the paternal allele of λ5/14.1 are the same as those found at the corresponding site in exon 3 of the λ5/14.1 pseudogene 16.1, suggesting that this mutations was the result of a gene conversion event (Minegishi et al., 1998). Analysis of λ5/14.1 in controls showed that this gene is highly polymorphic. Thirteen variant alleles of λ5/14.1, the majority of which could be attributed to gene conversion events, were found in 134 unrelated individuals (Conley et al., 1999). Nine of these variants resulted in amino acid substitutions. Although gene conversion is an unusual mechanism of mutation, some species use gene conversion to generate diversity in the variable region of immunoglobulin and immunoglobulin-like loci (Bajoghli et al., 2011; Reynaud et al., 1987; Thompson 1992). Immunoglobulin and immunoglobulin-like genes may be unusually susceptible to gene conversion events.

The second patient with mutations in λ5/14.1 had the onset of recurrent otitis and sinusitis in early childhood and had his first pneumonia at 18 years of age. He was hospitalized for pneumococcal pneumonia and sepsis at 28 and 32 years of age. An immune evaluation documented a serum IgG of 330 mg/dL, IgM 12.5 mg/dL, and IgA 6 mg/dL. By flow cytometry, he had less than 0.01 percent $CD19^+$ cells. Mutation detection documented a homozygous single base pair deletion, a G deletion in codon 85 in exon 2 of λ5/14.1.

The signal transduction molecules Igα and Igβ (also called CD79a and CD79b or mb-1 and B29) are essential components of the pre-BCR and BCR complex (Hombach et al., 1990). Both molecules are B-cell-specific proteins with structural similarities to the CD3γ, δ, and ε chains in T cells. Both have a single extracellular immunoglobulin domain, a transmembrane domain, and an intracytoplasmic domain containing an ITAM characterized by the sequence $YXXL(X)_7YXXL$ in which Y represents tyrosine, L represents leucine, and X

denotes any amino acid. Igα and Igβ form a covalently linked heterodimer that masks the hydrophobic transmembrane domain of μ heavy chain and escorts it to the cell surface. When the BCR is cross-linked, an SRC family member phosphorylates the tyrosines in the ITAM motif, converting this sequence into a docking site for the downstream tyrosine kinase, SYK.

The gene for Igα consists of 5 exons encoded at 19q13.2 (Ha et al., 1994), and the gene for Igβ is made up of 6 exons at chromosome 17q23 (Wood et al., 1993). Four patients with defects in Igα have been identified (Conley et al., 2009; Minegishi et al., 1999; Wang et al., 2002). All have been homozygous for their mutations. The first, a Turkish girl, was found to have a A-to-G substitution at the invariant −2 position of the splice acceptor site for exon 3. This mutation resulted in the skipping of exon 3, which contains the region encoding the transmembrane domain of Igα (Minegishi et al., 1999). A different splice defect, a G-to-A substitution at the +1 position of the splice donor site for exon 2, was identified in another Turkish child (Wang et al., 2002). The third mutation, a premature stop codon due to a G-to-T substitution in codon 48 in exon 2 in Igα, was identified in a little girl from Mexico (Conley et al., 2009). The last patient, of Pakistani descent, had a 2 base pair deletion, a GC deletion at codon 68, exon 2 of Igα. All of these mutations would be expected to result in absence of Igα protein. All four patients were hospitalized for infection by 13 months of age, and two of the patients had clinical findings consistent with vaccine-associated polio or enteroviral-induced dermatomyositis. All of the patients had less than 1 percent $CD19^+$ cells. Two patients, the first and the third, were evaluated in more detail at 2 to 5 years of age. Both had less than 0.01 percent $CD19^+$ cells in the blood. Bone marrow studies documented a block in differentiation at the pro-B to pre-B cell transition that was indistinguishable from that seen in patients with null mutations in μ heavy chain (Minegishi et al., 1999).

Two patients with defects in Igβ have been identified. One patient, an Italian, was homozygous for a C-to-T single base pair substitution at codon 80, resulting in a premature stop codon in exon 2 (Ferrari et al., 2007b). The other patient, from the Caucasus Mountains, had a single base pair substitution in codon 137 (Dobbs et al., 2007). The change at this site, which is immediately downstream of the cysteine that forms the disulfide bridge with Igα, replaces the wild-type glycine with serine. This glycine is conserved not only in Igβ from humans, mice, dogs, and cattle but also in Igα from humans, mice, dogs, and cattle.

Both patients with mutations in Igβ were hospitalized for infection in the first year of life. The patient with a premature stop codon had laboratory findings that were the same as those seen in the patients with mutations in Igα. He had less than 1 percent $CD19^+$ cells in the peripheral circulation and a complete block in B-cell development at the pro-B to pre-B cell transition (Ferrari et al., 2007b). The patient with the G137S mutation in Igβ had a small number of B cells in the peripheral circulation (0.08 percent $CD19^+$ cells). These B cells showed striking similarities and differences when compared to those seen in patients with mutations in *BTK*. B cells from both were variable in intensity of CD19 expression and had increased expression of CD38 and decreased expression of CD21. However, the B cells from the patient with the Igβ mutation showed decreased or absent expression of surface IgM, whereas those from patients with mutations in *BTK* showed increased expression of surface IgM. These findings suggested that the alteration in Igβ influenced the ability of the BCR to reach the cell surface.

To examine the ability of the G137S mutant Igβ to bring the BCR to the cell surface, Jurkat T cells were transfected with retroviral vectors that would allow the production of a wild-type or mutant BCR (Dobbs et al., 2007). Cells transduced with the mutant Igβ consistently demonstrated less surface IgM in which all of the components of the BCR were wild type.

Cross-linking of the BCR complex initiates a cascade of tyrosine phosphorylation events. One of the first proteins to be phosphorylated is a 456-amino-acid adaptor protein referred to as BLNK (Fu and Chan, 1997; Fu et al., 1998; Goitsuka et al., 1998) (also called SLP-65 and BASH), which is encoded at 10q23.22 in 17 exons. BLNK has significant homology to SLP-76, a protein expressed in T cells, myeloid cells, and platelets (Clements et al., 1998; Jackman et al., 1995). Once BLNK is phosphorylated by Syk, it acts as a scaffold to assemble to the downstream targets of BCR-mediated activation, including BTK, PLCγ2, Grb2, Vav, and Nck.

Several observations suggested that mutations in the *BLNK* gene might result in a selective defect in B-cell development. First, expression of BLNK is limited to B cells and myeloid cells (Fu et al., 1998). Second, absence of BLNK in a chicken B-cell line, DT40, like absence of BTK, results in defective calcium mobilization (Ishiai et al., 1999; Kurosaki, 1999). Third, mice that are null for the T-cell homolog of BLNK, SLP-76, fail to develop T cells (Clements et al., 1998; Pivniouk et al., 1998).

Three patients with mutations in *BLNK* have been identified. The first, a 20-year-old male from Appalachia, had two noncontiguous base pair substitutions in exon 1. The first alteration, a C-to-A substitution at the third base pair in codon 10, does not change the proline encoded at this position and would not be expected to have functional consequences. The second alteration, an A-to-T substitution, was seen at the conserved +3 position of the splice donor site of intron 1, 20 base pairs downstream from the alteration in codon 10 (Minegishi et al., 1999). Analysis of cDNA from the bone marrow of this patient demonstrated a complete absence of *BLNK* transcripts.

The second patient, a Turkish girl, was homozygous for a C-to-T base pair substitution in codon 123, resulting in the replacement of the wild-type arginine with a premature stop codon (Conley et al., 2009). This patient had a very small number of B cells in the peripheral circulation, approximately 0.01 percent. By analyzing 500,000 events, it was possible to show that the phenotype of these cells was very similar to that seen in patients with mutations in the *BTK* gene. The cells demonstrated increased expression of surface IgM but variable and decreased expression of CD19. The shared phenotype of B cells from patients with mutations in *BTK* or *BLNK* suggests

that the decreased expression of CD19 is due to faulty signaling through the BCR.

TREATMENT

GAMMAGLOBULIN REPLACEMENT THERAPY

There is widespread agreement that Ig therapy, which is discussed in detail in Chapter 59, is essential for patients with antibody deficiencies, including patients with XLA or ARA (Cunningham-Rundles 2011; Orange et al., 2010; Roifman et al., 1985). Both intravenous and subcutaneous routes of administration can be used to provide normal concentrations of serum IgG. Intramuscular administration and plasma therapy have been used in the past but do not allow an adequate level of IgG to be attained. The exact dose of Ig that should be used may depend on the clinical situation. Patients with chronic lung disease or enteroviral infection may need a higher dose than patients who were started on Ig therapy at an early age and have minimal complications of the disease. In an industry-sponsored meta-analysis of clinical studies comparing various doses of gammaglobulin in 676 antibody-deficient patients, Orange et al. (2010) reported that pneumonia incidence declined by 27 percent for each 100-mg/dL increment in trough IgG. However, the differences were most noticeable for patients who had a trough level less than 600 mg/dL, and none of the studies stratified patients based on the presence of chronic lung disease prior to the onset of Ig therapy.

It seems likely that high doses of Ig may reduce the risk of enteroviral infection (Misbah et al., 1992; Quartier et al., 1999, 2001), although this has not been formally proven. Thus, the risk of enteroviral infection appears to be limited to patients with profound hypogammaglobulinemia and likely also to patients infected with rare forms of enteroviruses against which protecting antibodies in gammaglobulin preparations are scarce. A dose of 400 to 600 mg/kg/4 weeks, the standard dose of gammaglobulin, should result in an IgG trough of at least 600 mg/dL. If the serum IgG is lower than that, one should consider protein loss, particularly through the gastrointestinal tract.

There are no published studies that indicate superiority of of either intravenous or subcutaneous Ig therapy. Subcutaneous administration is less likely to result in side effects, and some patients find it more convenient. In a series of patients treated with high-dose subcutaneous γ-globulin, the majority of whom had CVID, only 0.2 patient days/year were spent in the hospital for respiratory tract infections (Gardulf et al., 1991). Furthermore, a significantly increased health-related function and improved self-rated health were reported (Gardulf et al., 1993, 1995). Subcutaneous delivery may also be in the form of express infusions, further decreasing the time (Hansen et al., 2002).

Like all drugs, Ig therapy can be associated with side effects or complications. In the 1980s hepatitis C-contaminated IVIG batches caused several fatal cases of infection worldwide in immunoglobulin-deficient patients (Bjøro et al., 1994; Razvi et al., 2001; Rossi et al., 1997). However, current procedures for gammaglobulin manufacturing are much less likely to transfer infectious agents of any kind. Although hepatitis C may run a more severe course in patients with agammaglobulinemia than in otherwise healthy individuals, patients with XLA and hepatitis C appear to develop a less fulminant hepatitis than that in CVID patients (Bjøro et al., 1994; Hermaszewski and Webster, 1993; J. Björkander, personal communication). In one series reported by Bjøro et al. (1994), all five infected CVID patients developed severe cirrhosis, including one with a fatal outcome, whereas only one of six XLA patients developed cirrhosis and end-stage liver disease. This patient was co-infected with hepatitis B and D viruses. However, in a study by Razvi et al. (2001), the outcome of a hepatitis C infection did not differ between CVID and XLA patients, whereas Quinti et al. (2002) reported a better prognosis in XLA than that in CVID.

Severe adverse events, including myocardial infarction, renal failure, and thromboembolitis, have been reported in adults treated with high doses of intravenous Ig for autoimmune disease, but these complications have not been seen in immunodeficient patients receiving standard Ig doses (Gupta et al., 2001; Rajabally and Kearney, 2011).

ANTIBIOTICS

Treatment of infections is essential in all forms of primary immunodeficiency. The use of antibiotics to combat bacterial infections represents one of the cornerstones in the management of agammaglobulinemia, and prolonged administration is often necessary. Some centers use chronic prophylactic antibiotics; others cycle antibiotics. The use of low-dose chronic antibiotics is not recommended because of the increased risk of developing bacterial resistance. Chronic prophylactic antibiotics seem to be more beneficial to patients who are less than 15 years old than in teenagers and adults, perhaps because of anatomical vulnerability or because T-cell immunity has not yet developed. If a patient develops a new cough that lasts more than 3 weeks or if a patient is hospitalized for infection, a course of antibiotics of at least 6 weeks should be given. However, as in CVID, it is frequently not possible to eradicate an infectious agent completely. For a more detailed description of treatment with antibiotics, see Chapter 59.

BONE MARROW TRANSPLANTATION AND GENE THERAPY

Bone marrow transplantation is an option for patients with agammaglobulinemia, as for other primary immune deficiencies. However, transplantation is not a risk-free procedure, as graft-versus-host reactions and severe infections may ensue. The stem cell grafting procedure may or may not be ablative. Thus, conditioning increases the chance for engraftment, whereas under nonablative conditions insufficient chimerism may develop. Howard et al. (2003) reported on three patients receiving cord blood or bone marrow grafts from human leukocyte antigen (HLA)-matched siblings without receiving any preparative regimen or antirejection drugs, and another three who received treatment with cyclosporin A and

mycophenolate mofetil after transplant. However, none of the patients showed an increase in serum IgM or peripheral B-cell counts.

Gene therapy was suggested as a future treatment in both the original reports on cloning of the *BTK* gene (Tsukada et al., 1993; Vetrie et al., 1993). In theory, the defect underlying XLA makes this disease particularly suitable for gene therapy, since the differentiation defect would enable gene-corrected cells to selectively proliferate and/or survive. This characteristic is seen also in adenosine deaminase (ADA) deficiency and severe combined immune deficiency caused by mutations in the common γ-chain (*XSCID1*), mainly affecting T-lineage development. For both these disorders, successful gene therapy has been conducted (see Chapter 61). Further, animal studies suggest that expression of 25 to 50 percent of the normal amount of BTK by homozygous transgene or retroviral vectors corrects serum immunoglobulin concentrations but not the ability to make antigen-specific antibodies (Conley et al., 2000; Satterthwaite et al., 1997). Because all forms of ARA are rare, it is less likely that techniques that are gene-specific will be developed for these disorders.

PROGNOSIS

Prior to antibiotic therapy and γ-globulin substitution therapy, the prognosis of patients with XLA or ARA was poor. Analysis of patients born before 1950 in a large Dutch pedigree revealed that there was a 90 percent probability of children with XLA dying between 2 months and 8 years of age (Mensink et al., 1984). With the advent of antibiotics and γ-globulin replacement therapy in the 1950s, the prognosis improved considerably (Lederman and Winkelstein, 1985), and it continues to improve (Hermaszewski and Webster, 1993; Howard et al., 2006; Ochs and Smith, 1996). This can be attributed to earlier diagnosis, more effective antibiotics, and the ability to achieve normal serum concentrations of IgG with newer preparations of γ-globulin. The majority of patients with XLA who were born after 1980 are reaching adulthood, and many of them have not been hospitalized for infection after initiation of therapy (Howard et al., 2006). The potential for gene therapy for XLA (Moreau et al., 2007; Ng et al., 2010; Sather et al., 2011; Yu et al., 2004) encourages us to think that further improvements in prognosis and quality of life will be seen in the future.

DIFFERENTIAL DIAGNOSIS

In a male child with the early onset of recurrent bacterial infections, panhypogammaglobulinemia, and less than 1 percent CD19+ cells, a mutation in the *BTK* gene can be identified in approximately 85 percent of patients (Conley et al., 1998). Some mutations affecting BTK, including duplications, inversions, and mutations that occur outside of the coding regions, are difficult to detect by standard techniques. If there is no BTK protein in monocytes or platelets (Futatani et al., 1998, 2001), additional techniques including Southern blot analysis and/or cDNA sequencing may be required to identify the mutation (Kralovicova et al., 2011, Rohrer et al., 1999).

A female with agammaglobulinemia and absent B cells is unlikely to have mutations in BTK. During embryogenesis of the female, random inactivation of one of the two X chromosomes occurs in every somatic cell and all of the descendants of that cell (Lyon, 1966). Thus, the normal female is a mosaic with approximately half of the cells in every tissue having the maternally derived X as the active X, and the remaining cells having the paternally derived X as the active X. However, if one of the two X chromosomes carries a gene defect that is detrimental to the proliferation or survival of cells of a particular lineage, all the cells of that lineage will have the nonmutant X chromosome as the active X. BTK provides a very strong selective advantage to B-cell precursors, such that a female heterozygous carrier of a *BTK* mutation has normal numbers of B cells, all of which were derived from B-cell precursors with the nonmutant X chromosome as the active X (Conley et al., 1986; Conley and Puck, 1988; Fearon et al., 1987). One can anticipate that a female might have XLA if she had Turner's syndrome (females with a single X chromosome and no Y chromosome), uniparental disomy (two copies of the same affected X chromosome), or one X chromosome bearing the BTK mutation and the other X unable to function as an active X chromosome (Conley and Sweinberg, 1992). The latter situation has been reported in a single female whose father had XLA and the maternally derived X could not be used as the active X chromosome (Takada et al., 2004). No other female patients with XLA have been reported.

Male and female patients who have an "XLA phenotype" but no mutation affecting BTK may have one of the autosomal recessive forms of agammaglobulinemia (Conley et al., 2009). ARA is more likely in consanguineous families or families who live in a geographically isolated area. About 75 percent of patients with ARA are homozygous for their mutation, indicating that their parents have an ancestor in common (Conley et al., 2005a). Screening of genomic DNA is the most reliable way to identify one of the autosomal recessive forms of agammaglobulinemia. A single patient with mild dysmorphic features, hypogammaglobulinemia, reduced numbers of peripheral B cells, and a translocation in the gene for LRRC8 has been reported (Sawada et al., 2003). This clinical syndrome may be due to the expression of a LRRC8-fusion protein rather than an abnormality in expression of LRRC8 itself.

Other immunodeficiencies or clinical disorders can be confused with XLA or ARA. A single family has been described in which the four affected males had hypogammaglobulinemia, decreased or absent B cells, and growth hormone deficiency inherited in an X-linked pattern (Fleisher et al., 1980). Screening of the *BTK* cDNA in this family did not reveal any mutations, and normal BTK protein was detected by Western blot (Stewart et al., 1995). Alterations in the *ELF4* gene in this family have been implicated, but the results are inconclusive (Stewart et al., 2008). Several other males with XLA and growth hormone deficiency have been reported, but mutations in BTK have been found in all of these patients (Conley et al., 1994; Duriez et al., 1994; Vihinen et al., 1994c).

Some patients with WHIM syndrome have hypogammaglobulinemia and reduced numbers of B cells (Hernandez et al., 2003; Kawai and Malech 2009). Although many of these patients, particularly young children, do not have a history of warts, most have persistent neutropenia. Some patients with XLP have reduced numbers of B cells as well as hypogammaglobulinemia (Morra et al., 2001). Patients with myelodysplasia, including the various forms of dyskeratosis congenital, may have hypogammaglobulinemia with markedly reduced numbers of B cells (Gupta and Kumar, 2010; Srivannaboon et al., 2001). These patients usually, but not always, have other hematopoietic abnormalities. Some patients with CVID have severely reduced numbers of B cells in the peripheral circulation (Cunningham-Rundles and Bodian, 1999; Wehr et al., 2008). In a patient with absent B cells, particularly a male patient, the diagnosis of XLA or one of the autosomal recessive forms of agammaglobulinemia should be considered before the patient is given the diagnosis of CVID. An early onset of recurrent infections and a family history of disease or consanguinity suggest that more detailed genetic analysis might be appropriate, irrespective of the patient's age. However, there are clearly patients who have delayed onset of infections, severe hypogammaglobulinemia, and absent B cells who do not have mutations in any of the known genes associated with agammaglobulinemia.

ANIMAL MODELS OF BTK LOSS OF FUNCTION

Shortly after *BTK* was identified as the defective gene in XLA, two groups showed that a well-characterized mouse model of immunodeficiency, X-linked immunodeficiency or xid mice, is caused by a point mutation in the PH domain of BTK that leaves kinase activity intact (Rawlings et al., 1993; Thomas et al., 1993). Xid is a relatively mild immune deficiency with loss of some B-cell subpopulations and humoral responses (Scher, 1982). Allele-specific variation in disease severity seemed a plausible explanation until mice with null mutations of *Btk* were created and shown to have a mild xid-like phenotype (Hendriks et al., 1996; Khan et al., 1995), rather than the panhypogammaglobulinemia and profound loss of B cells seen in XLA. The difference in the severity of the xid defect compared to that seen in patients with XLA, and other studies described below strongly support the concept that the effects of the B-cell immune deficit due to loss of Btk function is strongly influenced by genetic context.

The xid mutation was first defined in the early 1970s as abnormal responses to polysaccharide antigens in the highly inbred CBA/N strain of mice, a defect that segregated in a sex-linked manner (Amsbaugh et al., 1972). This strain of mice and congenic derivatives of the xid mutation on other backgrounds show normal fecundity and have minimal if any elevation of cancer risk. They also do not have to be housed in specialized animal facilities.

Detailed analysis of the immune defects in xid show cell-autonomous defects only for the B-cell lineage. These include the loss of specific cell subpopulations such as $CD5^+$ or B1 cells that normally accumulate in the peritoneum. The remaining B cells that emigrate from the marrow to peripheral sites show an immature phenotype exemplified by a high IgM-to-IgD ratio, low major histocompatibility complex (MHC) class II antigen expression, and inability to secrete IgM or class switch for certain isotypes such as IgG3. In xid mice, responses to type II T-cell-independent antigens, exemplified by the trinitrophenyl-derivatived Ficoll, are absent, and B cells cannot form multicellular colonies in response to certain mitogens (Bona et al., 1980, Scher, 1982).

Responses to T-cell-dependent antigens are normal. If T-cell help is removed through neonatal thymectomy or because of the simultaneous presence of the nu/nu gene, B-cell development in the bone marrow is blunted, and the immune deficit is severe (Karagogeos et al., 1986; Wortis et al., 1982). The presence of the xid allele can relieve the systemic lupus-like autoimmune disease complex seen in mouse strains such as NZB/NZW (Taurog et al., 1979), reduce the susceptibility to *S. aureus*-induced arthritis (Zhao et al., 1995) and *M. pulmonis* pneumonia (Sandstedt et al., 1997), and ameliorate diabetes in the NOD mouse (Kendall et al., 2009). These effects can be at least partially explained by the altered production of pathogenic antibodies associated with the xid allele, but an altered balance of cytokines produced by B cells may also play a role. More subtle and complex genetic interactions are seen when the severity of the xid allele is evaluated in the context of specific backcrosses or different congenic strains that do not harbor any obvious immune or developmental defect.

Development of wild-type levels of Btk by transgenesis experiments can reconstitute normal B-cell function and development (Drabek et al., 1997). Several studies have combined the xid mutation with loss of function in a second gene to create more severe B-cell phenotypes and help define pathways that are likely rate-limiting for Btk function. A striking result is the severe block in B-cell development at the pre-B-cell stage observed when a loss of Btk function is combined with a loss of Tec function (Ellmeier et al., 2000). This can be most simply interpreted as Btk and Tec serving essential but redundant roles in the pathways connected to the pre-BCR. The phenotype of this mouse more closely resembles that seen in patients with XLA but is still not quite as severe.

Several strains of knockout mice result in a xid-like phenotype. Mutation affecting PLCγ2, the p85 form of PI3K, PKCβ, or the adaptor protein BLNK all show an xid-like phenotype with selective loss of B cells and antigen responses, defective activation from the Ig receptor, and loss of Ca^{2+} flux in residual peripheral B cells (reviewed in Fruman et al., 2000). The proteins encoded by these gene all work in a complex or signalosome that mediates signals from cell-membrane receptors, including but not limited to the BCR.

The concept that there is an optimal dose of Btk is supported by the phenotype of a transgenic strain of mice expressing a mutant (E41K) form of the enzyme (Dingjan et al., 1998; Maas et al., 1999). This mutation was first isolated by random mutagenesis and selection for an allele of Btk that could transform fibroblast cells to grow suspended in agar. The

mutation increases the ability of the enzyme to associate with membranes and the fraction of enzyme chronically modified by phosphotyrosine, indicating that it is an activated allele (Li et al., 1995). The transgenic E41K strain did not overproduce B cells or have hyperactivated B cells, but rather produced a more severe block in B-cell development at the pre-B-cell stage similar to that in the human XLA phenotype. However, this phenotype was seen only in transgenic animals carrying several copies of the mutated gene fragment, suggesting that this phenomenon would be highly unlikely to occur in human beings. This finding implicates that too much Btk activity creates negative signals, which are even more potent as inducers of phenotypic alterations as compared to loss-of-function mutations. *Drosophila melanogaster* also develop an overt phenotype upon transposon-mediated Btk loss-of-function mutations. These can be complemented by heat-shock-induced expression of human BTK (Hamada et al., 2005). Even if flies represent an interesting model for Btk-mediated signaling, the downstream pathway of Btk has been evolutionarily rewired (Nawaz et al., 2012).

ANIMAL MODELS OF AUTOSOMAL RECESSIVE AGAMMAGLOBULINEMIA

In the early 1990s Kitamura et al. (1991) produced a strain of mice, called μMT mice, that had a premature stop codon in the membrane exons of μ heavy chain. These mice, which were among the first knockout mice to be created, were able to make the secretory form of μ heavy chain but not the membrane form. By deleting all of the JH segments a second model of μ heavy chain deficiency was generated (Chen et al., 1993). In both strains, the earliest precursors of B cells could be found in the bone marrow, but there was a complete block in differentiation at the pre-B-cell stage, indicating that an intact membrane form of μ heavy chain is critical for early B-cell development. Chen et al. noted that the block in differentiation was identical to that seen in RAG1- or RAG2-deficient mice. The homozygous mutant mice had no measurable serum IgM or IgG and there were no B cells in the spleen, lymph nodes, or peritoneum. Heterozygous mice were normal. This phenotype is identical to that seen in patients with defects in μ heavy chain.

B-cell precursors from the JH deletion mice showed abundant production of VH sterile transcripts but no VH-to-DH rearrangement, supporting the hypothesis that DH-to-JH rearrangement must occur prior to VH-to-DH rearrangement. However, a low level of kappa chain V-to-J rearrangement was seen in both the μMT mice and the JH deletion mice, indicating that production of an intact membrane form of μ heavy chain is not required for light chain rearrangement.

Studies in the μMT mice showed that allelic exclusion, the exclusive production of a heavy chain protein from one of the two chromosomes, required the expression of an intact membrane form of μ heavy chain (Kitamura and Rajewsky, 1992). Mice that were heterozygous for the mutant μMT locus and a wild-type locus had B-lineage cells expressing secretory μ heavy chain from both alleles.

Later studies showed that the genetic background could influence the phenotype of the μMT mice. When the μMT mutation was placed on a Fas or Fas ligand-deficient background, normal or nearly normal concentrations of all IgG subclasses were produced (Melamed et al., 2000). These mice made several autoantibodies but they did not produce antigen-specific antibody in response to exogenous antigens. The original μMT mice were on a mixed 129/B6 background. When the μMT mutation was placed on the CBA/J background, there were no changes in the phenotype. However, when the mutation was placed on the BALB/C background, the serum IgA, IgG1, IgG2a, and IgG2b levels were within the normal range and the IgD and IgE levels were elevated compared to wild-type mice (Hasan et al., 2002). The serum IgM was undetectable and the IgG3 was significantly decreased. Backcross experiments indicated that the ability of BALB/C μMT mice to make IgG was controlled by a single autosomal dominant gene. Macpherson et al. (2001) reported that IgA production could be detected in the intestinal tract of μMT mice on the C57BL/6 background, but this finding was not seen by others (Hasan et al., 2002; Melamed et al., 2000). Careful search for IgA in the serum and intestines of patients with defects in μ heavy chain did not reveal any immunoglobulin production (Pan et al., 2002).

Many studies have used μ heavy chain-deficient mice to examine the role of B cells and/or antibody in protection from infection. The majority of these studies suggest that the lack of B cells exacerbates infection with parasites, like cryptosporidium or toxoplasma (Chen et al., 2003a, 2003b); viruses like West Nile virus, influenza, or adenovirus (Diamond et al., 2003; Graham and Braciale, 1997; Moore et al., 2004); and fungus (Montagnoli et al., 2003). None of these organisms causes significantly greater problems in B-cell-deficient patients compared to healthy controls. The μMT mice have also been used as a model for mycoplasma infections, which are more common and severe in patients with agammaglobulinemia and absent B cells (Berglöf et al., 1997; Roifman et al., 1986).

Several different strains of mice that are deficient in Igα or Igβ have been produced. Mice that are null for either or both of these genes have a block in B-cell differentiation at the same stage of development as mice with defects in μ heavy chain or RAG (Gong and Nussenzweig, 1996; Pelanda et al., 2002). By contrast, mice that express truncated forms of either Igα or Igβ, forms that lack the cytoplasmic ITAM motif, are able to generate immature B cells but have defects in later stages of maturation (Reichlin et al., 2001; Torres et al., 1996). However, in knockin mice with mutations in the ITAM motifs of both Igα and Igβ, the block in B-cell development is equivalent to that seen in μ heavy chain-deficient mice (Kraus et al., 2001). These findings indicate that Igα and Igβ are essential and nonredundant for the expression of the pre-BCR, and at least one ITAM motif is needed to support the pro-B-cell to pre-B-cell transition, but the signaling motif of either Igα or Igβ is sufficient for progression from pre-B cells to immature stages of B-cell development. Like the murine models, patients with null mutations in either Igα and Igβ have a complete block in B-cell development that is identical to that seen in patients with defects in μ heavy chain. There are no murine models for

alterations in the extracellular domains of Igα or Igβ, as was seen in one of the patients with an amino acid substitution in Igβ (Dobbs et al., 2007).

Mice with defects in λ5 have a milder immunodeficiency than patients with mutations in the same gene. At 6 weeks of age the mutant mice have approximately 5 percent of the normal number of B cells in the peripheral blood and 15 percent of the normal number of B cells in the spleen (Kitamura et al., 1992). However, with age, the number of B cells improves. At 4 months of age, the λ5-deficient mice have 20 percent of the normal number of B cells and normal amounts of serum IgM. These mice are able to make antigen-specific antibody in response to both T-cell-dependent and T-cell-independent antigens, although the titer of antibody to T-cell-dependent antigens is decreased. Mice that lack VpreB as well as λ5 have a phenotype that is very similar to that seen in mice that are deficient in λ5 alone (Shimizu et al., 1992). This suggests that neither VpreB nor λ5 has a function in the absence of its partner. Patients with defects in λ5 have a severe, profound defect in B-cell development that does not improve with age (Minegishi et al., 1998, and personal observation).

Several different strains of mice with mutations in BLNK (also called SLP-65 or BASH) have been produced (Hayashi et al., 2000; Jumaa et al., 1999; Pappu et al., 1999; Xu et al., 2000). All of these mice have a leaky block in B-cell differentiation at the pre-B-cell stage of development, but there is some variability in the severity of the defect in the different strains of mice. These differences may be due to the particular construct used to create the knockout, the genetic background of the mice, or the environmental conditions of the mice. Like the λ5-deficient mice, the BLNK-deficient mice demonstrated improved B-cell numbers with age (Pappu et al., 1999; Xu et al., 2000). Serum IgM and IgG3 levels are decreased or absent and the concentrations of IgG1, IgG2a, and IgG2b are less severely affected. Although the number of patients with mutations in BLNK is small, all of these patients have a defect that is more severe than the most severe BLNK-deficient murine stain, the strain produced by Pappu et al. (1999). Further, there has been no improvement in B-cell development with age in the BLNK-deficient patients.

It has been suggested that BLNKmay function as a tumor suppressor. There is a markedly increased incidence of pre-B-cell leukemia in the mildest strain of BLNK-deficient mice, the strain produced by Jumaa et al. (1999). If the BLNK mutation is placed on a BTK-deficient background, the incidence of leukemia increases further (Kersseboom et al., 2006). The Jumaa group reported that abnormal splicing of the BLNK message was seen in 16 of 34 patients with acute lymphocytic leukemia (ALL) (Jumaa et al., 2003). However, in a much larger series of patients with ALL, only 9 of 284 patients had decreased expression of BLNK as evaluated by the Affymetrix GeneChip (Imai et al., 2004). It may be that the increased incidence of leukemia seen in the BLNK-deficient mice is due to hyperproliferation of early B-cell precursors. It has been noted that many of the murine strains with blocks at the pre-B-cell stage of differentiation have increased numbers of pro-B cells (Jumaa et al., 1999; Pappu et al., 1999). This might be attributed to a positive feedback signal responding to the low B-cell numbers in the periphery. Patients with early defects in B-cell development do not show an increased number of pro-B cells, perhaps because the niche for pro-B cells is more limiting in the human compared to the mouse.

CONCLUDING REMARKS

Although *BTK* was identified as the gene responsible for XLA two decades ago, much still needs to be learned about the function of this molecule. For example, BTK is clearly required for signaling through the BCR; however, the other signaling pathways that influence BTK function are less clear. We know that there are modifying genetic factors that influence the severity of XLA. What are these factors? It is likely that some of them are intrinsic to the B cell. Others may be extrinsic to the B-cell lineage and influence B-cell homeostasis or survival; some may provide alternative routes for protection from infection. Understanding the modifying genetic factors that make some patients more susceptible to enteroviral infection or inflammatory bowel disease may help us treat those patients.

As noted above (see the section "Activation of BTK by Receptors in Non-B Cell S"), absence of BTK can result in monocyte and platelet abnormalities that can be demonstrated in the laboratory; however, it is not clear if there are clinically significant effects in these cell lineages. Comparison of clinical complications seen in patients with *BTK* mutations with patients who have mutations in one of the B-cell-specific genes, for example μ heavy chain, may begin to answer this question.

Murine models of disease have proved to be very useful in understanding the framework of B-cell development. However, findings in mice cannot be directly extrapolated to humans. Mutations affecting BTK, λ5, and BLNK result in a more severe phenotype in humans compared to mice. What is the basis of this difference? Could it be due to differences in positive or negative selection at early stages of B-cell development? Or perhaps it is due to differences in the bone marrow niche that supports the pro-B-cell to pre-B-cell transition.

The prognosis for patients with XLA or ARA has improved each decade over the past 50 years due to earlier age at diagnosis, improved preparations of gammaglobulin, and more effective antibiotics. Yet further improvements are needed. These diseases are still associated with a significant incidence of complications and they are very expensive to treat. Patients and their families are eager for new treatment modalities that "fix" their immunodeficiency.

It is also interesting to note that inhibitors of BTK have become increasingly useful in the treatment of leukemia, lymphoma, and autoimmunity. On a global scale it does not seem unlikely that patients receiving BTK inhibitors eventually will outnumber those with inherited defects by orders of magnitude.

CD40 AND CD40 LIGAND DEFICIENCIES

Luigi D. Notarangelo, Silvia Giliani, and Alessandro Plebani

INTRODUCTION

The primary B-cell repertoire is generated in the bone marrow by means of antigen-independent stochastic rearrangement and assembly of Variable (V), Diversity (D), and Joining (J) gene elements of immunoglobulin heavy and light chain genes. In the periphery, two key events mark maturation of the antibody response upon antigen encounter: class-switch recombination (CSR) and somatic hypermutation (SHM). During CSR, the mu heavy chain is replaced by a downstream constant heavy chain gene element. This process results from deletional recombination between characteristic repetitive sequences (switch regions) located 5′ of the Cμ gene and of each C_H gene, except Cδ. Replacement of the μ heavy chain with other constant heavy chain elements has a significant impact on the biological properties of the immunoglobulin that is produced. SHM, on the other hand, consists of the introduction of nucleotide substitutions in the immunoglobulin V regions and may thus cause changes in the amino acid sequence and in the affinity of the immunoglobulin for the antigen. As a result of this process, B-cells expressing surface immunoglobulins with higher affinity for the antigen are positively selected during the germinal center reaction.

A variety of defects of CSR are known in humans and are characterized by recurrent infections and very low levels of serum IgG, IgA, and IgE, with normal or elevated IgM (Notarangelo et al., 2006). Both primary and acquired forms of the disease have been reported. Among primary CSR defects, X-linked, autosomal recessive, and (less frequently) autosomal dominant forms have been reported, reflecting genetic heterogeneity. Defects of CSR are often associated with abnormalities of SHM and of generation of memory B-cells. Based on the underlying cellular pathophysiology, CSR defects can be divided into B-cell–intrinsic and B-cell–extrinsic disorders. The latter group includes an X-linked variant of the disease, due to mutations of the *CD40LG* gene, that encodes for CD40 ligand (also known as CD154), a molecule predominantly expressed by activated $CD4^+$ T lymphocytes. CD40LG interacts with CD40, which is constitutively expressed by B-cells. CD40LG/CD40 interaction elicits B-lymphocyte intracellular signaling, with induction of the NF-κB signaling pathway and expression of activation-induced cytidine deaminase (AICD) and uracil N-glycosylase (UNG), two B-cell–specific enzymes that play a key role in CSR and SHM (Notarangelo et al., 2006). In humans, mutations of *CD40LG*, *CD40*, *IKBKG* (encoding for IKK-γ/NEMO, a regulator of the NF-κB signaling pathway), and *AICD* and of the *UNG* genes are all associated with defective CSR. In this chapter, we will focus on CD40LG and CD40 defects. Deficiencies of AICD, UNG, and IKK-γ/NEMO will be discussed in Chapters 27 and 36, respectively.

BIOLOGY OF CD40 AND CD40 LIGAND

EXPRESSION AND BIOLOGICAL ROLE OF CD40

CD40, a 50kDa glycoprotein, is a member of the tumor necrosis factor receptor (TNFR) family of surface molecules. The gene, *CD40* (*109535), encodes a Cys-rich type I transmembrane protein of 277 amino acids (a.a.) (Stamenkovic et al., 1989). CD40 is constitutively expressed on all B-cells but also on other cell types, including dendritic cells (DCs), monocytes, and macrophages (Brouty-Boye et al., 2000; van Kooten and Banchereau, 2000). Expression of CD40 has been demonstrated also on $CD34^+$ hematopoietic precursor cells (Pyrovolaki et al/, 2009), T lymphocytes (Munroe et al., 2007; Vaitaitis et al., 2008), and platelets (Inwald et al.,

2003). Finally, CD40 is also expressed by nonhematopoietic cell types such as thymic epithelial cells, some other epithelial and endothelial cells, and neurons (van Kooten and Banchereau, 2000).

CD40 plays an important role in B-cell survival, growth, and differentiation. CD40 ligation on the surface of B-cells in the presence of interleukin-4 (IL-4) initiates proliferation and growth and induces homotypic cell adhesion and upregulation of the expression of CD23, CD54, CD80, CD86, CD95 (Fas), and lymphotoxin-α. CD40-mediated upregulation of Fas expression on B-cells makes them susceptible to killing by Fas ligand$^+$ (FasL$^+$)-activated T-cells (Banchereau et al., 1994; van Kooten and Banchereau, 2000). This may play a role in the CD40-mediated apoptosis of tumor B-cells (Georgopoulos et al., 2006) and in peripheral purging of self-reactive B lymphocytes, as indicated by the increased frequency of self-reactive B-cells in patients with CD40LG deficiency (Hervé et al., 2007). However, CD40 also delivers an antiapoptotic signal to B-cells by inducing antiapoptotic genes that include Bcl-xL and A20 (Ishida et al., 1995; Sarma et al., 1995). It has been shown that C4 binding protein (C4BP), a regulator component of the classical complement pathway, may also bind to CD40 on human B-cells at a site that differs from that used by CD40LG. Engagement of CD40 by C4BP triggers signaling pathways similar to those triggered by CD40LG, as demonstrated by the fact that this interaction induces proliferation, upregulation of CD54 and CD86 expression, and IL-4–dependent IgE isotype switching in normal B-cells (Brodeur et al., 2003). IL-4 and IL-13, the switch factors for IgE, induce the transcription of a 1.8 kb ε germline mRNA that initiates 5′ of the Sε region. This transcript is sterile, as it is not translated into a functional protein. Induction of a mature 2.0 kb ε mRNA and of IgE protein synthesis requires a second signal, provided by T-cells, via CD40LG/CD40 interactions (Oettgen, 2000). *Cd40*$^{-/-}$ mice fail to undergo T-cell–dependent isotype switching and fail to develop germinal centers following immunization with T-cell–dependent antigens (Castigli et al., 1994; Kawabe et al., 1994). Similar results were obtained in mice with disrupted *CD40LG* genes (Borrow et al., 1996; Xu et al., 1994). Cross-linking of CD40 in the presence of IL-4 induces the expression of AICD. AID has a critical role in CSR, as demonstrated by the fact that B-cells from AID$^{-/-}$ mice and from patients with AID deficiency are unable to undergo isotype switching (Muramatsu et al., 2000; Revy et al., 2000). Several molecules that play a role in DNA repair have been found to be important or essential for isotype switching; these include Ku70, Ku80, DNA-PK, Msh2, Pms2, and others (Stavnezer et al., 2008).

CD40/CD40LG interaction is also important for the maturation of myeloid DCs (marked by upregulation of CD80, CD83, CD86, and CD203) and for IL-12 production (Cella et al., 1996; Fontana et al., 2003). CD40LG-expressing CD8$^+$ T-cells activate CD8α$^+$ DC for IL-12 p70 production during antigen-specific T-cell responses and favor cross-presentation and cross-priming of cytotoxic T-cells (Wong et al., 2008). In addition, engagement of CD40 on the surface of plasmocytoid DCs drives a potent Th1 polarization and promotes interferon (IFN)-α secretion in response to viral infections (Cella et al., 2000). In keeping with these observations, both maturation and activation of myeloid and plasmocytoid DCs are severely impaired in patients with CD40 deficiency (Fontana et al., 2003).

CD40 plays also a critical role in the induction of inflammatory responses and in thrombosis. Both CD40 and CD40LG are expressed on the surface of platelets. CD40LG/CD40-mediated platelet–platelet and platelet–lymphocyte interactions favor recruitment of leukocytes to sites of thrombosis or inflammation (Li, 2008). It has recently been shown that CD40 may also be expressed by T-cells, in particular activated CD4$^+$ T lymphocytes, and that it can act as a co-stimulatory molecule and synergize with CD28 during TCR-mediated activation (Munroe et al., 2007).

CD40 plays an important role also in establishing the thymic medullary microenvironment and self-tolerance. In postnatal life, cooperation between CD40- and RANK-mediated signaling was found to be required to support differentiation and maintenance of thymic medulla in mice through a TNF-associated factor 6 (TRAF-6)-, NF-κB inducing kinase (NIK)-, and IκB kinase β (IKKβ)-dependent manner (Akiyama et al., 2008). In this process, CD40 on the surface of medullary thymic epithelial cells (mTECs) is engaged by CD40LG expressed by positively selected CD4$^+$ thymocytes that bear self-reactive TCR-recognizing self-antigens expressed by mTECs in the context of major histocompatibility complex (MHC) class II molecules (Irla et al., 2008). Furthermore, negative selection of endogenously expressed antigens and superantigens is blocked by the administration of antibodies to CD40 ligand (Foy et al., 1995). Altogether, these findings establish a critical role for CD40 in central tolerance.

REGULATION OF CD40 EXPRESSION AND SIGNIFICANCE OF CD40 VARIANTS

In humans, transcription of the *CD40* gene results in production of a 277-a.a. protein, which contains of a 22-a.a. signal sequence, a 171-a.a. extracellular domain, a 22-a.a. transmembrane domain, and a 62-a.a. cytoplasmic domain. Murine CD40 is a 289-a.a. protein and includes a C-terminal 11-a.a. sequence that is not present in human CD40. Regulation of CD40 expression and function is driven by posttranscriptional and posttranslational mechanisms.

CD40 expression is regulated at the transcriptional level by the AT-hook transcription factor AKNA. This factor is known to bind A/T-rich regulatory elements of the promoter DNA and to change their architecture, increasing promoter accessibility. This transcription factor coordinately regulates CD40LG expression as well and thus is important to promote homotypic cell interactions (Siddiqa et al., 2001).

Regulation of CD40 expression is achieved also at the posttranscriptional level through alternative splicing. Modulation of CD40 mRNA isoform expression appears to play an important role in the regulation of CD40LG-mediated signaling. Five different CD40 splicing variants are differentially expressed in activated murine macrophages and DCs (Tone et al., 2001). The type I isoform corresponds to the full-length, functional mRNA and is also the most abundant

splicing variant. A C-terminal truncated *CD40* mRNA isoform (type II) represents the major alternative splicing variant and encodes for a protein unable to deliver intracellular signaling. Type III and IV mRNA products also encode for nonfunctional protein and may act through a dominant negative mechanism by forming nonfunctional trimers with type I CD40 protein. Differential expression of *CD40* mRNA splicing variants during brain development has been implied to play an important role in modulating neuronal differentiation, and CD40-deficient mice have aberrant neuron morphology and gross brain abnormalities (Hou et al., 2008).

In humans, various alternative CD40 splice variants have been also described. In particular, three splice variants have been identified that differ from full-length *CD40* mRNA because they lack exon 5, exon 6, or both exons 5 and 6. Using computational biology tools, the first two of these variants were predicted to encode for soluble decoy receptors because of the lack of the transmembrane domain. Indeed, soluble forms of CD40 have been detected in the serum of uremic patients, but only the isoform lacking the a.a. encoded by exon 6 has the ability to bind CD40LG and may thus serve as a true decoy receptor (Eshel et al., 2008).

Several variants have been identified in the *CD40* gene, and some of these have been associated with an increased risk to develop certain diseases. Association of *CD40* single nucleotide polymorphisms (SNPs) with autoantibody-positive rheumatoid arthritis (possibly involving increased NF-κB-mediated signaling) has been reported (Raychaudhuri et al., 2008). This association suggests that CD40 signaling could mediate rheumatoid pathogenesis through NF-κB activation. Contradictory data are available on the association between CD40 known variants (particularly one in the Kozak fragment) and increased susceptibility to Graves disease, with some evidence that increased thyroidal expression of mutated CD40 may contribute to this disease specificity (Jacobson et al., 2007; Kurylowicz et al., 2005). The same intronic variant has been associated with an increased risk of follicular lymphoma associated with lower expression of CD40 molecule (Skibola et al., 2008).

Some of these SNPs have been characterized from the functional point of view. The P227A CD40 variant resides in the cytoplasmic domain, has been found only in heterozygosity, and has a frequency of 29 percent in South American–descent subjects and less than 1 percent in all the other ethnic groups. This variant has been found to result in increased IgM production, augmented secretion of IL-6 and TNF-alpha, and phosphorylation of the JNK (MAPK8) target, c-Jun, even if binding affinity for TRAF molecules is similar to that reported for wild-type CD40 (Peters et al., 2008).

A single nucleotide change, resulting in an a.a. substitution (p.H78Q) in the second cysteine-rich extramembrane region of CD40, has been described in a multiple myeloma cell line (U266) and in freshly isolated tumor cells. This mutant protein has unique functional properties, including decreased binding affinity for CD40LG and constitutive association with TRAF6 in the absence of CD40LG stimulation. The overall survival rate of patients with multiple myeloma carrying this CD40 mutation was significantly poorer than those expressing wild-type CD40, suggesting that the mutated protein has a role in tumor invasion and metastasis and that CD40/CD40LG interaction may modulate tumor pathogenesis and/or progression (Qi et al., 2009).

CD40-MEDIATED SIGNALING

A schematic representation of CD40-mediated signaling pathways is shown in Figure 26.1. CD40 lacks intrinsic catalytic activity, but its cytoplasmic domain contains binding motifs for several signal-transducing molecules, thus permitting CD40-mediated regulation of humoral and cellular immunity processes (Elgueta et al., 2009). In particular, CD40 binds Jak3 in its proline-rich Box 1 membrane proximal region (a.a. 222–229) and has one additional binding site for TRAF-6 and one for TRAF-2/3/5 proteins (Hanissian and Geha, 1997). Recently, another TRAF-2 binding site has been identified, which is also involved in mediating B-cell activation, proliferation, and differentiation (Lu et al., 2007). CD40 ligation by membrane-bound trimeric CD40LG causes a higher degree of oligomerization and, most importantly, a conformational change that results in translocation of CD40 and associated TRAF proteins to lipid rafts (Xia et al., 2007). When TRAF proteins bind to the cytoplasmic tail of CD40, various signaling cascades are activated, including JAK3-STAT5, NF-κB, c-Jun N-terminal kinase (JNK), and p38 mitogen-activated protein (MAP) kinase pathways (Jabara et al., 2009; Jalukar et al., 2000; Revy et al., 1999; Zarnegar et al., 2004). In B lymphocytes, CD40-induced activation of TRAF-6 is required for IgM production and isotype switching, whereas CD40 interaction with TRAF-2/3/5 promotes CD80/CD86 upregulation and protection from B-cell-antigen-receptor–mediated growth arrest (Ahonen, 2002).

TRAF2 and TRAF6 play an important physiological role in CD40 signaling also in nonhematopoietic cells, and their role is mutually linked, as TRAF6 regulates CD40 signal transduction not only through its direct binding to CD40 but also indirectly via its association with TRAF2 (Davies et al., 2005). A truncated derivative of TRAF2 lacking an amino-terminal RING finger domain is a dominant-negative inhibitor of NF-κB activation mediated by CD40 (Rothe et al., 1995). An 11-a.a motif in the intracellular domain of CD40 that spans the core Px-QxT TRAF2,3 binding sequence was found to be sufficient for the activation of Jun, p38, and NF-κB. A CD40 mutant that binds TRAF2 but not TRAF3 (or TRAF5) was shown to activate NF-κB. This finding, together with the inability of TRAF1 to activate NF-κB, suggests that TRAF2 is the most important element in CD40-mediated activation of NF-κB. TRAF2 has also been found to bind to the kinase NIK, which can also phosphorylate and activate the IKK complex. TRAF2 also binds to RIP, a protein that is central to NF-κB activation by TNFR1 and to the protection of cells from TNF-mediated death. RIP binds to MEKK3, which then phosphorylates and activates IKK (Wang et al., 2001). It has been shown that TRAF6 functions as an E3 ubiquitin ligase to catalyze, together with Ubc13/Uev1A, the synthesis of polyubiquitin chains linked through lysine-63 (K63) of ubiquitin and the activation of a TAK1–TAB1/2 complex,

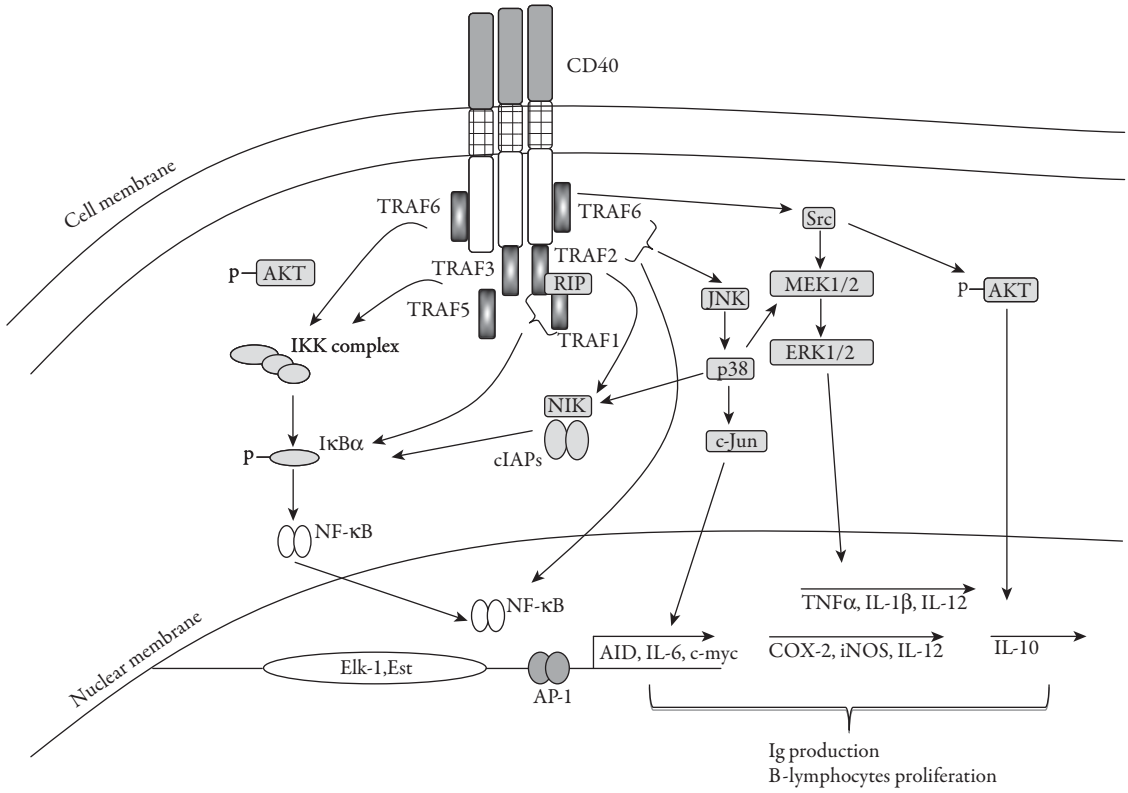

Figure 26.1 Hypothetical model of CD40 signaling. CD40 ligation causes enhanced association of CD40 with tumor necrosis factor receptor-associated factor (TRAF) proteins, resulting in activation of various signaling pathways. In B lymphocytes CD40-induced activation results in transcription of critical genes involved in B-cell proliferation and terminal B-cell differentiation. TRAF2 and TRAF6 interact and activate both the NF-κB and the JNK/p38 pathways. NF-κB activation is regulated via the binding with the RIP protein. Various signaling pathways induce phosphorylation of the IKK complex, leading to nuclear translocation of NF-κB and transcription of target genes.

which phosphorylates and activates IKK (Deng et al., 2000; Shuto et al., 2001; Yang et al., 2000).

Data from knockout mice and from patients with IKKγ/NEMO mutations (Döffinger et al., 2001; Jain et al., 2001; Zonana et al., 2000) strongly suggest that NF-κB plays an important role in CD40-mediated isotype switching. Traf2$^{-/-}$ mice die perinatally, but Traf2$^{-/-}$Tnfr1$^{-/-}$ and Traf2$^{-/-}$ Tnf$^{-/-}$ double-mutant mice are viable (Yeh et al., 1997). Isotype switching to IgG is impaired in Traf2$^{-/-}$ Tnfr1$^{-/-}$ mice. This finding further supports the idea that a pathway consisting of TRAF2-mediated activation of NF-κB in CD40-activated B-cells is critical for isotype switching. Two different NF-κB activation pathways have been described: type 1 (p50-dependent) and type 2 (p52-dependent). In resting B-cells, the alternative NK-κB signaling pathway is inhibited by TRAF2, TRAF3, cIAP1, and cIAP2 by targeting and ubiquitin-dependent degradation of NIK (NF-κB-inducing kinase), thus preventing cleavage of p100 precursors. CD40 and B-cell activating factor receptor (BAFF-R) engagement results in TRAF3 degradation, which blocks association of NIK with the cIAP1–cIAP2–TRAF2 ubiquitin ligase complex and p100 processing and hence enables activation of the type 2 NF-κB signaling pathway (Vallabhapurapu et al., 2008). CD40 and lipopolysaccharide (LPS) can both mediate activation of the type 1 NF-κB signaling pathway. The observation that CD40LG/CD40 interaction promotes homotypic cell adhesion, whereas neither LPS nor BAFF is proficient in this process, indicates that simultaneous activation of type 1 and type 2 NF-κB signaling pathways is required to induce homotypic B-cell adhesion (Zarnegar et al., 2004). Finally, the redox factor APE/Ref-1 has been reported to act as a key signaling intermediate in response to CD40-mediated B-cell activation. Upon CD40 cross-linking, TRAF2 adapter is involved in APE/Ref-1 translocation from the cytoplasm to the nucleus, where it modulates the DNA-binding activity of the Pax5 and EBF transcription factors. APE/Ref-1 appears to be required for CD40-mediated Pax5 activation, as the repression of APE/Ref-1 protein production is able to block CD40-induced Pax5 binding activity (Merluzzi et al., 2008).

CD40 LIGAND

The murine CD40LG has been identified and the gene cloned as an EL4 thymoma cell surface molecule that binds to soluble CD40 (Armitage et al., 1992). Subsequently, the human *CD40LG* gene (*300386), encoding for CD40LG (CD154), was cloned from activated T-cells (Graf et al., 1992; Hollenbaugh et al., 1992; Spriggs et al., 1992). Independently, Lederman et al. identified a subclone of Jurkat T-cells that is able to provide contact-dependent helper function to B-cells (Lederman et al., 1992); the molecule responsible for this helper activity was cloned and confirmed to be CD40LG. The human

cDNA has an open reading frame of 783 base pairs (bp) that codes for a type II membrane protein 261 a.a. long. The extracellular domain is 215 a.a. long, the transmembrane domain is 24 a.a. in length, and the intracellular domain is 22 a.a. long. The presence of a proteolytic cleavage site (His-Arg-Arg-Leu) immediately proximal to the transmembrane domain allows production of soluble forms of CD40LG. Platelets represent the major source of soluble CD40LG in the blood, and recent data indicate that the matrix metalloproteinase-2 (MMP-2) might be the protease primarily responsible for CD40LG cleavage from platelet surface (Reinboldt et al., 2009). Molecular modeling of CD40LG based on the crystal structure of TNF indicates that a.a. residues 189 to 209 are critical for the binding of CD40LG to CD40 (Peitsch and Jongeneel, 1993).

Although de novo synthesis of CD40LG occurs following antigen recognition by T lymphocytes, surface mobilization of preformed, intracellular CD40LG has been also observed in both effector and memory $CD4^+$ T-cells following antigen recognition. Intracellular CD40LG is stored in secretory lysosomes and co-localizes more strongly with Fas ligand than with CTLA-4, two other molecules that are delivered to the cell surface following antigen recognition (Koguchi et al., 2007).

Detailed organization of the murine (Tsitsikov et al., 1994) and human (Shimadzu et al., 1995; Villa et al., 1994) *CD40LG* genes has been reported. The gene consists of five exons. Exon 1 encodes for the 5′ untranslated region and the first 52 a.a., including 22 a.a. of the intracytoplasmic tail, 24 a.a. of the transmembrane domain, and 6 a.a. of the extracellular domain. Exons 2, 3, and 4 encode a.a. 53 to 96, a.a. 97 to 114, and a.a. 115 to 135, respectively. Exon 5 encodes the rest of the protein (a.a. 136–260) and the 3′ untranslated region. There is no homology in the position of the exons between CD40LG and any of the known genes from the TNF family, but in all these genes the sequence encoding the receptor binding domain is located in the last exon.

Several studies have illustrated the importance of CD40 and its ligand, CD40LG, in humoral immunity. Recombinant CD40LG mimics the action of CD40 monoclonal antibody (MAb) and is able to stimulate B-cell proliferation in the presence of phorbol myristate acetate (PMA) and to induce immunoglobulin synthesis (Lane et al., 1993; Spriggs et al., 1992). Immunoglobulin secretion by B-cells is highly modulated by cytokines. In the presence of recombinant CD40LG, IL-2 and IL-10 induce specifically the secretion of IgM, IgG1, and IgA (Durandy et al., 1993), whereas IL-4 is necessary for the secretion of IgG4 and IgE. Antibody to CD40LG can block T-cell–dependent B-cell activation (Noelle et al., 1992a, 1992b). Immunization of mice with KLH (a thymus-dependent antigen) or DNP-Ficoll (a thymus-independent antigen) induces the expression of CD40LG by T helper (Th) cells, and this induction coincides with the development of cytokine-producing cells. Through the use of immunocytochemical techniques, it was elegantly demonstrated that CD40LG cells and cytokine-producing cells are juxtaposed in the lymphoid organs (Van den Eertwegh et al., 1993). Short-term treatment with anti-CD40LG antibody suppressed the immune response against these antigens, but adoptive transfer of cells from anti-CD40LG–treated mice could fully reconstitute Th-cell function in irradiated recipient mice, showing that immune suppression does not involve clonal anergy or deletion (Foy et al., 1993). Thus it appears that CD40LG expression is essential for both thymus-dependent and thymus-independent antigens. However, in mice with targeted disruption of the *Cd40* or *Cd40lg* gene, only the antibody response against the T-dependent antigen is impaired. This finding suggests that stimulation via CD40/CD40LG may not be critical for antibody responses to T-independent antigens.

As reported above, CD40LG is also essential for the maturation of myeloid DCs and the activation of plasmacytoid DCs. In addition, it promotes macrophage effector function, as shown by the fact that $Cd40lg^{-/-}$ mice are less effective in stimulating allogenic macrophages to produce inflammatory cytokines and reactive nitrogen intermediates (Stout et al., 1996). CD40LG/CD40-dependent interaction between activated $CD4^+$ T-cells and DCs is also essential for efficient T-cell priming and licensing of cytotoxic $CD8^+$ T lymphocytes. On the other hand, recent data have shown that stimulation of TLR3 and TLR9 with agonists and certain viruses (such as influenza virus) can induce CD40LG expression of the surface of DCs and may promote efficient priming of cytotoxic $CD8^+$ T-cells, even in the absence of $CD4^+$ T lymphocytes (Johnson et al., 2009). Finally, $CD40LG^+$ T-cells that are generated under strong antigenic stimulation, in concert with certain microbial stimuli, synergistically increase DC IL-6 production and Th17 polarization. CD40-deficient DCs exhibit reduced cytokine release and fail to drive Th17 development in vitro (Iezzi et al., 2009).

REGULATION OF CD40 LIGAND EXPRESSION

CD40LG is a highly inducible gene and is mainly expressed by $CD4^+$ T-cells, although it can also be expressed by other cell types, including $CD8^+$ cells, monocytes, natural killer (NK) cells, and megakaryocytes (Cocks et al., 1993; Crist et al., 2008). In addition, masT-cells, basophils (Gauchat et al., 1993b), and eosinophils (Gauchat et al., 1995) can also express functional CD40LG. The T-cell expression of CD40LG is well regulated; resting T lymphocytes do not express CD40LG. In α/β T-cells, *CD40LG* mRNA becomes detectable as early as 1 hour after stimulation with PMA and ionomycin, peaks at 3 hours, and disappears by 24 hours. Surface CD40LG is detected as early as 3 hours after stimulation with PMA and ionomycin, peaks at 6 hours after stimulation, starts to decline by 8 hours, and is barely detectable by 16 hours. However, activation with anti-CD3 results in sustained expression of CD40LG for 24 hours after stimulation (Castle et al., 1993; Roy et al., 1993). Simultaneous engagement of the T-cell co-stimulatory molecule CD28 by mAb enhances CD40LG expression (Ding et al., 1995; Klaus et al., 1994). Highly purified peripheral blood $\gamma\delta$ T-cells also express CD40LG after stimulation (Horner et al., 1995). The kinetics of mRNA synthesis and surface expression closely resembles that of $\alpha\beta$ T-cells, but the levels are much lower. Prolonged *CD40LG* mRNA half-life has been observed following activation of antigen-primed T-cells as compared to naïve T-cells, indicating that posttranscriptional mechanisms play an important role in controlling CD40LG expression

during immune responses. In particular, it has been demonstrated that a CU-rich site within the 3′-untranslated region of CD40LG mRNA binds to a polypyrimidine tract-binding protein-containing complex (mComplex I) that is activation dependent (Vavassori et al., 2009).

CD40LG expression is developmentally regulated. Newborn T-cells were found to be deficient in CD40LG expression and in their ability to induce isotype switching in B-cells (Brugnoni et al., 1994; Durandy et al., 1995; Fuleihan et al., 1994; Nonoyama et al., 1995), and reduced CD40LG expression persists for the first 6 months of age (Gilmour et al., 2003).

Cyclosporin A (CsA) inhibits the surface and mRNA expression of CD40LG in human (Fuleihan et al., 1994) and murine (Roy et al., 1993) T-cells. CsA is a naturally occurring immunosuppressant that binds to its cellular receptor(s), cyclophilin, forming a complex that inhibits the activity of the phosphoprotein phosphatase calcineurin. Calcineurin dephosphorylates the cytoplasmic subunit of the transcription factor, NFAT, which translocates into the nucleus to form the functional NFAT complex and regulates the expression of the gene encoding IL-2 (Jain et al., 1993). The transcription of *CD40LG* mRNA and the surface expression of the protein are inhibited by pretreatment of T-cells with CsA in a dose-dependent manner. The ability of CsA analogs to inhibit CD40LG expression correlated with the affinity of the cyclophilin–drug complex to calcineurin and not with the affinity of the drug to cyclophilin. These results suggest that transcription factors activated by calcineurin, such as NFAT, regulate the transcription of the *CD40LG* gene, and this has been experimentally confirmed (see below).

Hydrocortisone upregulates *CD40LG* mRNA and protein expression in peripheral blood mononuclear cells (PBMCs) and induces IgE synthesis in IL-4–stimulated normal human B-cells. Disruption of CD40LG–CD40 interaction by soluble CD40-Ig fusion protein or anti-CD40LG mAb blocks the capacity of hydrocortisone to induce IgE synthesis in normal B-cells. Upregulation of *CD40LG* mRNA and induction of IgE synthesis by hydrocortisone were inhibited by the steroid hormone receptor antagonist RU-486 (Jabara et al., 2001). These results indicate that ligand-mediated activation of the glucocorticoid receptor (GR) upregulates CD40LG expression in human lymphocytes. It is possible that hydrocortisone acts by inducing GR binding to glucocorticoid-responsive elements present in the *CD40LG* promoter.

The organization of the murine and human *CD40LG* genes shows remarkable conservation even in the 5′ upstream regulatory sequences. The transcription originates from a G residue 68 bp upstream from the A of the initiation codon in both species (Schubert et al., 1995; Tsitsikov et al., 1994). Sequences up to 1.5 kb upstream from the murine gene lack the TATAA or CCAAT boxes but have an Sp1 sequence, six NFAT-like sequences, and one OAP-like site. Three of the NFAT-like consensus sequences (including the two most proximal ones) are conserved in the human *CD40LG* gene. The most proximal NFAT-binding motifs of the murine gene form two complexes as detected by electrophoretic mobility shift analysis (EMSA). Both complexes contain NFATc and NFATp and are sensitive to CsA (Tsytsykova et al., 1996). Similar findings have been reported for the human *CD40LG* promoter (Schubert et al., 1995).

A T-cell–specific *CD40LG* transcriptional enhancer is located upstream of the promoter. This enhancer binds NFAT1 and the Th2 transcription factor GATA-3 (Brunner et al., 2008). The 3′ untranslated region of the murine gene has two adjacent microsatellite repeats (a 50-bp-long CT and a 90-bp-long CA repeat) as well as two ATTTA elements that are putatively responsible for the stability of mRNA.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF CD40 LIGAND DEFICIENCY

CD40LG deficiency is characterized by an X-linked pattern of inheritance and clinical features that are suggestive of a combined immunodeficiency. Most patients with CD40LG deficiency present in infancy with recurrent upper and lower respiratory tract infections and have a unique predisposition to *Pneumocystis jiroveci* pneumonia, which may even mark the clinical onset of the disease (Levy et al., 1997; Marshall et al., 1964; Ochs and Wedgwood, 1989; Winkelstein et al., 2003). The frequency of *P. jiroveci* pneumonia in CD40LG deficiency varies from 31.7 to 48.1 percent in the European and U.S. series of patients (Winkelstein et al., 2003; L. Notarangelo et al., unpublished observation). Lung infections due to cytomegalovirus, respiratory syncytial virus, cryptococcus, and mycobacteria, including bacillus Calmette-Guérin, have been also reported and may lead to disseminated disease (Banatvala et al., 1994; Fremerey et al., 2009; Hostoffer et al., 1994; Iseki et al., 1994; Kyong et al., 1978; Levy et al., 1997; Tabone et al., 1994; Tu et al., 1991). An increased risk for paracoccidioidomycosis and other unsual infections has been recently reported (Cabral-Marques et al., 2012).

Diarrhea occurs in over 50 percent of CD40LG-deficient patients (Levy et al., 1997; Notarangelo et al., 1992; Winkelstein et al., 2003) and may become chronic and require total parenteral nutrition. Chronic watery diarrhea is often associated with *Cryptosporidium* infection (Stiehm et al., 1986), which may also contribute to sclerosing cholangitis, a severe and often fatal complication (Banatvala et al., 1994; DiPalma et al., 1986; Hayward et al., 1997; Levy et al., 1997; Winkelstein et al., 2003). The incidence of liver and biliary tract disease increases with age (Hayward et al., 1997).

Oral ulcers and proctitis are common manifestations (Banatvala et al., 1994; Benkerrou et al., 1990; Hong et al., 1962; Kyong et al., 1978; Macchi et al., 1995; Notarangelo et al., 1992; Rieger et al., 1980) and are usually associated with neutropenia, either chronic (Aruffo et al., 1993; Levy et al., 1997) or cyclic (Notarangelo et al., 1992; Shimadzu et al., 1995; Wang et al., 1994).

CD40LG-deficient patients have osteopenia, with lower bone mineral density and elevated levels of N-terminal telopeptides of type I collagen, a urinary marker indicative of osteoclast activity. Osteoclast differentiation of myeloid cells is induced by RANKL, and osteoclastic activity is modulated by IFN-γ. $CD4^+$ CD40LG-deficient human T-cells have normal

expression of RANKL and promote marked osteoclastogenesis of myeloid cells; however, this activity cannot be properly modulated because of impaired T-cell priming and reduced IFN-γ production (Lopez-Granados et al., 2007).

Patients with *CD40LG* mutations are also at increased risk for lymphomas (Filipovich et al., 1994) and liver/biliary tract and gastrointestinal tumors (including peripheral neuroectodermal tumors), which are rarely observed in other primary immunodeficiencies (Erdos et al., 2008; Facchetti et al., 1995; Hayward et al., 1997).

Autoimmune manifestations (arthritis, thrombocytopenia, hemolytic anemia, hypoparathyroidism, immune complex–mediated nephritis, and retinal pigment epithelium hypersensitivity) may occur in CD40LG deficiency, although they are less common than in autosomal forms of CSR defects (Benkerrou et al., 1990; Hollenbaugh et al., 1994, Pascual-Salcedo et al., 1983; Schuster et al., 2005). Anemia may also be secondary to chronic infections or to parvovirus B19-induced red blood cell aplasia. The latter may even be the only manifestation of disease in patients with a mild phenotype (Blaeser et al., 2005; Seyama et al., 1998a).

Severe neurological involvement has also been reported. Meningoencephalitis due to enterovirus infection may occur, despite regular administration of intravenous immunoglobulins (IVIG) (Cunningham et al., 1999; Halliday et al., 2003). Cerebral toxoplasmosis and progressive multifocal leukoencephalopathy, in some cases caused by reactivation of the human neurotropic JC virus, have been reported as the first sign of disease in adults with hypomorphic *CD40LG* mutations (Aschermann et al., 2007; Suzuki et al., 2006; Yong et al., 2008).

Lymph nodes of CD40LG-deficient patients lack germinal centers (Facchetti et al., 1995; Hong et al., 1962; Rosen et al., 1961; Stiehm and Fudenberg, 1966) (Color Plate 26.I). This is the consequence of ineffective CD40–CD40LG interaction in the extrafollicular areas, resulting in poor recruitment of germinal-center precursors. In addition, severe depletion and phenotypic abnormalities of follicular DCs have been reported that may contribute to poor antigen trapping and result in inefficient rescue of the few germinal-center B-cells from apoptosis (Facchetti et al., 1995). Bone marrow examination in patients with concurrent neutropenia often reveals a block of myeloid differentiation at the myelocyte/promyelocyte stage (Benkerrou et al., 1990; Hong et al., 1962; Kyong et al., 1978; Notarangelo et al., 1992). By contrast, serum levels of granulocyte colony-stimulating factor (G-CSF) in neutropenic CD40LG-deficient patients are normal or elevated (Wang et al., 1994).

A European registry of CD40LG-deficient patients has been organized that includes clinical, immunological, and molecular data (Notarangelo et al., 1996). The registry is accessible through at http://bioinf.uta.fi/CD40Lbase. A similar registry has been set up in the United States by USIDnet.

LABORATORY FINDINGS

Immunoglobulin Levels

Like all forms of impaired CSR, CD40LG deficiency is characterized by markedly reduced serum IgG, IgA, and IgE with variable IgM levels and a normal number of circulating B-cells (Geha et al., 1979; Levy et al., 1987; Notarangelo et al., 1992; Winkelstein et al., 2003). Variability of IgM serum levels has been reported among affected members of the same family, indicating that increased IgM may reflect chronic antigenic stimulation rather than the direct effect of a molecular defect (Kroczek et al., 1994). In a series of 56 CD40LG-deficient patients, the majority (53 percent) had normal IgM serum levels at the time of diagnosis (Levy et al., 1997). In another study, however, as many as one quarter of patients with confirmed CD40LG deficiency had low concentrations of serum IgM, indicating that even low serum IgM levels should not preclude testing for CD40LG deficiency (Gilmour et al., 2003). Altogether, the variability of IgM serum levels and the broad range of clinical manifestations, which go beyond abnormalities of humoral immunity, have led researchers to abandon the older designation of "X-linked hyper-IgM" that was previously used to indicate CD40LG deficiency. Although serum levels of IgG, IgA, and IgE are normally very low in patients with CD40LG deficiency, exceptional cases with elevated IgA, IgE, or even IgG have been observed (Levy et al., 1997; L. Notarangelo, unpublished observation), indicating that environmental and/or other genetic factors may have an impact on CSR. In particular, signaling through Toll-like receptors may permit CD40LG/CD40-independent CSR (Glaum et al., 2009; Pasare et al., 2005; Xu et al., 2008).

Serum isohemagglutinins are usually normal (Benkerrou et al., 1990; Kyong et al., 1978; Rosen et al., 1961). In contrast, immunization with T-dependent antigens (e.g., bacteriophage ϕx174) leads to reduced primary and secondary IgM antibody responses and little or no production of IgG-specific antibodies following recall immunization (Benkerrou et al., 1990; Nonoyama et al., 1993; Stiehm and Fudenberg, 1966). In addition, analysis of V_H gene segments in patients with *CD40LG* mutations has revealed a lower frequency of somatic mutations in IgM-expressing B-cells than that in controls (Chu et al., 1995; Razanajaona et al., 1996). This defect is particularly pronounced at the hypermutable G in the RGYW motif, which is a typical target of AICD. Along with the defect in frequency, SHM in patients with CD40LG deficiency is characterized by an increase in transitions versus transversions, reminiscent of decreased UNG activity (Longo et al., 2009). These data are in keeping with the notion that both AICD and UNG are transcriptional targets of CD40LG.

Defects of CSR and SHM are a direct consequence of the underlying genetic defect. Because of the inability to express functional CD40LG trimers, activated T-cells are unable to provide a key helper signal for terminal B-cell differentiation. The functional integrity of their B-cells, by contrast, was initially suggested by the experiments performed by Mayer et al. (1986), who demonstrated that B-cells from these patients can be driven to secrete immunoglobulins of various isotypes in the presence of pokeweed mitogen when co-cultured with "helper T lymphoblasts" from a patient with a Sézary-like syndrome. Subsequently, it was shown that co-culture of patient-derived PBMCs with anti-CD40 mAb (or soluble CD40LG) and appropriate cytokines, such as IL-4 and IL-10, results in normal CSR and in vitro production of IgG, IgA, and IgE

(Allen et al., 1993a; Aruffo et al., 1993; Callard et al., 1994; Durandy et al., 1993; Fuleihan et al., 1993a; Korthauer et al., 1993; Saiki et al., 1995).

B and T Lymphocytes

Subjects with CD40LG deficiency have a normal number of circulating B lymphocytes, and this allows differentiation from X-linked agammaglobulinemia. However, circulating B-cells express IgM and/or IgD, but not other isotypes (Benkerrou et al., 1990; Levitt et al., 1983). Furthermore, since CD40LG–CD40 interaction is essential for memory B-cell generation, the number of circulating $IgD^{-}CD27^{+}$ switched memory B-cells is strongly diminished in patients with CD40LG mutations (Agematsu et al., 1998).

In spite of the T-cell nature of the defect in CD40LG deficiency, the number and distribution of T-cell subsets are normal, although the proportion of $CD45R0^{+}$ primed T-cells is reduced (Jain et al., 1999). In vitro proliferative response to mitogens is normal, but T-cell proliferation to antigens is often reduced (Ameratunga et al., 1997; Levy et al., 1997). A defect in TH1 responses has been reported, with reduced secretion of IFN-γ and failure to induce antigen-presenting cells to synthesize IL-12 (Jain et al., 1999; Subauste et al., 1999). A summary of laboratory features typically observed in CD40LG deficiency is shown in Table 26.1.

MOLECULAR BASIS OF CD40 LIGAND DEFICIENCY

The gene causing X-linked hyper-IgM (as CD40LG deficiency was originally known) was mapped to Xq26.3–27 by linkage analysis (Mensink et al., 1987; Padayachee et al., 1992, 1993). Cloning of the human *CD40LG* gene and coincidental mapping to the same region of the X chromosome (Graf et al., 1992) were soon followed by the recognition that *CD40LG* mutations account for the disease (Allen et al., 1993a; Aruffo et al., 1993; DiSanto et al., 1993; Fuleihan et al., 1993b; Korthauer et al., 1993) and by definition of the gene organization (Shimadzu et al., 1995; Villa et al., 1994). The human *CD40LG* gene encompasses about 13 kb of genomic DNA and is organized in five exons and four introns. Definition of the exon–intron boundaries has

Table 26.1 **SYNOPSIS OF LABORATORY FINDINGS IN PATIENTS WITH CD40LG DEFICIENCY**

PARAMETER	TYPICAL PHENOTYPE	PERCENT OF CD40LG-DEFICIENT PATIENTS SHOWING PHENOTYPE* PHENOTYPE*
Immunological Features		
Serum IgG	<2 SD below normal range	99–100
Serum IgA (mg/dL)	Undetectable	76–93
Serum IgM (mg/dL)	Normal	53–59 (at diagnosis)†
	Elevated	32–47 (at diagnosis) †
Antibody response to T-dependent antigens (φ × 174)	Lack of specific IgG production	100‡
B-cell count	Normal	90
$CD4^{+}$ cell count	Normal	94
$CD8^{+}$ cell count	Normal	98
Proliferative response to PHA	Normal (>50,000 cpm)	93
Proliferative response to T-dependent antigens	Often reduced (<5,000 cpm)	37
CD40LG expression**		
As assessed with CD40-Ig	Absent	Nearly 100††
As assessed with mAb	Usually absent	95
As assessed with polyclonal antiserum	Detectable in some cases	23
Hematological Features		
Neutropenia	Generally present (mostly chronic)	63–68
Anemia	Often present	15–32

* Unless differently specified, data are from Levy et al. (1997) and from Winkelstein et al. (2003).

† Elevated levels of IgM are detected in about 70% of patients during follow-up.

‡ From Nonoyama et al. (1993).

** From a series of 22 patients analyzed at the Department of Pediatrics, University of Brescia, Italy.

†† Activated $CD4^{+}$ T-cells from patients with missense mutations in intracytoplasmic or transmembrane domains of CD40LG may occasionally react with CD40-Ig (Seyama et al. 1998b).

enabled a search for mutations at the genomic level (Lin et al., 1996; Villa et al., 1994).

CD40LG MUTATIONS

Since 1993, a long list of unique *CD40LG* gene mutations have been identified in patients with CD40LG deficiency. Figure 26.2 illustrates the mutations identified in 188 patients included in the European CD40LGbase Registry or the Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php). Although mutations may affect the entire gene, they are unequally distributed and the majority are located in exon 5, which contains most of the TNF-homology domain (Hollenbaugh et al., 1992).

Missense mutations are the most common cause of the disease. Mutational hot-spots (leading to missense or nonsense mutations) have been identified at codons 140, 155, and 254; none of these involves the presence of CpG dinucleotides. In some cases, for example the Trp140stop mutation, premature termination is compatible with expression of a truncated molecule at the cell surface, as shown by staining with polyclonal anti-CD40LG antibody (Korthauer et al., 1993, Seyama et al., 1998b). Small insertions or deletions in the *CD40LG* gene are also common; these may be due to polymerase slippage, occurring at sites of nucleotide duplications or tandem repeats in the CD40LG sequence (Macchi et al., 1995). A few patients with two different mutations have been described (Aruffo et al., 1993; Grammer et al., 1995; Lin et al., 1996).

Investigation of the effect of amino acid substitutions on CD40LG expression and function, studied through several approaches, has contributed to definition of the role that single residues play in determining folding, assembling, and CD40-binding properties of CD40LG. For some naturally occurring mutations, transfectants that express surface membrane or soluble forms of mutant CD40LG molecules have been generated. The mutagenized recombinants fail to bind CD40-Ig or to induce B-cell proliferation and immunoglobulin secretion in the presence of IL-4 (Allen et al., 1993a; Aruffo et al., 1993).

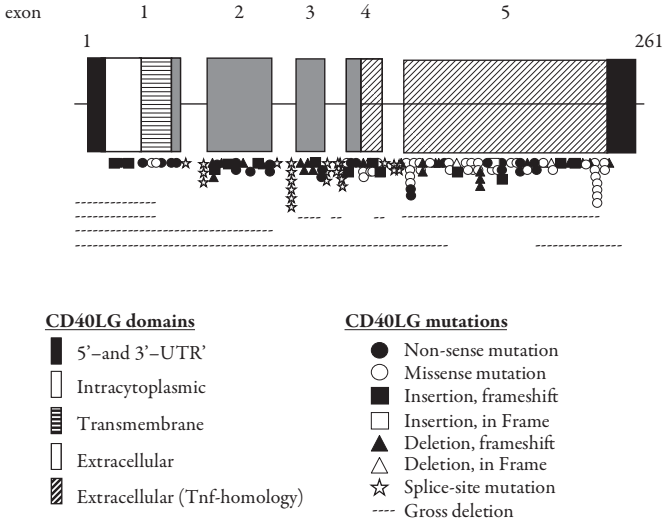

Figure 26.2 Description of *CD40LG* mutations identified in 188 patients from independent families enrolled in the European CD40Lbase Registry or reported to the Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php). The various mutations are shown with different symbols, as indicated in the figure, and aligned along the CD40LG protein. Correspondence between the protein and the five exons of the *CD40LG* gene is also shown.

FUNCTIONAL ASPECTS OF CD40LG DEFICIENCY

Human CD40LG belongs to the TNF family (Hollenbaugh et al., 1992). As mentioned above, mutations cluster predominantly in the extracellular TNF-homology domain. Despite the rather limited sequence identity of the CD40LG TNF-like domain with TNF (27.3 percent), the homology is sufficient to allow computer modeling based on the crystal structures available for TNF and for the TNF/TNFR complex (Banner et al., 1993; Eck and Sprang, 1991; Jones et al., 1989). Thus, models have been generated for murine (Peitsch and Jongeneel, 1993) and human (Bajorath et al., 1995a, 1995b; Notarangelo et al., 1996) CD40LG, and an X-ray structure of the extracellular portion of human CD40LG has been produced (Karpusas et al., 1995). Analogous to TNF, CD40LG forms a trimer and exhibits a remarkably similar overall fold, with the extracellular portion assuming the shape of a truncated pyramid (Karpusas et al., 1995). A disulfide bond between Cys178 and Cys218 stabilizes the top of the molecule. The CD40 binding site consists of a shallow groove formed between two monomers. Buried and solvent-accessible residues of the CD40LG molecule have been identified (Bajorath et al., 1995a, 1995b; Karpusas et al., 1995). Interestingly, several residues (Gly144, Lys143, Tyr145, Arg203, and Gln220) that are predicted to be directly involved in CD40 binding (Bajorath et al., 1995a, 1995b) were found to be mutated in patients with CD40LG deficiency. The crystal structure of the extracellular portion of CD40LG has shown that both hydrophobic and hydrophilic residues form the surface of the CD40 binding site (Karpusas et al., 1995). In addition, a number of buried residues appear to be important for proper monomer folding and trimer formation. By applying structural and bioinformatics tools, the consequences of the missense *CD40LG* mutations have been analyzed in detail in several studies. In one recent study, 40 percent of the missense mutants were predicted to cause major structural abnormalities, and 37 percent affect residues that are important for trimerization or for ligand binding (Thusberg and Vihinen, 2007). In particular, Ser128 and Glu129 (which have both been reported to be mutated) lie close to Lys143 in the three-dimensional structure. Since Lys143 is involved in CD40 binding, it is likely that mutations at codons 128 and 129 disturb ligand–receptor interaction (Bajorath et al., 1996; Karpusas et al., 1995); furthermore, they were shown to cause clashes with other side chains of the molecule (Thusberg and Vihinen, 2007). Similarly, Val126 and Leu 155 (also mutated in patients) participate in the formation of a hydrophobic core that is very close to residues 143–145, which are involved in CD40 binding; it is predicted that these mutations also affect the CD40 binding property of CD40LG, and replacement of Leu155 was also found to have an impact on protein structure.

Finally, three additional mutations (Thr147Asn, Thr211Asp, Gly250Ala) involve residues that are either buried (Thr147) or exposed (Thr211, Gly250) and are located at the interface between monomers; they participate in the formation of three equivalent CD40 binding sites, one per interface between monomers. Mutation at these residues should also affect CD40 binding (Bajorath et al., 1996).

However, the majority of missense mutations reported in patients do not involve the CD40 binding site. The amino acids affected may participate in the generation of the hydrophobic core, so mutations at these residues compromise core packing and folding of the monomer (this is the case for Trp140Arg, Trp140Cys, Trp140Gly, Leu232Ser, Ala235Pro, Val237Glu, Thr254Met, and Leu258Ser) (Bajorath et al., 1996). Alternatively, they may involve buried residues at the interface between monomers; mutations at these sites are likely to disturb trimer formation, as predicted for Ala123Glu, Tyr170Cys, Tyr172His, and Gly227Val (Bajorath et al., 1996; Karpusas et al., 1995). Finally, the amino acid substitutions Met36Arg and Gly38Arg in the transmembrane domain of CD40LG introduce a polar residue in a very hydrophobic sequence, causing severe problems for the insertion of the molecule in the membrane. Indeed, these mutations are associated with a marked reduction in cell surface expression (Garber et al., 1999). By analogy with similar mutations in other proteins, it has been speculated that these mutations promote retention of the mutant in the endoplasmic reticulum and degradation (Thusberg and Vihinen, 2007).

STRATEGY FOR DIAGNOSIS

Along with typical clinical and immunological features that distinguish CD40LG deficiency from XLA, a positive X-linked family history is important in the diagnosis of CD40LG deficiency; however, sporadic occurrence in males is not rare. For this reason, diagnosis of CD40LG deficiency is usually accomplished by demonstrating in vitro the inability of activated patient $CD4^+$ T-cells to express functional CD40LG (CD154) molecules, as assessed by binding of soluble CD40-Ig chimeric constructs or of anti-CD40LG mAbs. However, false-negative results may be obtained with use of mAbs, because occasionally they may recognize mutant forms of CD40LG expressed at the cell surface. This phenomenon is even more common when polyclonal antisera to CD40LG are used in the staining procedure, as they may recognize even truncated forms of the protein (Seyama et al., 1998b). Therefore, polyclonal antisera to CD40LG should not be used for diagnosis. However, rarely even the chimeric CD40-Ig molecule may bind to mutant CD40LG, particularly in patients with missense mutations in the transmembrane or cytoplasmic domains, which are permissive for membrane protein expression (Lee et al., 2005; Seyama et al., 1998a, 1998b). Ultimately, mutation analysis at the *CD40LG* locus may be required for a definitive diagnosis.

A number of critical factors should be considered when performing diagnostic assays for CD40LG deficiency. First, appropriate controls for T-cell activation (e.g., expression of CD69) should be included. This is particularly important to distinguish CD40LG deficiency from common variable immunodeficiencies (CVIDs); a subgroup of CVIDs patients have defective CD40LG expression in the context of a broader T-cell activation defect (Farrington et al., 1994). Second, because CD40LG is preferentially expressed by activated $CD4^+$ cells (Lane et al., 1992), any condition characterized by CD4 lymphopenia would also result in a low proportion of CD40LG-expressing cells upon activation in vitro. In particular, it has been recognized that activated T-cells from patients with MHC class II deficiency fail to express CD40LG because of the markedly reduced proportion of $CD4^+$ T lymphocytes (Callard et al., 1994). Third, the age of the proband has to be considered. There is ample evidence showing that expression of CD40LG by activated neonatal T-cells is physiologically reduced (Brugnoni et al., 1994; Durandy et al., 1995; Fuleihan et al., 1994; Nonoyama et al., 1995). As mentioned above, definitive confirmation of CD40LG deficiency can be achieved through *CD40LG* gene mutation analysis.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

In contrast to carriers of other X-linked immunodeficiencies (e.g., X-linked agammaglobulinemia [XLA]; X-linked severe combined immunodeficiency [X-SCID]; Wiskott-Aldrich syndrome [WAS]), carrier females of CD40LG deficiency exhibit a random pattern of X inactivation and are indeed mosaics for two populations of circulating T lymphocytes (one expressing the wild-type CD40LG allele and the other expressing the mutated one) (Hollenbaugh et al., 1994). In carriers with skewed lyonization, no clinical or immunological abnormalities are found, indicating that limited CD40LG expression is sufficient to induce isotype switching and normal generation of memory B-cells (Callard et al., 1994; Hollenbaugh et al., 1994). However, extreme lyonization with selective expression of the mutant form of CD40LG may exceptionally result in an overt clinical phenotype (de Saint Basile et al., 1999).

Carrier detection is best achieved with *CD40LG* gene molecular analysis. In families with clear X-linked inheritance, linkage analysis can be performed, taking advantage of two sets of hypervariable microsatellites at the 3′ untranslated region of the *CD40LG* gene (Allen et al., 1993b; DiSanto et al., 1993, 1994; Gauchat et al., 1993a; Ramesh et al., 1994; Shimadzu et al., 1995). Whenever the mutation is known, DNA sequencing, with a search for heterozygosity for the specific mutation, is the most simple and direct way to attempt carrier detection (Lin et al., 1996; Shimadzu et al., 1995; Villa et al., 1994). Heterozygosity for the mutation (e.g., carrier detection) can also be investigated at the cDNA level, as for splice-site mutations that cause exon skipping (DiSanto et al., 1993; Hollenbaugh et al., 1994).

Knowledge of the specific *CD40LG* gene defect also allows prenatal diagnosis on chorionic villi DNA by 10 to 11 weeks of gestation (Villa et al., 1994). Segregation analysis with hypervariable microsatellites at the 3′ untranslated region of the *CD40LG* gene has been also successfully used for this purpose (DiSanto et al., 1994).

Despite the reduced ability of activated T-cells from neonates to express CD40LG (Brugnoni et al., 1994; Durandy et al., 1995; Fuleihan et al., 1994; Nonoyama et al., 1995), surface membrane CD40LG was detected on activated T-cells from 19- to 28-week-old fetuses (Durandy et al., 1995). However, because of the obviously complex developmental control of CD40LG expression, staining for CD40LG on fetal cord blood T lymphocytes should not be used as the sole technique for prenatal diagnosis of CD40LG deficiency.

TREATMENT AND PROGNOSIS

The long-term prognosis of CD40LG deficiency appears to be worse than that in other forms of congenital hypogammaglobulinemia—for example, XLA. Data from the European registry on 128 patients with CD40LG deficiency indicated that survival at 25 years of age was only 40 percent. In addition, 30 of the 128 patients had died. Mortality was somewhat lower in the U.S. registry, in which 8 of 79 subjects had died. This difference in mortality between the European and the U.S. series may reflect a lower incidence of *Cryptosporidium* infection, sclerosing cholangitis, and irreversible liver damage in the latter (Winkelstein et al., 2003). The main causes of death in patients with CD40LG deficiency include infections early in life and, later on, severe liver disease and malignant tumors (Hayward et al., 1997; Levy et al., 1997).

The complex array of clinical manifestations and the increased risk of opportunistic infections and chronic neutropenia require multiple therapeutic approaches. Regular infusion of IVIG (400–600 mg/kg every 21–28 days) is the most important form of treatment. It significantly reduces the severity and frequency of infections (Levy et al., 1997) and may occasionally correct neutropenia (Banatvala et al., 1994; Levy et al., 1997). In addition, prophylaxis with co-trimoxazole is necessary to prevent *P. jiroveci* pneumonia (Banatvala et al., 1994; Levy et al., 1997; Notarangelo et al., 1992). Long-term treatment with amphotericin B and flucytosine has been used in patients who have developed cryptococcosis (Iseki et al., 1994; Tabone et al., 1994). Patients with severe neutropenia may benefit from treatment with recombinant G-CSF; in some cases, this approach has caused a change from chronic to cyclic neutropenia (Shimadzu et al., 1995; Wang et al., 1994). Total parenteral nutrition may be necessary in patients with protracted diarrhea and malabsorption, particularly if these are due to *Cryptosporidium* (Benkerrou et al., 1990). *Cryptosporidium* infection should be prevented by avoiding risk factors (such as swimming in lakes), but use of filtered or sterile water at home has been also suggested. Early detection of *Cryptosporidium* infection is best achieved by PCR-based amplification of stool DNA and microscopy of bile fluid (McLauchlin et al., 2003). Acute infection has been treated with azithromycin or nitazoxanide, but results have been often unsatisfactory.

Because of the rather dismal prognosis, more radical forms of treatment have been proposed, in particular hematopoietic cell transplantation (HCT), which at the moment remains the only strategy that can result in permanent cure of the disease (Thomas et al., 1995). In a series of 38 European CD40LG-deficient patients treated by HCT, 58 percent were cured; among those without preexisting liver disease the survival rate was 72 percent. However, the overall mortality rate was high (31.6 percent) (Gennery et al., 2004), and in all cases, death was from infections. Preexisting lung disease was associated with a poor outcome. Promising results have been obtained using a nonmyeloablative conditioning regimen in CD40LG-deficient patients with severe liver disease (Jacobsohn et al., 2004; Kikuta et al., 2006). Importantly, lack of a strict genotype–phenotype correlation in CD40LG deficiency prevents selection of high-risk patients who might benefit from HCT early in life.

Attempts to treat severe liver disease (sclerosing cholangitis, cirrhosis) with liver transplantation usually fail because of relapse of the disease in the transplanted organ (Hayward et al., 1997; Levy et al., 1997). Combined bone marrow and cadaveric orthotopic liver transplantation has resulted in disease correction in one patient (Hadzic et al., 2000); however, additional severely affected CD40LG-deficient patients treated with HCT and liver transplantation have failed to survive (Notarangelo, unpublished).

The recognition that expression of the *CD40LG* gene is under tight regulatory control makes gene therapy a less viable option, particularly since deregulated expression of CD40LG in transgenic mice has been shown to result in tumor development (Brown et al., 1998; Sacco et al., 2000). Use of lentiviral vectors might enable insertion of autologous regulatory gene elements (Barry et al., 2000), thus making gene therapy–based treatment with acceptable risks possible in the future. However, the finding that mutant forms of CD40LG interact with wild-type molecules and prevent expression of functional trimers (Seyama et al., 1999; Su et al., 2001) raises further doubts that gene therapy could become an effective form of treatment for CD40LG deficiency. These problems may be circumvented by *trans*-splicing (a process by which two different pre-mRNAs are joined by the cellular splicing apparatus), which allows complementation of the gene defect while preserving the natural regulation and cell specificity of CD40LG expression. Indeed, this strategy has been successfully used to correct a murine model of CD40LG deficiency (Tahara et al., 2004).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF CD40 DEFICIENCY

Defective expression of CD40 by B lymphocytes (CD40 deficiency, MIM *606843) has been detected in five children from four unrelated families from the Mediterranean region (Ferrari et al., 2001; Kutukculer et al., 2003; Lougaris et al., 2005; Mazzolari et al., 2007). Twelve additional patients with molecularly proven CD40 deficiency have been identified in Saudi Arabia (El-Ghonaium, personal communication). Clinical and immunological data at presentation were very similar to those observed in CD40LG deficiency, but autosomal recessive inheritance was indicated by parental consanguinity and by the fact that four of the five reported patients were female. Patient 1, an 8-year-old Italian girl, suffered from

P. jiroveci pneumonia at 4 months of age and had another episode of pneumonia at age 2, when she was found to be panhypogammaglobulinemic and was started on IVIG treatment (Lougaris et al., 2005). At the age of 7 years, she developed persistent eosinophilia (800–13,500/μL) and a mild increase of liver enzymes. Liver biopsy showed a severe pattern of sclerosing cholangitis, and microscopic examination of bile specimens revealed the presence of *Cryptosporidium* oocysts. The patient died at the age of 9 years from liver insufficiency. Patients 2 and 3 are first cousins from a multiply related Arabian family. Patient 2 is a 5-year-old boy who suffered from recurrent pneumonia, hypogammaglobulinemia with elevated IgM, and neutropenia. Patient 3 is a 7-year-old girl who also experienced recurrent lower respiratory tract infections. She was diagnosed with immunodeficiency with hyper-IgM at 8 months of age, and substitution treatment with IVIG was started. At 3 years of age, she was admitted to a pediatric intensive care unit for severe interstitial pneumonia. Patient 4, a 12-month-old Turkish girl born to consanguineous parents, was hospitalized for respiratory distress. She developed necrotizing pneumonia caused by *Pseudomonas aeruginosa* and chronic watery diarrhea and disseminated *Cryptosporidium parvum* infection. She received a matched-sibling stem cell transplantation but died of cardiorespiratory arrest at day 16 posttransplant. Patient 5 was hospitalized at 2 years of age because of recurrent pneumonia, otitis, and skin infections and was diagnosed with a hyper-IgM phenotype associated with impaired CD40 expression. She developed neutropenia that required treatment with G-CSF. At 3 years of age, she received HCT from her HLA-identical healthy carrier sibling. She is now fully reconstituted at 4 years after HCT.

All five children had very low levels of IgG and IgA, and three of them had increased serum IgM levels. Lymphocyte numbers and subset distributions were normal, as were in vitro proliferative responses to mitogens. However, CD40 expression on the surface of B lymphocytes and monocytes was abrogated or severely reduced. Importantly, in contrast to what observed in CD40LG deficiency, B-cells from CD40-deficient patients could not be induced to secrete IgG and IgA upon in vitro activation with anti-CD40 mAb and IL-10, indicating a B-cell intrinsic defect.

MOLECULAR AND IMMUNOLOGICAL FEATURES OF CD40 DEFICIENCY

Patients with CD40 deficiency are clinically and immunologically undistinguishable from those with CD40LG deficiency. However, circulating B-cells and monocytes lack surface membrane CD40, whereas expression of CD40LG on the surface of in vitro activated $CD4^+$ T-cells is preserved. Western-blot analysis of lymphoblastoid cell lines showed that the CD40 protein was also undetectable intracellularly in patient 1, whereas an aberrant pattern of migration of the CD40 protein was detected in patients 2, 4, and 5. Mutation analysis at the *CD40* gene showed that all of the patients carried homozygous mutations (Fig. 26.3). In particular, patient 1 was homozygous for a silent mutation (A-to-T substitution at nucleotide 408, corresponding to the fifth nucleotide of exon 5), which involves and disrupts an exonic splicing enhancer, thus preventing incorporation of exon 5 in the mRNA. Consequently, cDNA from this patient lacked 94 nucleotides (matching exon 5), resulting in frameshift and premature termination. Patients 2 and 3 were both homozygous for a C-to-T change at nucleotide 247, resulting in a nonconserved Cys83-to-Arg amino acid substitution. The mutation in patient 4 occurred at position 2 of the acceptor site of intron 3; use of a cryptic splice site in this patient resulted in a 2-a.a. deletion (ΔN86_L87) and replacement of the next a.a. (G88R). Patient 5 was homozygous for a 3-nucleotide deletion in exon 2, resulting in one a.a. deletion (del I33) in the extracellular domain of CD40. This was also the only patient who had residual, though markedly reduced, CD40 expression at the cell surface.

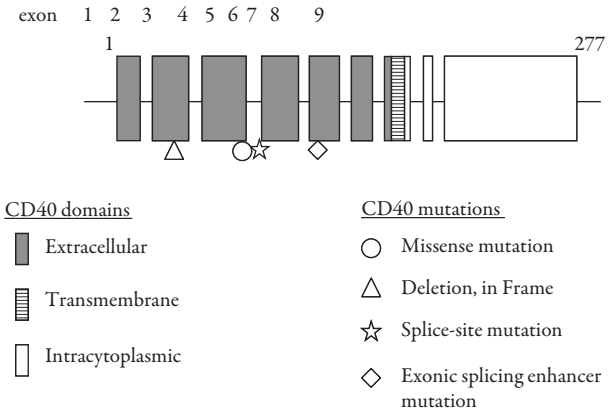

Figure 26.3 Description of *CD40* mutations in affected individuals from four unrelated families with CD40 deficiency. The different types of mutations identified are indicated with different symbols and are aligned along the structure of the CD40 protein with its extracellular, transmembrane, and intracytoplasmic domains. Correspondence between the protein and the nine exons of the gene is also shown.

Investigation of the intracellular fate and biochemical properties of CD40 mutants carrying amino acid substitutions has revealed that the mutant proteins are synthesized but retained in the endoplasmic reticulum (ER). Moreover, accumulation of the C83R is associated with ER stress and activation of the unfolded protein response. By contrast, the ΔN86_L87;G88R mutant is efficiently disposed of by the ER-degradation pathway, whereas the ΔI33 partially negotiates transport to the cell membrane and is competent for CD40LG binding and intracellular signaling (Lanzi et al., 2010). Further investigation of the functional consequences of CD40 deficiency showed that both memory B-cell generation and somatic mutation were affected. DCs, cultured with TNF-α or with lipopolysaccharide (LPS) combined with IFN-γ, displayed a consistent defect in their ability to induce proliferation of allogeneic T-cells and secretion of IFN-γ. The defective co-stimulatory activity of DCs derived from patients with CD40 deficiency was associated with lower cell surface levels of MHC class II antigen and with a decreased release of IL-12. These findings support the notion that CD40 deficiency is not an exclusive defect of humoral immunity but should be considered a combined defect of B- and T-cell compartments (Fontana et al., 2003).

The diagnosis of CD40 deficiency is usually made by demonstrating the inability of peripheral blood B-cells to express CD40, as assessed by flow cytometry, in patients with clinical features and an immunoglobulin profile suggestive of impaired CSR. However, the possibility of false-negative results, due to recognition of mutant CD40 molecules by the monoclonal antibody, exists. Furthermore, because CD40 is expressed as a trimer, is it theoretically possible that heterozygous mutations that allow expression of CD40 but affect its function may result in an HIGM phenotype through a dominant-negative effect. Ultimately, diagnosis of CD40 deficiency requires mutation analysis at the *CD40* locus.

TREATMENT AND PROGNOSIS

Management of patients with CD40 deficiency is similar to that outlined for patients with CD40LG deficiency. Treatment includes regular infusions of IVIG, *Pneumocystis* pneumonia prophylaxis with co-trimoxazole, measures to prevent *Cryptosporidium* infection, and monitoring of liver status by ultrasound scanning and biochemical analysis. A persistent increase of liver enzymes and/or eosinophils requires a careful investigation for the presence of sclerosing cholangitis and/or *Cryptosporidium* infection, as these events seem to be highly correlated. For this purpose, microscopic examination of the stools may not be sensitive enough, and more sensitive methods should be applied, such as PCR-based amplification of stool DNA and microscopy of bile fluid. Although CD40 expression is not restricted to hematopoietic cells, successful experience with HCT in one patient with CD40 deficiency indicates that correction of the defect on hematopoietic cells is sufficient to cure the disease.

ANIMALS MODELS OF CD40 AND CD40LG DEFICIENCY

GENE DISRUPTION

Mice with Disruption of the *CD40LG* Gene

Cd40lg$^{-/-}$ mice exhibit normal percentages of B- and T-cell subpopulations but display selective deficiencies in humoral immunity. Basal serum immunoglobulin isotype levels are significantly lower than in normal mice, and IgE is undetectable. Furthermore, *cd40lg*$^{-/-}$ mice fail to mount secondary antigen-specific responses to immunization with T-dependent antigens. By contrast, they produce antigen-specific antibody of all isotypes except IgE in response to thymus-independent antigens. These results underscore the requirement of CD40LG for T-cell–dependent antibody responses (Renshaw et al., 1994; Xu et al., 1994). Moreover, Ig class switching to isotypes other than IgE can occur in vivo in the absence of CD40LG, a phenomenon supporting the notion that alternative B-cell signaling pathways (such as TLR-mediated B-cell activation) regulate responses to thymus-independent antigens.

CD4^{+} T-cells from *cd40lg*$^{-/-}$ mice were fourfold less effective than normal T-cells in activating the nitric oxide response in allogeneic macrophages. *Cd40lg*$^{-/-}$ T-cells fixed with paraformaldehyde after a 6-hour activation period, a time point at which CD40LG dominates the macrophage-activating capability of T-cells, failed to activate the production of inflammatory cytokines (TNF-α) or the generation of reactive nitrogen intermediates. After 24 hours of activation, however, both *Cd40lg*$^{-/-}$ and normal T-cells could induce similar but weak responses from activated macrophages (Stout et al., 1996). These studies demonstrate that *Cd40lg*$^{-/-}$ mice have a deficient T-cell–dependent macrophage-mediated immune response. However, *Cd40lg*$^{-/-}$ mice are able to generate normal primary cytotoxic T-cell responses (in spite of a defective humoral response) to a viral infection (Whitmire et al., 1996).

Cd40lg$^{-/-}$ mice are susceptible to *P. jiroveci* infection (as are CD40$^{-/-}$ mice). Treatment of wild-type mice with soluble CD40LG-fusion protein evokes a pulmonary inflammatory response that is not observed in identically treated *Cd40*$^{-/-}$ mice (Wiley et al., 1997). This finding supports evidence that ligation of CD40 results in inflammatory responses and that soluble CD40LG is a potent inflammagen that may be important for protection against *P. jiroveci* infection.

Finally, when injected with *Cryptococcus neoformans*, *Cd40lg*$^{-/-}$ mice show increased fungal growth in the brain, associated with reduced production of IL-12, IFN-γ, and nitrites (Pietrella et al., 2004).

MICE WITH DISRUPTION OF THE *Cd40* GENE

Cd40$^{-/-}$ mice have normal numbers of T and B-cells, indicating that CD40 is not essential for B-cell development. Their B-cells fail to proliferate and undergo isotype switching in response to soluble CD40 ligand (sCD40LG) and IL-4 but respond normally to LPS in the presence of IL-4. *Cd40*$^{-/-}$ mice completely fail to mount an antigen-specific antibody response or to develop germinal centers following immunization with T-cell–dependent antigens, but they respond normally to the T-cell–independent antigens. The most noticeable alteration in the serum immunoglobulin levels of young *Cd40*$^{-/-}$ animals is absence of IgE and a severe decrease of IgG1 and IgG2a (Castigli et al., 1994; Kawabe et al., 1994). These results indicate an essential role of CD40–CD40LG interactions in the antibody response to T-cell–dependent antigens and in isotype switching.

B-cells deficient in CD40 expression are unable to elicit the proliferation of allogeneic T-cells in vitro. More importantly, mice immunized with *Cd40*$^{-/-}$ B-cells become tolerant to allogeneic MHC antigens as measured by a mixed lymphocyte reaction and cytotoxic T-cell assay. The failure of *Cd40*$^{-/-}$ B-cells to serve as antigen-presenting cells in vitro is corrected by the addition of anti-CD28 mAb. Moreover, LPS stimulation, which upregulates CD80/CD86 expression, reverses the inability of *Cd40*$^{-/-}$ B-cells to stimulate an alloresponse in vitro and abrogates the capacity of these B-cells to induce tolerance in vivo (Hollander et al., 1996). These results suggest that CD40 engagement by CD40 ligand expressed on antigen-activated T-cells is critical for the upregulation of

CD80/CD86 molecules on antigen-presenting B-cells that subsequently deliver the co-stimulatory signals necessary for T-cell proliferation and differentiation.

In addition to susceptibility to *P. jiroveci* infection, CD40-deficient mice are also prone to *Mycobacterium avium* infection (Florido et al., 2004). Furthermore, when inoculated with the defective murine leukemia retrovirus LP-BM5def, *Cd40*$^{-/-}$ mice become infected and show virus expression similar to that in wild-type mice. However, unlike the wild-type mice, CD40-deficient mice do not develop symptoms of immunodeficiency, lymphoproliferation, and the typical histological changes in the lymphoid tissue (Yu et al., 1999). These results show that the CD40–CD40LG interaction in vivo is essential for anergy induction and the subsequent development of immunodeficiency and pathological expansion of lymphocytes.

In keeping with similar in vitro observations, mice deficient in CD40LG or in CD40 expression show impaired cross-talk between activated T-cells and DCs, with failure to expand IL-17–producing cells, and are resistant to the development of experimental autoimmune encephalitis (Iezzi et al., 2009).

Cd40$^{-/-}$ adult mice develop neuronal cell dysfunction and gross central nervous system abnormalities with age. These findings suggest that CD40 signaling plays an important role in normal neuronal cell maintenance and confers resistance to aging-induced stress (Tan et al., 2002).

CONCLUSION

Detailed clinical, molecular, and immunological analysis of patients with CD40LG or with CD40 deficiency has been instrumental in unraveling the complex effects that CD40LG (CD154) exerts in vivo upon interaction with CD40, and that extend beyond promoting B-cell activation and differentiation. The broad range of cellular effects that CD40LG/CD40 interaction promotes also account for the complexity of immune defects that characterize deficiency of CD40LG or of CD40. Accordingly, these disorders are currently classified among human combined immunodeficiencies (Notarangelo et al., 2009), and use of more aggressive forms of treatment (such as HCT) than immunoglobulin replacement therapy alone has been advocated. At the same time, involvement of CD40LG/CD40 signaling in inflammation and in tumor cell killing has prompted use of biological modifiers that interfere with the CD40-signaling pathway in autoimmune, inflammatory, and neoplastic diseases and in prevention of graft rejection and graft-versus-host disease (Durie et al., 1994).

AUTOSOMAL Ig CSR DEFICIENCIES CAUSED BY AN INTRINSIC B-CELL DEFECT

Anne Durandy, Sven Kracker, and Alain Fischer

The study of inherited hyper-IgM syndromes (Ig CSR deficiency) has greatly contributed to our understanding of the normal processes of antibody maturation because these syndromes have in common a defect in immunoglobulin (Ig) class-switch recombination (CSR), as demonstrated by normal or elevated serum IgM levels. This is in contrast to absent or strongly decreased levels of the other Ig isotypes. Antibody maturation leads to the production of antibodies of different isotypes and formation of B-cell receptors (BCRs) with high affinity for antigen. This event usually takes place in the secondary lymphoid organs (spleen, lymph nodes, tonsils) in an antigen- and T-lymphocyte–dependent manner. When mature (but still naïve) IgM^+IgD^+ B cells, after emigrating from the bone marrow (or fetal liver), encounter an antigen that is specifically recognized by their BCRs, they proliferate vigorously and give birth to a unique lymphoid formation, the germinal center. In this location, B cells undergo the two major events of maturation: CSR and somatic hypermutation (SHM).

CSR AND SHM

CSR is a process of DNA recombination between two different switch (S) regions located upstream of the constant (C) regions, while the intervening DNA is deleted by forming excision circles (Iwasato et al., 1990; Kinoshita and Honjo, 2000; Manis et al., 2002; Matsuoka et al., 1990; von Schwedler et al., 1990). Replacement of the Cμ region by a Cx region from another class of Ig results in the production of antibodies of different isotypes (IgG, IgA, and IgE) with the same variable (V) region and thus the same antigen specificity and affinity. The different Ig isotypes vary in activities (half-life, binding to Fc receptors, ability to activate the complement system) and tissue localization (IgA is secreted by mucosal membranes). Thus CSR is necessary for an optimal humoral response against pathogens.

Through SHM, missense mutations and, less frequently, deletions or insertions are introduced into the V regions of immunoglobulins. This process is triggered by activation of the BCR and signaling via CD40 (Jacobs et al., 2001; Storb et al., 1998). These mutations occur at a high frequency in the V regions and their proximal flanks (1×10^3 bases/generation). SHM is required as a basis for the selection and proliferation of B cells expressing a BCR with a high affinity for antigen in close interaction with follicular dendritic cells (Frazer et al., 1997; Rajewsky, 1996). The CSR and SHM processes occur simultaneously in germinal centers, but neither is a prerequisite for the other because IgM may be mutated whereas IgG or IgA can remain unmutated (Jacob and Kelsoe, 1992; Kaartinen et al., 1983).

Three successive steps are required for the process of CSR and SHM:

1. Transcription of the targeted DNA (S and V regions). In S regions, this step leads to the formation of RNA–DNA hybrids, known as stable R-loops, on the template DNA strand, leaving the single nontemplate strand accessible for cleavage (Bransteitter et al., 2003; Chaudhuri et al., 2003; Dickerson et al., 2003; Ramiro et al., 2003; Yu et al., 2003).
2. DNA cleavage. During CSR, single-stranded DNA breaks result in double-stranded DNA breaks (DSBs) by a mechanism currently unknown. It has been suggested that the template DNA strand may also be attacked in transcription bubbles (Bransteitter et al., 2003), resulting in scattered DSBs, eventually processed by exonucleases and error-prone polymerases into blunt DSBs. This

error-prone DNA processing is suggested by the high frequency of mutations found in Sμ–Sx junctions (Chen et al., 2001). In V regions, single-stranded DNA breaks are either directly repaired or processed into staggered DSBs. Alternatively, recent data suggest that blunt DSBs could occur spontaneously in V regions and secondarily lead to staggered DSBs (Catalan et al., 2003; Zan et al., 2003).

3. DNA repair. The mechanisms involved in DNA repair differ for CSR and SHM. During CSR, histone H2AX is phosphorylated, and the repair protein 53BP1 and the complex MRE11/RAD50/NBS1 are recruited at DSBs in repair foci. Thereafter, the DNA repair machinery joins Sμ and Sx sequences by means of the widespread, constitutively expressed nonhomologous end-joining (NHEJ) enzymes, including the KU proteins that act on DNA blunt DSBs (Casellas et al., 1998; Manis et al., 1998; Rolink et al., 1996). In contrast, SHM DNA repair does not require the NHEJ complex (Bemark et al., 2000), but probably the error-prone polymerases η and the mismatch repair (MMR) enzymes (Cascalho et al., 1998; Evans and Alani, 2000; Kenter, 1999; Schrader et al., 1999; Wiesendanger et al., 1998).

CSR and SHM are initiated by T- and B-cell interaction, involving CD40 ligand (CD40L or CD154), a molecule transiently expressed on activated $CD4^+$ T cells, and CD40, constitutively expressed on B lymphocytes. The CD40L–CD40 interaction is required for B-cell proliferation, germinal-center formation, CSR, and SHM, as demonstrated by the phenotype of patients with loss of function of either the *CD40L* (Aruffo et al., 1993; DiSanto et al., 1993) or *CD40* gene (Ferrari et al., 2001). The role of the CD40 activation pathway in antibody maturation has been underscored by the recent demonstration of a profound immune deficiency, including the Ig CSR deficiency phenotype, as the result of defective nuclear factor-κB (NF-κB) signaling following CD40 activation. This is illustrated by the fact that hypomorphic mutations in the zinc finger domain of the NF-κB essential modulator gene (also called *NEMO* or *IKKγ*) (Döffinger et al., 2001; Jain et al., 2001; Zonana et al., 2000) or mutation producing a gain of function of the NF-κB inhibitor IκBα (Courtois et al., 2003) result, respectively, in a syndrome of X-linked or autosomal dominant anhidrotic ectodermal dysplasia (AED) associated with a T-cell immunodeficiency and the Ig CSR deficiency condition.

Ig CSR deficiency syndromes with an autosomal recessive mode of inheritance have been described over the years by a number of investigators (Callard et al., 1994; Conley et al., 1994; Durandy et al., 1997). This condition is characterized by a specific B-cell defect, resulting in increased susceptibility to bacterial infections (but not to opportunistic infections) that can be easily controlled by regular intravenous Ig (IVIG) substitution. Lymphadenopathy is frequent (50–75 percent) and autoimmunity is reported in 25 percent of patients. SHM is found to be either normal or defective, according to the molecular defect. B cells are intrinsically defective; although they normally proliferate, they are unable to undergo CSR after activation by CD40L and cytokines. The precise delineation of the defects leading to abnormal CSR allowed the definition of molecularly defined autosomal recessive Ig CSR deficiency conditions.

ACTIVATION-INDUCED CYTIDINE DEAMINASE DEFICIENCY

The activation-induced cytidine deaminase (*AICDA*) gene (*605257) was first identified in mice (Muramatsu et al., 1999) and cloned by substractive hybridization between murine lymphoma CH12F-2 B cells with and without induction of CSR in vitro. The *AICDA* RNA transcripts are detected only in B cells undergoing CSR or SHM either in vivo (in germinal-center B cells) or in vitro (Diaz and Casali, 2002; Faili et al., 2002; Muramatsu et al., 1999; Papavasiliou and Schatz, 2002; Revy et al., 2000). The activation-induced cytidine deaminase (AID) protein is structurally similar (34 percent amino acid sequence identity) to the apoB mRNA-editing enzyme APOBEC-1. RNA editing is widely used to create new functional RNAs from a single gene. APOBEC-1 edits ApoB mRNA by deamination of a cytosine into a uracil residue at a specific site, resulting in a stop codon. ApoB 100 and ApoB48, the translation products of the unedited and edited apoB mRNAs, respectively, have entirely different functions and expression profiles (Mehta et al., 2000; Navaratnam et al., 1993; Teng et al., 1993). APOBEC-1 requires an auxiliary factor (ACF) for the site-specific editing of apoB mRNA. This auxiliary factor is widely expressed, including in tissues that do not express APOBEC-1 (Navaratnam et al., 1993; Teng et al., 1993; Yamanaka et al., 1994).

The open reading frame of the *AICDA* cDNA encodes a 198-residue protein with a molecular mass of approximately 24 kDa. This protein contains an active site for cytidine deamination, whose sequence is conserved throughout the large cytidine deaminase family, and has been shown to display cytidine deaminase activity *in vitro* (Muramatsu et al., 1999). The C-terminal domain also contains a leucine-rich region that may be important for protein–protein interaction. This region is thought to bind accessory factors required for AID activity and may be important in AID tetramerization (Dickerson et al., 2003). Recently, a nuclear localization signal (NLS) and a nuclear export signal (NES) have been described in the N and C termini of the molecule (Ito et al., 2004), although the function of this NLS is still debated (Brar et al., 2004; McBride et al., 2004). An APOBEC-1-like domain is also described but its function remains unknown (Fig. 27.1).

AID-deficient patients and $AID^{-/-}$ mice display a defect in both CSR and SHM, which demonstrates the crucial role of AID in both these processes required for B-cell terminal differentiation. The mechanism of action of AID, however, remains open to debate. Because the sequence of AID is similar to that of the RNA-editing enzyme APOBEC-1, originally it was proposed that AID edits an mRNA encoding a substrate common to CSR and SHM, probably an endonuclease (Chen et al., 2001; Honjo et al., 2002; Kinoshita and Honjo,

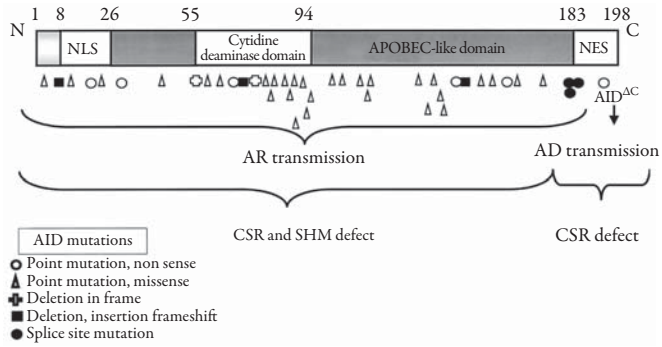

Figure 27.1 Schematic representation of activation-induced cytidine deaminase (AID) and localization of mutations in AID deficiency. Mutations are scattered throughout the entire gene. Each symbol represents a unique mutation. Mutations in the C-terminal domain do not affect somatic hypermutation (SHM). A mutation of the C-terminal region ($AID^{\Delta C}$) results in truncation of the last nine amino acids of the nuclear export signal (NES) and is responsible for an autosomal dominant (AD) form of Ig CSR deficiency. AR, autosomal recessive; CSR, class-switch recombination; NLS, nuclear localization signal; AD, autosomal dominant.

2001). The recently described requirement for de novo protein synthesis downstream of AID expression in CSR, compatible with the synthesis of a recombinase, is consistent with the RNA-editing model (Doi et al., 2003).

However, recent data strongly indicate that AID exerts a DNA-editing activity. Following the transfection of *Escherichia coli*, AID deaminates deoxycytidine (dC) residues within DNA into deoxyuridine (dU) (Petersen-Mahrt et al., 2002). Subsequently, several groups have demonstrated in cell-free assays a direct role for AID on single-stranded DNA but not on double-stranded DNA, RNA–DNA hybrids, or RNA (Bransteitter et al., 2003; Chaudhuri et al., 2003; Dickerson et al., 2003; Ramiro et al., 2003). The transcription of S regions increases AID activity (Ramiro et al., 2003; Shinkura et al., 2003), probably by generating the secondary structures required for this activity (Yu et al., 2003). R-loops are generated by the formation of RNA–DNA hybrids on the template DNA strand, rendering the single nontemplate strand a target for AID to generate the first lesion required for DNA cleavage. Although these observations provide strong evidence that AID has DNA-editing activity, they were obtained in nonphysiological conditions (overexpression in *E. coli*, using in vitro assays) in which the well-known RNA-editing protein APOBEC-1 exerts a similar effect (Harris et al., 2002; Petersen-Mahrt and Neuberger, 2003).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF AID DEFICIENCY

Four reports describing AID deficiency (MIM #605258) have been published in the literature (Lee et al., 2005; Minegishi et al., 2000; Quartier et al., 2004; Revy et al., 2000). Although the onset of symptoms occurs during early childhood (mean age, 5 years), the diagnosis is frequently established at a later age.

According to clinical data from 51 AID-deficient patients, all presented with recurrent bacterial infections; more than half (58 percent) had respiratory tract infections, with 14 percent of the patients reporting bronchiectasis. Gastrointestinal infections were observed in 27 percent of cases, sometimes related to persistent *Giardia* infections. Such infections may result in failure to thrive. Infections of the central nervous system (e.g., meningitis) have been reported in 25 percent of AID-deficient patients, often associated with inadequate Ig substitution. One case each of herpes virus encephalitis and poliomyelitis have been described. Two adult patients died prematurely, one of pulmonary hemorrhage at 47 years of age, the other of septicemia at age 63.

A striking lymphoid hyperplasia is present in the majority (75 percent) of patients, affecting predominantly the cervical lymph nodes and tonsils. In one case, mesenteric lymph node hyperplasia resulted in intestinal obstruction. Hepatosplenomegaly has been reported in 10 percent of the patient cohort. Other manifestations include arthritis (12 percent) and autoimmune manifestations (hemolytic anemia, thrombopenia, and autoimmune hepatitis) (29 percent); autoantibodies of the IgM isotypes are detectable in some cases. Systematic lupus erythematosus, diabetes mellitus, and Crohn's disease have been reported in one patient each (Table 27.1).

LABORATORY FINDINGS IN AID DEFICIENCY

All patients had normal or elevated IgM at the time of diagnosis and markedly diminished or, most often, undetectable serum levels of IgG and IgA. In some patients, 7S IgM can be demonstrated. In agreement with the aberrant serum immunoglobulin levels, antigen-specific (vaccine or infectious agents) antibodies of the IgG isotype were not detectable. When analyzed, IgM iso-hemagglutinins and antipolysaccharide IgM antibodies were present. IgM serum levels often diminish after Ig substitution, a finding suggesting that increased IgM reflects chronic antigenic stimulation rather than a direct effect of the AID deficiency.

Numbers of peripheral blood T cells ($CD3^+$) and T-cell subsets ($CD4^+$ and $CD8^+$) as well as in vitro T-cell proliferation to mitogens and antigens are normal. Peripheral blood B cells ($CD19^+$) are normal in number mostly and express wild-type CD40 in normal concentrations. All $CD19^+$ B cells co-express sIgM and sIgD, in contrast to age-matched controls, who have a population of $CD19^+$ B cells that express sIgG or sIgA and not sIgM/sIgD.

Soluble CD40-L (sCD40L)-induced B-cell proliferation in vitro is normal. However, in vitro activation of B lymphocytes by sCD40L and interleukin (IL)-4, which induces IgE production in controls and CD40L-deficient patients (Durandy et al., 1993), is ineffective in AID-deficient patients. Under the same culture conditions, S-region transcription is normally induced, whereas DNA DSBs are not detected in Sμ regions, providing evidence that the CSR defect is located downstream from transcription and upstream from DNA cleavage (Catalan et al., 2003). A normal fraction (20–50 percent) of B cells express the CD27 marker, which indicates memory B cells, even if limited to the IgM^+/IgD^+ B-cell compartment (Klein et al., 1998). However, the frequency of

SHM on $CD19^+CD27^+$ B cells is dramatically reduced. Thus, AID deficiency leads to not only lack of CSR but also defective SHM (Revy et al., 2000) (Table 27.2).

Most of the patients exhibit enlarged secondary lymphoid organs, which may require surgical resection (tonsils) or biopsy (cervical lymph nodes); histological evaluation shows marked follicular hyperplasia. Germinal centers are giant, being 2 to more than 10 times larger than those from control reactive lymph nodes (Plate 27.I). The mantle zone and interfollicular areas appear thin. The giant germinal centers contain a normal follicular dendritic cell network and B cells that are PNA^+, $CD38^+$, $CD23^+$, $CD83^+$, $CD95^+$, $CD40^+$, IgM^+, $Bcl2^+$, and $Ki67^+$. Strikingly, many germinal-center B cells express sIgD, in contrast to normal reactive germinal centers, in which IgD^+ B cells are rarely found. The high proliferation index of germinal-center B cells is associated with a dense network of macrophages filled with apoptotic bodies, giving a starry-sky appearance. The characteristic markers and size of the germinal-center B cells identify them as proliferating ($Ki67^+$) germinal-center founder cells ($CD38^+$, $sIgM^+$, $sIgD^+$), prone to undergo SHM and selection (Lebecque et al., 1997). Occasional $CD27^+$ B cells as well as IgM- and IgD-expressing plasma cells are found in germinal centers and T-cell areas; however, neither IgG- nor IgA-expressing plasma cells are observed.

MOLECULAR BASIS OF AID DEFICIENCY

Because the analysis of informative pedigrees suggested an autosomal recessive inheritance, genetic mapping was attempted by studying the segregation of polymorphic microsatellite markers in several consanguineous families. Random screening of the genome indicated that disease segregation was compatible in all studied families with the telomeric region of the short arm of chromosome 12 at p13 with a multipoint LOD score of 10.45 (Revy et al., 2000). Recombination analysis defined the critical genetic interval as a 4.5 cM region, in which a gene coding for AID had recently been localized (Muto et al., 2000). The human *AICDA* gene encompasses about 10 kb of genomic DNA and is organized in five exons and four introns. Definition of the exon–intron boundaries allowed a search for mutations at the genomic level. Deleterious mutations were found in all regions of the gene, including the cytidine deaminase domain (Lee et al., 2005; Minegishi et al., 2000; Quartier et al., 2004; Revy et al., 2000).

Forty different mutations have been found in 45 families, most often as homozygous defects (29 families) and less frequently as compound heterozygous mutations (16 families). They include missense mutations (28 families), nonsense mutations, and small deletions (6 families) (Fig. 27.1). In addition, deletions of the entire coding region (3 families) or splice-site mutations (3 families) leading to either a longer RNA transcript or to frameshift and premature stop codon were reported. The same mutations were found in a number of unrelated families of the same ethnic origin (e.g., French Canadians, Turkish); analysis of flanking polymorphic markers in these families indicated a common ancestral origin of the mutation (Minegishi et al., 2000; Revy et al., 2000).

Several mutations, located in the C-terminal part of the *AICDA* gene, were recently shown to result in defective CSR, whereas SHM is not affected (Ta et al., 2003). This observation suggests that, in addition to its cytidine deaminase

activity, AID acts on CSR by binding a CSR-specific cofactor. Because mutations and DNA double-strand breaks (Doi et al., 2009) are normally found in Sμ regions, a defect in targeting AID to the S regions is unlikely and a defect in DNA repair can be suspected (Barreto et al., 2003). Another unexpected finding recently reported (Imai et al., 2005; Kasahara et al., 2003) is that a heterozygous nonsense mutation, also located in the C-terminal domain, results in the loss of the nine last amino acids of NES ($AID^{\Delta C}$) and a variable Ig CSR deficiency condition transmitted as an autosomal dominant disease (Fig. 27.1). Haploinsufficiency, although reported in mice with weak consequences on Ig levels (Takizawa et al., 2008), is highly unlikely because all other human subjects heterozygous for AID deficiency always exhibit normal Ig levels. The accumulation of AID devoid of normal NES in the nucleus overriding the wild-type AID (Ito et al., 2004) could account for this phenotype, an hypothesis reinforced by the in vitro study of artificial mutants (Doi et al., 2009; Patenaude et al., 2009).

URACIL-N-GLYCOSYLASE DEFICIENCY

URACIL-N-GLYCOSYLASE

Uracil-N-glycosylase (UNG) belongs to the family of uracil-DNA-glycosylases capable of deglycosylating uracil residues that are misintegrated into DNA. Each of the two different UNG promoters creates a different isoform: UNG1 (305 amino acids), which is mitochondrial and ubiquitinously expressed, and UNG2 (314 amino acids), which is nuclear and expressed in proliferating cells, including B cells undergoing CSR. The catalytic domain binds the replication protein A (RPA) and the proliferating cell nuclear antigen (PCNA) in a multimolecular complex involved in DNA base excision repair (Fig. 27.2). According to a model proposed by Petersen-Mahrt and Neuberger (2002), AID deaminates cytosine into uracil residues on single-stranded DNA. Following the deglycosylation and removal of uracil residues by UNG, an abasic site is created that can be attacked by an apyrimidinic endonuclease

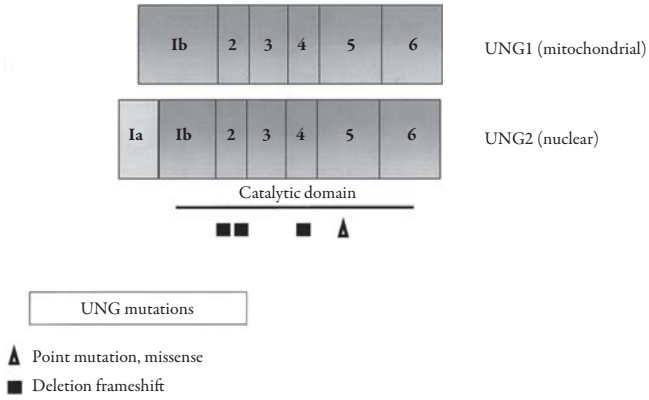

Figure 27.2 Schematic representation of uracil-N-glycosylase (UNG) and localization of mutations in UNG deficiency. Mutations affect the catalytic domain of both UNG 1 (mitochondrial isoform) and UNG2 (nuclear isoform).

(APE), leading to single-stranded DNA breaks. The processing and repair of the DNA nicks complete both CSR and SHM. In the absence of UNG, this pathway is impaired, resulting in defective CSR and abnormal SHM. The presence of SHM with a skewed pattern of G/C residues may arise from the replication of U/G lesions in the absence of U removal. MMR enzymes may also recognize and repair these lesions, introducing mutations on neighboring nucleotides that result in transitions and transversions of A/T residues (Petersen-Mahrt et al., 2002; Rada et al., 2002). Alternatively it has been proposed that rather than UNG's enzymatic activity on DNA, the UNG protein is required for CSR by its involvement in the recruitment of DNA repair molecules or its role in folding the CSR-induced DSBs (Honjo et al., 2004). However, this hypothesis does not explain the defect in DSB formation within Sμ regions observed in UNG-deficient B cells (Imai et al., 2003b).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF UNG DEFICIENCY

To date, only three UNG-deficient patients (MIM #608106, gene * 191525) have been reported (Imai et al., 2003b); two were diagnosed during childhood and the other was diagnosed as an adult. All three patients have had a history of frequent bacterial infections of the respiratory tract that are easily controlled by regular IVIG infusions. Lymphadenopathy was observed in two of the three patients, one with impressive enlargement of the mediastinal lymph nodes. The adult patient has developed Sjögren syndrome in recent years. The absence of metabolic abnormality suggests that UNG deficiency is compensated in mitochondria by other uracil-DNA-glycosylases (Table 27.1).

LABORATORY FINDINGS IN UNG DEFICIENCY

At the time of diagnosis, all three patients presented with Ig CSR deficiency, defined by markedly diminished serum levels of IgG and IgA and an increased serum level of IgM. No antibodies of the IgG isotype were detected to vaccines nor to infectious agents.

Peripheral blood T-cell and T-cell–subset numbers as well as in vitro T-cell proliferation to mitogens and antigens were normal. Peripheral blood B cells ($CD19^+$) were normal in number; expressed CD40, which was of wild type; and co-expressed sIgM and sIgD with a normal fraction expressing CD27.

When cultured in the presence of sCD40-L, B cells proliferate normally but fail to undergo CSR and secrete IgG, IgA, or IgE in the presence of appropriate cytokines. As in AID deficiency, the CSR defect occurs downstream from S-region transcription and upstream from DSBs in Sμ regions.

Somatic hypermutations were found in normal frequency in $CD19^+CD27^+$ B cells but exhibited a biased pattern. Almost all mutations are transitions at G/C residues (G > A, C > T), although transitions and transversions are equally present on A/T nucleotides (Table 27.2).

The association of an Ig CSR deficiency phenotype with UNG deficiency, together with the description of a mild CSR defect and a similarly biased SHM in UNG-deficient mice, provides a strong argument for DNA-editing activity of AID (Di Noia and Neuberger, 2002; Rada et al., 2002).

MOLECULAR BASIS OF UNG DEFICIENCY

Four different mutations affecting the catalytic domain of UNG1 and UNG2 have been found. Two patients have small deletions leading to a premature stop codon (homozygous

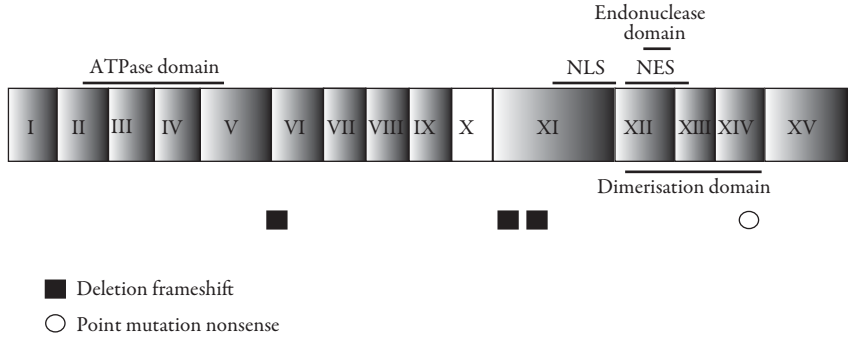

Figure 27.3 Schematic representation of PMS2 and localization of mutations in Ig CSR deficiencies associated with PMS2 defect. All mutations lead to predicted truncated proteins.

mutation in one patient born in a consanguineous family and two heterozygous mutations in the other). The third patient carries a homozygous missense mutation (Fig. 27.3). UNG expression and function were defective in Epstein-Barr virus (EBV) B-cell lines, providing evidence for the lack of any compensatory uracil-DNA glycosylase activity, at least in B cells.

POSTMEIOTIC SEGREGATION 2 DEFICIENCY

POSTMEIOTIC SEGREGATION 2

Postmeiotic segregation 2 (PMS2) belongs to the MMR pathway that recognizes and repairs mismatched nucleotides on DNA. The MMR system is known to play a role in CSR in mice, as shown by abnormal switched isotype levels and switch junctions (Ehrenstein et al., 2001; Schrader et al., 2002). There are two main MMR components: the MutS homolog (MSH1–6) and the MutL homolog (PMS2/MLH1/PMS1). The MSH2–MSH6 complex appears to recognize AID-induced DNA mismatches in the absence of UNG, leading to backup CSR and SHM, as shown by the phenotype of a double UNG-MSH2 knockout mutant (Rada et al., 2004). Recently, it has also been reported that MSH5 variants in humans can be associated with common variable immunodeficiency (CVID) and IgA deficiency phenotypes, including abnormal switch junctions that are characteristic of DNA repair defects (Sekine et al., 2007), although these results are controversial (Guikema et al., 2008). The role of the PMS2–MLH1 complex is less clear. Recently, it has been proposed that the MMR system can convert DNA SSBs into DSBs in Sμ regions upon CSR activation (Stavnezer and Schrader, 2006). In the SHM process, the repair of V regions requires the MMR and error-prone DNA polymerases. The MSH2–MSH6 complex is essential in SHM for recognizing the AID-induced U/G mismatch, and recruiting exonuclease (EXO1) and polymerase eta (Delbos et al., 2007). The role of the PMS2–MLH1 complex in SHM remains subject to debate (Kim et al., 1999; Phung et al., 1999).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF PMS2 DEFICIENCY

Heterozygous PMS2 mutations are associated with susceptibility to colorectal carcinoma (Hendriks et al., 2006), whereas homozygous mutations are responsible for early occurrence of various cancers (colorectal adenocarcinoma, T lymphoma, T acute lymphoid leukemia; Wimmer and Etzler, 2008). Another feature of the disease is the presence of café-au-lait skin spots. One patient (7 years of age) was referred to our unit for peculiar susceptibility to bacterial infections 2 years before developing colonic adenocarcinoma. The three other patients had no remarkable history of repeated infections before developing cancers.

LABORATORY FINDINGS

IMMUNOGLOBULIN LEVELS AND ANTIBODY PRODUCTION

The first patient was diagnosed as suffering from a CSR deficiency since serum IgG levels were markedly diminished and IgA was undetectable. She therefore received regular IVIG substitution. The three other patients presented with undetectable serum IgG2/IgG4 isotypes, associated with transient IgA decrease in one (Table 27.2).

T and B Lymphocytes

Although tested several years after chemotherapy, all four patients presented with a mild lymphopenia (around 1,000/mL). Peripheral blood T-cell ($CD3^+$) and T-cell–subset numbers ($CD4^+$ and $CD8^+$) as well as in vitro T-cell proliferation to mitogens and antigens were normal.

Peripheral blood B-cell ($CD19^+$) counts were normal. All $CD19^+$ B cells co-expressed sIgM and sIgD and a reduced fraction expressed CD27.

In vitro sCD40-L–induced B-cell proliferation was found to be slightly decreased compared to controls; B lymphocytes weakly undergo CSR toward IgA or IgE under activation by sCD40L and appropriate cytokines. As in AID or UNG deficiency the CSR defect occurs downstream from S-region transcription and upstream from the DSBs in Sμ regions.

SHM frequency was found to be slightly decreased in $CD19^+CD27^+$ B cells, but the SHM pattern was normal.

MOLECULAR BASIS OF PMS2 DEFICIENCY

The four patients carry homozygous nonsense mutations in the *PMS2* gene, leading to either a truncated protein or a lack of expression (Fig. 27.3). Expression of MLH1, PMS2's partner in MutLa, was slightly reduced but still present in nuclei, likely because of dimerization with PMS1. The decreased occurrence of DSBs in Sμ regions upon CSR activation in PMS2-deficient human B cells strongly suggests a role for PMS2 in DNA cleavage, likely through its endonucleasic domain. Since UNG-deficient patients exhibit a complete CSR defect, it appears that PMS2 does not play a role in CSR as an alternative pathway, but interacts downstream from UNG in the same pathway (Peron et al., 2008).

Ig CSR DEFICIENCIES WITH UNKNOWN MOLECULAR DEFECT(S)

Not all cases of Ig CSR deficiency due to an intrinsic B-cell defect are related to AID or UNG deficiency. Although most of these cases are sporadic, the mode of inheritance observed in a few multiplex or consanguineous families is compatible with an autosomal recessive pattern. The clinical phenotype is

similar to that of AID deficiency, including increased susceptibility to bacterial infections of the respiratory and gastrointestinal tracts. Lymphoid hyperplasia is milder and less frequent (50 percent), consisting of moderate follicular hyperplasia without the giant germinal centers typical of AID deficiency (Table 27.1).

The CSR defect appears to be milder, as residual serum levels of IgG can be detected in some patients. While isohemagglutinins and IgM antipolysaccharide antibodies are present in normal amounts, IgG antibodies against immunization antigens or infectious agents cannot be detected. Upon activation with sCD40L and cytokines, B cells proliferate but do not undergo CSR (Table 27.2).

The definition of the precise location of the CSR defect has led to the delineation of two distinct groups.

CSR DEFECT LOCATED UPSTREAM FROM S-REGION DNA CLEAVAGE

We are following a subgroup of 16 patients with an Ig CSR deficiency phenotype characterized by good prognosis, lack of autoimmune manifestations, and no increased risk of lymphoma or other malignancies. No CSR-induced DSBs occur in Sμ regions of patients' B cells, although both AID and UNG transcripts are normally expressed. The defect, located downstream from the S-region transcription and upstream from the S-region DNA cleavage, is restricted to CSR, as SHM is normal in both frequency and pattern in the $CD27^+$ B-cell subset, which is represented in normal numbers.

This type of Ig CSR deficiency could thus be caused by a direct or indirect impairment of AID targeting on S regions. Although targeting factors of AID are at present unknown, they most likely exist because AID deaminates cytosines only in the S and V regions in B cells. AID shares sequence similarity with the RNA-editing enzyme APOBEC-1, which is expressed only in the gut and requires a cofactor, ACF (APOBEC-1-cofactor), which targets APOBEC-1 on a unique C residue in ApoB mRNA. In addition, specific switch factors have been described in CSR-activated B cells. Although their role remains elusive, it has been proposed that these cofactors act as docking proteins for the recruitment of the recombinase complexes to DNA-specific regions (Ma et al., 2002; Shanmugam et al., 2000).

CSR DEFECT LOCATED DOWNSTREAM FROM S-REGION DNA CLEAVAGE

This condition has been found in 15 patients thus far (Imai et al., 2003a). The prognosis of this Ig CSR deficiency subgroup is complicated by the occurrence of autoimmune manifestations that were found in 4 of 15 patients and were sometimes life-threatening (severe autoimmune hemolytic anemia). DSBs are normally detected in Sμ regions in CSR-activated B cells, suggesting a defect downstream from DNA cleavage. The subsequent step, DNA repair, is impaired because excision circles and functional transcripts of switched isotypes cannot be detected. The normal presence of DSBs and of mutations in Sμ regions rules out a defect in AID targeting to S regions. SHM is present in normal frequency and pattern in the purified $CD27^+$ B-cell population. However, the $CD27^+$ B-cell count is decreased compared to that of controls (<10 percent of the B-cell population).

Two hypotheses can account for this unique phenotype: (1) a defect in survival signals delivered to switched B cells (this does not fit with the observed defective in vitro CSR) and (2) a DNA repair defect, because CSR-induced DSBs occur normally. CSR and SHM are known to use different pathways for DNA repair. NHEJ enzymes and the MRE11/hRad50/NBS1 protein complex have been shown to be involved in CSR DNA repair (Casellas et al., 1998; Rolink et al., 1996). Nevertheless, a defect in one of these proteins is unlikely, given the phenotype of patients carrying mutations in *MRE11* or *NBS1* genes (ataxia-like disease or Nijmegen breakage syndrome, respectively). A defective CSR with normal SHM has been reported in H2AX and 53BP1 knockout mice (Manis et al., 2004; Petersen et al., 2001; Ward et al., 2004), but a defect in one of these genes has been ruled out in our patients by sequence analysis. Thus, other DNA repair factor(s) have to be considered, including the undefined cofactor that binds to the C-terminal part of AID. Two of our 15 patients have developed Hodgkin's lymphoma. Although the number is small, this observation is compatible with a DNA repair defect, which could facilitate illegitimate recombination leading to oncogene activation.

STRATEGY FOR DIAGNOSIS OF HYPER-IGM SYNDROME DUE TO AN INTRINSIC B-CELL DEFECT

Like all patients with the diagnosis of Ig CSR deficiency, this group of patients with an intrinsic B-cell defect is defined by markedly diminished serum levels of IgG and IgA and a normal or increased level of IgM. Assessment of $CD27^+$ B-cell count and analysis of the frequency and pattern of SHM allow identification of these different autosomal recessive Ig CSR deficiency conditions (Table 27.2). A precise diagnosis is required for optimal prognosis assessment.

Other Ig CSR deficiency syndromes, not caused by a B-cell–specific abnormality, are associated with T-cell defects, which strongly worsens the prognosis. Defects of CD40L and CD40 are excluded by assessing membrane expression of these two molecules and/or direct gene sequencing. A defect in the NF-κB activation pathway (due to mutations in *NEMO*, also designated IKK-γ, or in IκBα) is often responsible for an Ig CSR deficiency phenotype characterized by a T-cell defect and frequently associated with an hidrotic ectodermal dysplasia.

Other causes of Ig CSR deficiency that should be excluded are the following:

1. Ataxia-telangiectasia (AT), in which elevated IgM can develop before the onset of neurological manifestations (Gatti et al.,1991; Meyts et al., 2003). The CSR defect is related to an intrinsic B-cell defect since AT-mutated (*ATM*), the gene responsible for this syndrome, plays

a role in CSR (but not SHM) DNA repair (Pan-Hammarstrom et al., 2003).

2. Congenital rubella, in which a defect of T-cell activation leads to defective CD40L expression on $CD4^+$ T cells (Kawamura et al., 2000).
3. Patients with major histocompatibility complex (MHC) class II deficiency have diminished expression of CD40L by activated $CD4^+$ T cells and can present with elevated serum IgM (Nonoyama et al., 1998).
4. An Ig CSR deficiency phenotype has been observed as part of combined immunodeficiencies linked to leaky mutations in genes encoding factors for NHEJ, such as Cernunnos, DNA ligase IV, or RAG (Buck et al., 2006).

PRENATAL DIAGNOSIS

Prenatal diagnosis can be performed by sequence analysis of the *AID* or *UNG* gene with genomic DNA obtained from the fetus. Prenatal diagnosis could raise ethical problems since the prognosis is generally good and nearly all patients reach adulthood with only a few recurrent bacterial infections, provided that prophylactic treatment with IVIG is started early and given on a regular basis. However, other life-threatening complications (autoimmunity, lymphoma) can occur, and UNG-deficient patients, as shown by the ung-deficient mice, and especially PMS2-deficient patients are prone to tumors.

PROGNOSIS AND TREATMENT

As soon as the diagnosis of Ig CSR deficiency is established, treatment with regular IVIG infusions (400–600 mg/kg every 21–28 days) must be initiated with the aim of maintaining a trough IgG level of 700 to 800 mg/dL. This protocol results in a significant reduction in the severity and frequency of infections and often reduces or even normalizes serum IgM levels. However, the lymphoid hyperplasia does not seem to be reduced by IVIG therapy.

With adequate prophylactic treatment, patients with Ig CSR deficiency due to intrinsic B-cell deficiency are protected from infections and can reach adulthood without developing bronchiectasis. Surprisingly, they do not appear to be unusually susceptible to enteroviral infections, a serious complication observed in patients with X-linked agammaglobulinemia (Quartier et al., 2000). This observation suggests a protective role of IgM (even without SHM) as a first barrier against some pathogens.

Autoimmunity has been reported in AID deficiency and in the Ig CSR deficiency condition characterized by a CSR defect located downstream from the S-region cleavage. Both conditions are characterized by an SHM defect (in the latter condition the B-cell memory subset is decreased). In contrast, autoimmunity has not been reported in the Ig CSR deficiency condition characterized by a CSR defect located upstream from the S-region cleavage, in which both SHM and memory B-cell numbers are normal. Autoimmunity could thus be related to defective SHM. It may be that autoimmunity, initiated by germline Ig sequences, is caused by the lack of negative selection in germinal centers.

A more serious complication, the occurrence of tumors, has to be considered for the prognostic assessment. The subgroup of Ig CSR deficiency characterized by a CSR defect located downstream from the S-region cleavage may be directly related to a DNA repair defect and patients could become susceptible to an increased risk of malignancy. UNG is part of the DNA base excision repair and is thus involved in the repair of spontaneously occurring base lesions as part of a major antimutagenic defense strategy. Interestingly, UNG-deficient mice develop B-cell lymphomas when aging (Nilsen et al., 2003), so UNG deficiency may predispose to malignancies in adulthood. Moreover, the hallmark of PMS2 deficiency is the occurrence of tumors from the first years of age (Wimmer and Etzler, 2008).

ANIMAL MODELS OF AID, UNG, AND PMS2 DEFICIENCIES

No naturally occurring mutants defective in AID, UNG, or PMS2 have been described in animals. However, AID- and UNG- and PMS2-deficient mice, as well as AID-transgenic mice, have been generated by gene-targeting techniques.

AID-DEFICIENT MICE

The phenotype of $AID^{-/-}$ mice resembles completely that observed in patients and is associated with the three main features of AID deficiency:

1. Defective CSR in vivo and in vitro. The CSR defect has been shown to occur downstream from S-region transcription and upstream from the occurrence of repair foci at DSBs on the Ig locus (Petersen et al., 2001).
2. Defective somatic hypermutation.
3. Giant germinal-center formation in spleen and lymph nodes with accumulation of $IgM^+/IgD^+/PNA^+$ proliferating B cells (Muramatsu et al., 2000).

AID-TRANSGENIC MICE

AID-transgenic mice express mutations in the T-cell receptor, a finding indicating that aberrantly expressed and overexpressed AID can exert its activity outside the B-cell compartment. All of these mice develop tumors affecting the lymphoid compartment (T lymphoma) and nonlymphoid tissues (e.g., epithelium of respiratory bronchioles). Interestingly, these transgenic mice do not develop B-cell lymphomas, an observation suggesting that AID activity and/or nuclear localization can be regulated effectively only in B cells (Okazaki et al., 2003).

UNG-DEFICIENT MICE

UNG-deficient mice have been generated to study the effects of base excision repair defects on the incidence of tumors (Nilsen et al., 2000). No striking biological effects could be shown, most likely because of compensatory mechanisms provided by other uracil-DNA glycosylases. A more recent study of CSR and SHM provided evidence for a mild in vivo and a profound in vitro CSR defect. The remaining CSR observed in vivo is likely related to MMR enzymes, which are known to be involved in CSR in mice (Rada et al., 2002). This study also showed a normal frequency of SHM that exhibit a skewed pattern. Since all mutations at G/C residues are transitions, likely occurring on U/G nucleotides after replication, mutations observed on A/T residues could be the consequence of the recognition and repair of U/G lesions by MMR enzymes. Both observations, confirmed by similar data in humans (although the CSR defect is much more pronounced in UNG-deficient patients), are a strong argument for a DNA-editing activity of AID.

Without exception, UNG-deficient mice develop B lymphomas when aging, an observation that could reflect the lack of compensatory uracil-DNA-glycosylases in B cells (Nilsen et al., 2003). Another adverse consequence has been reported in UNG-deficient mice: compared with wild-type mice, postischemic brain injury is much more severe, a complication likely related to the mitochondrial DNA repair defect (Endres et al., 2004).

PMS2-DEFICIENT MICE

B-cell–mediated immunity has been studied for a long time in MMR-deficient mice. The phenotype is different according to the inactivated enzyme: MSH2- or MSH6-deficient mice exhibit mild CSR defect with normal switch junctions but a skewed pattern of SHM (Martomo et al., 2004; Schrader et al., 2002). In contrast, PMS2- or MLH1-deficient mice exhibit a defective CSR with abnormal switch junctions but normal SHM (Ehrenstein et al., 2001; Kim et al., 1999; Schrader et al., 2002). It is however likely that the MMR enzymes do not play an equivalent function in CSR in humans and in mice since MSH2/MSH6 can compensate UNG deficiency in mice but not in humans.

CONCLUSIONS

The ongoing investigation of inherited Ig CSR deficiencies is shedding new light on the process of antibody maturation in human B cells. This is especially true for the evaluation of Ig CSR deficiencies due to an intrinsic B-cell defect, which has illustrated the complex mechanisms involved in both events of B-cell maturation—CSR and SHM. On the basis of clinical phenotypes, the following mode of action of AID and UNG is proposed: AID, at center stage of CSR and SHM, deaminates cytosine nucleotides to uracil in S and V regions of Ig genes. The integrated uridine nucleosides are deglycosylated and removed from DNA by UNG, resulting in an abasic site that becomes a target for an endonuclease. This DNA cleavage step appears to be sufficient for SHM, at least on G/C residues, but not for CSR, which requires DSB. Beyond its cytidine deaminase activity, AID requires specific cofactors. A CSR-specific cofactor, which could be involved in DSB DNA repair, is expected to bind to the C-terminal part of multimeric AID. It is likely that the molecular definition of the Ig CSR deficiency caused by a CSR defect located downstream from S-region cleavage will lead to the identification of this cofactor. Taken together, these observations indicate that AID acts in a multimolecular complex composed of individual partners that have yet to be defined. The precise diagnosis of these Ig CSR deficiencies, in addition to contributing to a better understanding of the antibody maturation processes, provides science-based guidelines for better prognosis assessment and treatment management.
