GENETIC APPROACH TO COMMON VARIABLE IMMUNODEFICIENCY AND IGA DEFICIENCY

Lennart Hammarström

Common variable immunodeficiency (CVID) affects approximately 1 in 10,000 to 100,000 individuals and is equally distributed between the sexes. It is likely that it consists of a number of genetically distinct disorders with a common phenotype. The patients display a marked reduction in serum levels of both IgG and IgA, and IgM levels are reduced in half of the patients. The age of onset of disease was previously suggested to show two peaks (Hermaszewski and Webster, 1993) but on reevaluation it seems to be a continuous process (Chapel et al., 2008). The disorder may appear in previously immunologically normal individuals, although the induction phase has been documented only in a few cases. Usually, the patients present with clinical symptoms due to the hypogammaglobulinemia, as they suffer from frequent respiratory and gastrointestinal tract infections (Table 28.1). Mortality is high and was recently estimated to be 19.6 percent, a significantly shorter survival than age- and sex-matched controls (Resnick et al., 2012). In addition to the B-cell defect, variable degrees of T-cell dysfunction have frequently been noted in CVID patients. Usually, low or normal proportions of $CD19^+$ cells are observed, a finding that distinguishes "classical" CVID patients from those with a concomitant thymoma.

Selective IgA deficiency (IgAD), based on 0.07 g/L of serum IgA as the upper limit for diagnosis, is the most common form of immunodeficiency in the Western world and affects approximately 1 in 600 individuals. Marked variability in the prevalence can, however, be found in different ethnic groups. A lower frequency has been reported in certain Asian populations, suggesting a genetic influence. In about two thirds of the cases, the deficiency does not lead to an increased occurrence of infections, whereas the remaining patients suffer from infections in both the upper and lower respiratory tract (Table 28.1). The defect is manifested already at the stem-cell level, and transfer of bone marrow from an IgA-deficient donor to a normal fully conditioned recipient results in IgA deficiency in the recipient (Hammarstrom et al., 1985a), whereas transfer of bone marrow from a normal individual to an IgA-deficient patient will correct the defect (Kurobane et al., 1991). The silent genes can be reexpressed in the children of IgA-deficient parents (Hammarstrom et al., 1987), strongly suggesting that the defect is due to dysregulation of the expression of the immunoglobulin (Ig) genes. In a few selected cases, the defect is restricted to one of the two IgA subclasses, and these cases are most often due to deletions of the corresponding α chain gene (*IGHA*) (Lefranc et al., 1991; Migone et al. 1984).

By definition, IgAD is expected to be selective and confined to the IgA class. However, in some cases, a simultaneous change in the IgG subclass pattern is seen with a lack of specific antipolysaccharide antibodies of the IgG2 subclass (Hammarstrom et al., 1985b) or a total lack of serum IgG2 (Oxelius et al., 1981), IgG4, and IgE (Hammarstrom et al., 1986a), reflecting a relative or absolute block in switching to genes downstream of α1. Progression from CVID has been observed in a few cases (for review see Aghamohammadi et al., 2008), suggesting that the two diseases are in fact related and may represent facets of the same underlying defect. However, the overlap appears to be smaller than previously suggested.

During the past few years, mutations in a number of genes associated with B-cell differentiation, including *ICOS*, TACI (*TNFRSF13B*), *CD19*, *MSH5*, BAFF receptor (BAFFR) *TNFRSF13C*, *CD21*, and *CD81* (for references, see below), have been found in patients with CVID. However, the molecular basis still remains unknown in the vast majority of cases.

HISTORICAL OVERVIEW

The first report of Ig deficiency appeared in 1952 (Bruton) and inspired a large number of investigators to analyze Ig

Table 28.1 CLINICAL VARIABLES IN IMMUNOGLOBULIN-DEFICIENT PATIENTS

levels in patients prone to infections (reviewed in Good et al., 1962; Smith and Notarangelo, 1997). At the time, knowledge on lymphocyte subsets was lacking, and patients with autosomal recessive severe combined immunodeficiency were sometimes referred to as having agammaglobulinemia (Keidan et al., 1953). Females with CVID were already reported the year after Bruton's original description (Olhagen, 1953). Subsequently, both adult-onset (Grant and Wallace, 1954; Jacobsen, 1954; Lang et al., 1954; Olhagen, 1953; Prasad and Koza, 1954; Saslaw and Wall, 1954) and congenital agammaglobulinemia in females (Pearce and Perinpanayagam, 1957) were described. Adult onset in male patients with a CVID phenotype was also reported (Olhagen, 1953), as reviewed in Citron (1957), who also described additional patients suffering from agammaglobulinemia with concomitant splenomegaly.

IgAD was first described in 1964, being noted in two healthy laboratory staff, clearly suggesting that IgA may be dispensable in certain individuals (Rockey et al., 1964). However, based on a review of 30 cases, it was subsequently determined that this defect frequently results in a propensity for infections (Ammann and Hong, 1971).

The classification of Ig deficiencies, including CVID and IgAD, is regularly being updated by the IUIS Expert Committee on Primary Immunodeficiencies, with the most recent report having been published in 2011 (al-Herz et al., 2011).

MODE OF INHERITANCE

Familial inheritance of the deficiency is observed in approximately 20 percent of the cases, and CVID and IgAD may both be present in the same family. In rare instances, patients with IgAD may progress to CVID, suggesting that the disorders may reflect facets of the same underlying disease in a limited subgroup of patients (for review see Aghamohammadi et al., 2008). The finding of Ig deficiency in only one of a set of monozygotic twins (Alper et al., 2006; Huntley and Stephenson, 1968, Lewkonia et al., 1976, Ulfarsson et al., 1982) suggests an environmental, possibly infectious, agent as a triggering factor.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

INFECTIONS

Patients with IgAD and CVID suffer from a variety of respiratory and gastrointestinal tract infections (Table 28.1). The severity of infections reflects the degree of immune dysfunction and is thus more pronounced in patients with profound hypogammaglobulinemia. Enlarged lymph nodes and spleen are noted in up to half of the patients with CVID, but not in patients with X-linked agammaglobulinemia (XLA) (Curtin et al., 1995), and may reflect persistence of low-grade infections. The lymph nodes may show a striking reactive follicular hyperplasia, and noncaseating granulomas may be present in the liver (Fig. 28.1) and skin (Fig. 28.2). The gastrointestinal tract may also be involved in this process, with a characteristic nodular lymphoid hyperplasia. The spectrum of infections in IgAD and CVID patients is, however, usually rather limited, and some of these are highlighted below.

Haemophilus influenzae is a common pathogen in the human respiratory tract. The majority of isolates are nonencapsulated and fall into the category of serologically nontypable strains, which often cause acute otitis media, acute sinusitis, conjunctivitis, pneumonia, and bronchitis in immunocompetent patients. These bacteria also constitute the major pathogen in CVID patients who suffer from frequent upper respiratory tract infections. The patients may remain colonized for years with the same strain in spite of "adequate" gammaglobulin therapy and antibiotics (Samuelson et al., 1995) and may develop multiple bouts of symptoms. It is still unclear why the bacteria are poorly cleared by antimicrobial therapy, but intracellular growth may occur in crypt cells in the adenoids and tonsils.

Moraxella catarrhalis and *Streptococcus pneumoniae* are the second and third most common pathogens in patients with CVID; both organisms give rise to upper respiratory

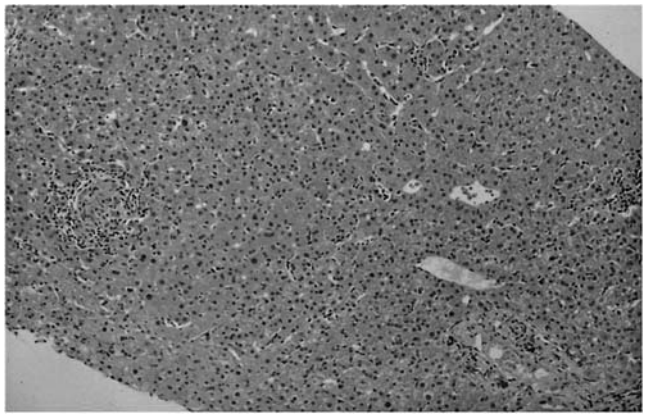

Figure 28.1 Granulomas in the liver of 47-year-old CVID patient. (See Color Plate.)

tract infections. In series of patients published earlier, serious pulmonary manifestations such as bronchiectasis, pulmonary fibrosis, and respiratory failure were not uncommon (Bjorkander et al., 1984; Dukes et al., 1978; Hausser et al., 1983). However, increasing awareness of immunodeficiency disorders, early diagnosis, and prompt institution of antibiotic therapy and gammaglobulin substitution have resulted in a far lower frequency of severe respiratory tract complications.

Mycoplasma/ureaplasma have been increasingly recognized as pathogens in humans, and hypogammaglobulinemic patients appear susceptible to these infections, but the diagnosis may be delayed due to the insidious onset of symptoms. CVID patients may suffer a protracted clinical course, and severe sequelae have been reported in a number of patients, including extensive joint destruction (Fig. 28.3).

Transient recovery of the ability to produce immunoglobulins has been reported in a few CVID patients at the time of hepatitis C infection (Hammarstrom and Smith, 1986b; Osur et al., 1987) and has also been demonstrated in patients infected with HIV (Morell et al., 1986; Webster et al., 1986; Wright et al., 1987), suggesting an immunoregulatory dysfunction as a cause of CVID in some patients.

INFLAMMATORY BOWEL DISEASE

A few IgAD patients and 6 to 10 percent of CVID patients have previously been described who suffer from Crohn's disease or ulcerative colitis, but an association has not yet been ascertained due to the lack of a sufficiently large number of patients.

Figure 28.2 Cutaneous granulomas on the legs of a 47-year-old man with CVID. (See Color Plate.)

CANCER INCIDENCE

A prospective study from 1985 (Kinlen et al., 1985) reported a 23-fold increased risk for malignant lymphoma and a 50-fold increase for gastric cancer among 377 patients with hypogammaglobulinemia, primarily CVID. Patients were followed for an average of 10 years. In another study, 98 patients with CVID were followed for up to 13 years, and the risk for lymphomas was estimated to be more than 100-fold increased (Cunningham-Rundles et al., 1987). However, only a slightly increased incidence in malignant lymphoma and stomach cancer was noted in Swedish CVID patients followed for 20 years, and no increased risk for malignancy could be observed in a large cohort of IgAD patients (Mellemkjaer et al., 2002).

AUTOIMMUNITY

The list of autoimmune disorders associated with IgAD and CVID has grown to include, among others, systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren syndrome, dermatomyositis, thyroiditis (Graves disease), celiac disease, insulin-dependent diabetes mellitus, pernicious anemia, Addison disease, idiopathic thrombocytopenic purpura (ITP), and autoimmune hemolytic anemia. This is in stark contrast to X-linked agammaglobulinemia, where autoimmunity is rarely observed (see Chapter 25). In a very early survey of IgAD patients, 37 percent were in fact found to have autoimmune disease or autoimmune phenomena (Ammann and Hong, 1971). First-degree relatives of IgAD patients also show a higher-than-expected prevalence of autoantibodies (Jorgensen et al., 2009), suggesting a sharing of genetic factors between IgAD and susceptibility for autoimmunity;

Figure 28.3 Destruction of carpal bones and subluxation of wrist joint in a 42-year-old patient with CVID and *Mycoplasma hominis* infection.

this notion was recently confirmed in a large cohort of IgAD patients (Ferreira et al., 2010).

ANTI-IGA ANTIBODIES

Antibodies against IgA are a common finding in patients with IgAD or CVID, and up to 40 percent show demonstrable titers. The etiology of this immune response is as yet unknown, as approximately 20 to 40 percent of the patients with IgAD have developed anti-IgA antibodies at the time of diagnosis without being exposed to IgA-containing blood products. Antibodies against IgA are usually of the IgG class, but IgM anti-IgA antibodies may also be present (Bjorkander et al., 1987). In exceptional cases, the antibodies are of the IgE class (Burks et al., 1986; Ferreira et al., 1988), and a few severe transfusion reactions have been attributed to these autoantibodies (Rachid et al., 2011).

Maternal transmission of IgAD, mediated by placentally transferred anti-IgA antibodies, could theoretically contribute to induction of the deficiency in selected cases (de Laat et al., 1991; Petty et al., 1985), and IgAD is overrepresented in children born to mothers with anti-IgA antibodies.

LABORATORY FINDINGS

The pathognomonic hallmark of IgAD is a low level of serum IgA (<0.07 g/L) with normal levels of IgM and IgG (Table 28.2). However, raised levels of IgG, mainly IgG1 and IgG3, may be seen in up to a third of the patients. Almost invariably, there is a concomitant lack of secretory IgA, although a dichotomy has been documented in exceptional cases.

In CVID, IgA is usually absent and serum IgG levels are decreased (≤3 g/L), whereas IgM is low or absent in only half of the cases (Table 28.2).

Surface IgA-expressing B cells are usually low in patients with IgAD, and most cells express an immature phenotype. However, the proportion of surface Ig-positive cells remains unaffected in a majority of CVID patients. These B cells do not mature properly into antibody-producing cells and plasma cell numbers are low in the bone marrow. A large number of cell surface CD markers have been analyzed in IgAD and CVID. Although their diagnostic value is limited in patients with IgAD, reduction of switched memory B cells ($CD27^+$ cells) and an expansion of $CD21(low)^+$ B cells has been suggested to serve as a basis for subclassification of CVID patients (Wehr et al., 2007).

IgAD is probably manifest already at birth in a majority of cases, and the prevalence in 4-year-old Swedish children is approximately 1 in 200 (Janzi et al., 2009), as compared to 1 in 600 adult Swedes. IgA production in most children matures gradually, and at 8 years of age, half of the children who were IgAD at 4 years of age have normal IgA levels. However, induction of IgAD has also been described in a number of children with celiac disease.

Antibodies against IgA are typical markers of IgAD and CVID, and these autoantibodies are not seen in individuals with normal levels of IgA.

GENETIC COMPONENT OF IgAD AND CVID

HERITABILITY OF IGAD AND CVID

Most cases of IgAD and CVID described to date have been sporadic, but familial cases have been observed, and a susceptibility trait can occasionally be traced back for many generations (Wollheim et al., 1964). Thus far, more than 100 families with multiple cases of IgAD and/or CVID have

Table 28.2 CHARACTERISTIC LABORATORY FINDINGS IN IGAD AND CVID

PARAMETER	CVID	IGAD
Serum IgM levels	Low/normal	Normal
Serum IgG levels	Low	Normal/high
Serum IgA levels	Low	Low
Secretory IgA	Low	Low
Surface IgM-positive cells	Normal	Normal
Surface IgG-positive cells	Normal	Normal
Surface IgA-positive cells	Normal	Low/normal
Autoantibodies (anti-IgA)	10–20%	20–40%
Lymphocyte CD markers	Altered	Normal
Mitogen responsiveness	Low/normal	Normal
Plasma cells (bone marrow)	Low	Normal

been reported in the literature (for references see Kralovicova et al., 2003; Vorechovsky et al., 1995), and the mode of inheritance of the deficiency has been suggested to be either recessive or dominant. In 20 percent of the published cases, both IgAD and CVID occurred in the same family, usually presenting with CVID in the parental generation and IgAD in the children.

The human leukocyte antigens (HLA), located within the MHC region on chromosome 6, are implicated in the genetic susceptibility to a large number of diseases, and as early as the late 1970s, an association between IgAD and certain HLA types was suggested. In the early 1980s, it was shown that there was indeed an association between isolated IgA deficiency and the MHC region (Oen et al., 1982), in particular the HLA class II region (Hammarstrom and Smith, 1983). A genetic predisposition, similar to that found in IgA deficiency, has also been observed in patients with CVID (Olerup et al., 1992; Schaffer et al., 1989). However, the latter appears to be restricted to a rather small subgroup of patients, and most CVID patients show no apparent HLA association.

In spite of intense research during the past decades, the susceptibility genes within the HLA region have not been identified (for recent review on MHC association of IgAD see Rioux et al., 2009). Several reports have suggested that distinct loci in the class II and class III region, located on different MHC haplotypes, confer susceptibility to development of IgAD (de la Concha et al., 2002; Gual et al., 2004; Kralovicova et al., 2003; Olerup et al., 1990, 1991; Schroeder et al., 2004).

Recently, we observed an association with several non-MHC genes in patients with IgAD (Ferreira et al., 2010). These susceptibility genes, including IFIH1 and CLEC16A, are also found in patients with "classical" autoimmune diseases. In this respect, it is worth noting that IgAD is also more common among patients with type 1 diabetes, SLE, and celiac disease, suggesting a genetic link between immunodeficiency and susceptibility to autoimmunity.

Monogenic Defects Underlying IgAD/CVID

The identification of a homozygous mutation in the inducible co-stimulation (*ICOS*) gene in four patients from two unrelated families from the Black Forest with CVID in 2002 was a major breakthrough in CVID research (Grimbacher et al., 2003). To date, five additional patients with the originally described large deletion in the *ICOS* gene have been identified (Yong et al., 2009), as have two Japanese patients with a unique *ICOS* deletion (Takahashi et al., 2009). ICOS belongs to the CD28 family of co-stimulatory molecules and is expressed exclusively on activated T cells. It has at least three major functions: germinal-center formation, isotype class switching, and the development of memory B cells. Recently, a critical role for ICOS in the development of human TH17 cells has also been suggested (Paulos et al., 2010). The discovery of human ICOS deficiency showed, for the first time, that a monogenic disorder could account for the full spectrum of manifestations seen in childhood- and adulthood-onset CVID, including autoimmune, inflammatory, and malignant disease complications, as well as recurrent infections.

TACI and BAFFR are TNF-like receptors, responding to a number of ligands (BAFF, BCMA, and APRIL) involved in maturation and differentiation of B cells. In view of the impaired Ig class switching described in APRIL- (Castigli et al., 2004) and BAFF-deficient mice (Schiemann et al., 2001), it seems likely that similar defects, involving this family of receptors/ligands, may be involved in the pathogenesis of selected cases of CVID in man. Indeed, truncating and missense mutations have been described both in TACI (*TNFRSF13B*) (Salzer et al., 2005, 2008) and BAFFR (*TNFRSF13C*) (Warnatz et al., 2009) and shown to be associated with a CVID phenotype. The former may account for up to 10 percent of all patients, whereas the latter seems much less frequent.

The CD19 molecule expressed by B lymphocytes and follicular dendritic cells of the hematopoietic system is the earliest of B-lineage restricted surface antigens. It is expressed on the cell surface associated with CD21, CD81, and CD225, forming the B-cell receptor complex. The CD19 molecule is involved in development of B1 and marginal-zone B cells; when lacking, antibody responses and B-cell memory are strongly affected. Mutations in *CD19* in patients with CVID have recently been described in three separate families (Kanegane et al., 2007; van Zelm et al., 2006). It is likely, however, that this is a very rare cause of CVID.

MSH5, a gene encoded in the central MHC class III region, and its obligate heterodimerization partner Msh4 play a critical role in regulating meiotic homologous recombination. Genetic variation in *MSH5* has been shown to be associated with IgAD and CVID in humans (Sekine et al., 2007) One of the human MSH5 alleles identified contains two nonsynonymous polymorphisms, where the variant protein shows impaired binding to Msh4. Ig switch region joints from CVID and IgAD patients carrying the disease-associated *MSH5* alleles show increased donor/acceptor microhomology, involving pentameric DNA repeat sequences and lower mutation rates than controls. Thus, Msh4/5 heterodimers may contribute to class-switch recombination (CSR) where

Msh4/5 promotes the resolution of DNA breaks with low or no terminal microhomology.

CD81 is complexed with CD19, CD21, and CD225, which together form the B-cell receptor. A patient was recently reported with severe nephropathy and profound hypogammaglobulinemia characterized by decreased memory B-cell numbers, impaired specific antibody responses, and an absence of CD19 expression on B cells (van Zelm et al., 2010). The patient carried a homozygous *CD81* mutation resulting in a complete lack of CD81 expression on leukocytes. Similar to CD19-deficient patients, the CD81-deficient patient had B cells that showed impaired activation upon stimulation via the B-cell antigen receptor but no overt T-cell defects.

A recently identified 28-year-old man with hypogammaglobulinemia, recurrent respiratory infections, diarrhea, and splenomegaly was found to have a compound heterozygous deleterious mutation in the *CD21* gene, which encodes the complement receptor (CD21) expressed by B cells as part of the B-cell receptor. Functional studies of patient B cells showed complete loss of co-stimulatory activity of C3d-containing immune complexes. B-cell numbers as determined by CD19 and CD81 were normal, but the percentage of class-switched memory B cells was markedly reduced. Antibody responses to pneumococcal polysaccharide antigens were abnormal, while antibody responses to protein antigens were normal (Thiel et al., 2011).

Absence of CD27, a marker for memory B cells, was recently observed in two brothers with homozygous mutation in the *CD27* gene (van Montfrans et al., 2012). In addition to hypogammaglobulinemia, abnormal antibody responses to T-dependent antigens, and T-cell dysfunction, both patients suffered from persistent symptomatic Epstein-Barr virus (EBV) viremia, with one of the two brothers developing aplastic anemia thought to be caused by EBV, leading to fulminant gram-positive sepsis and the death of one brother at age 4 years. The surviving brother, now 21 years old, became progressively hypogammaglobulinemic and developed hepatosplenomegaly. He is responding well to regular IVIG infusions.

Mutations in *CD20* (Kuijpers et al., 2010) have recently also been suggested to cause a mild form of hypogammaglobulinemia, yet not fulfilling the criteria of CVID.

FUNCTIONAL ASPECTS

DEFECTIVE IG CLASS SWITCH IN IGAD AND CVID

Ig isotype switching is preceded by transcription of the germline mRNA for immunoglobulins (I) and switch regions upstream of the Ig heavy-chain constant-region gene, generating germline transcripts. Germline Iα transcripts are easily detected in unstimulated peripheral blood mononuclear cells from normal donors, whereas they are absent in cells from IgAD individuals (Islam et al., 1994). However, α-containing transcripts can be readily induced by the addition of TGF-β, demonstrating that the locus is accessible for transcription provided that the required signals are supplied.

A cell culture system that allows the expression of immunoglobulins by cells from IgAD and CVID patients has previously been described (Borte et al., 2009; Briere et al., 1994; Zielen et al., 1993). This system utilizes anti-CD40 antibodies or CD40L in conjunction with interleukin (IL)-4, IL-10, or IL-21, demonstrating that secretion of IgA can indeed be achieved if appropriate stimuli are added. However, although the timing and concentration of cytokines may play a crucial role in the switching process, there is as yet no strong evidence to implicate any cytokine or cytokine receptor as playing a role in the disease process.

DRUG-INDUCED IG DEFICIENCIES

IgA deficiency is seen, although infrequently, in patients treated with a variety of antirheumatic and antiepileptic drugs (Table 28.3). CVID and IgG2-IgA deficiency is also induced by some of the implicated drugs. Selected individuals may be genetically predisposed to develop drug-induced Ig deficiency, as multiple drugs can induce immunodeficiency in a given patient (Farr et al., 1991). In approximately half of the reported patients the deficiency has been reversible after cessation of treatment, although full recovery requires months or even years.

The mechanism underlying the drug-induced form of IgAD and CVID has not been determined, and there is as yet no common molecular denominator in the drugs used.

STRATEGIES FOR DIAGNOSIS

Selective IgAD presents hardly any diagnostic problems in adults, but as serum IgA levels may remain low for a protracted period in children (Janzi et al., 2009; Plebani et al., 1986), a definite diagnosis of IgAD cannot be made before the teens, although the concomitant absence of IgG2 and IgG4, even in early childhood, is a strong indicator of persistent IgAD.

Surface Ig-positive cells remain unaffected in the blood in a majority of CVID patients. However, in patients with XLA, these cells are low or absent, which may aid in differential diagnosis in young boys. The latter could also be identified by demonstrating absence of BTK or by mutation screening. The spectrum of infections also differs slightly, and some patients with CVID are also prone to nonbacterial infections as a subset of patients show a concomitant T-cell defect.

A tentative distinction between CVID and the class-switch recombination defects can be made based on sex, as most patients show an X-linked inheritance pattern. Again, the spectrum of infections appears slightly different, and as most implicated genes involved have been cloned (see Chapters 26 and 27), a correct diagnosis is possible by mutation screening.

X-linked lymphoproliferative disease (XLP) is a primary immunodeficiency caused by a defect in the *SH2D1A*, *XIAP*, or *MAGT1* gene (Al-Herz et al., 2011). The disease is characterized by severe, often fatal infectious mononucleosis, lymphomas, and Ig deficiencies. Although patients with "typical" cases (see Chapter 44) are easily distinguishable from CVID patients, problems in establishing the differential diagnosis may

Table 28.3 PATTERN OF DRUG-INDUCED IMMUNOGLOBULIN DEFICIENCIES

[a] Requires independent confirmation

occur (Morra et al., 2001, Soresina et al., 2002), and sequencing of the implicated genes may therefore be warranted.

The WHIM (warts, hypogammaglobulinemia, immunodeficiency, myelokathexis) syndrome, due to mutations in the chemokine receptor *CXCR4* gene (see Chapter 40), represents yet another potential, although rare, differential diagnosis to CVID. Again, sequencing of the implicated gene might be required.

In patients with hypogammaglobulinemia due to thymoma (Good's disease), B cells are lacking altogether in both peripheral blood and in the bone marrow, and a scan of the thymus may indicate the presence of a thymoma. Age at onset may also be of some help in the differential diagnosis of hypogammaglobulinemia. Adult onset of infections clearly suggests CVID rather than XLA, and thymoma-affected patients are usually, although not invariably, older than the average CVID patient.

TREATMENT OPTIONS

The foundation of therapy for CVID and IgAD patients is antibiotics and Ig replacement. Gammaglobulin infusions have been used for decades in patients with CVID and in infection-prone patients with IgAD (Gustafson et al., 1997). The doses employed have gradually risen, and today a weekly dose of 100 to 150 mg/kg of body weight is recommended.

Prior to being introduced as replacement therapy for XLA patients, Ig had been given intramuscularly as prophylaxis against various viral diseases. Bruton (1952), however, started his agammaglobulinemic patients on prophylactic treatment using subcutaneous Ig injections, a treatment regimen later altered to intramuscular administration. The intramuscular injections remained the mode of therapy for immunodeficiency patients for almost two decades, but owing to the limited amount that could be given, IVIG preparations were subsequently developed.

Berger et al. (1980) reintroduced treatment with slow subcutaneous infusions, and a number of reports on the treatment of hypogammaglobulinemic patients followed (for references, see Gardulf et al., 1991). However, due to the slow rate of infusion, this form of treatment did not meet with widespread appreciation.

Home treatment of patients with primary immunodeficiency disorders using gammaglobulin for intravenous use (IVIG) was introduced in 1986 (Ochs et al., 1986) and represented a significant step forward in replacement therapy. This initial report was soon followed by additional reports (Ashida and Saxon, 1986; Chapel et al., 1988; Ryan et al., 1988) showing the effectiveness of the method.

Rapid subcutaneous infusion of Ig preparations intended for intramuscular administration was first described by Gardulf et al. (1991). The method can be used in patients with a previous history of adverse reactions even in a home setting, does not require the presence of a trained partner, and results in a very low incidence of adverse reactions (Gardulf et al., 1995, 2007). Thus, this method currently represents an attractive mode of Ig administration.

Daily self-administered subcutaneous replacement therapy using small doses of gammaglobulin has recently been introduced as therapy for selected patients (Shapiro, 2010). The opposite regimen (i.e., prolonging the intervals between injections) has also been attempted, where subcutaneously administered gammaglobulin is given every second week (Gustafson et al., 2008).

In spite of replacement therapy with intravenous or subcutaneously administered Ig, some patients still suffer from respiratory and gastrointestinal tract infections. Topical application of Ig preparations (nasal, ocular, oral) has therefore been tried with some therapeutic success in selected patients.

ANIMAL MODELS

Although there are a number of reports of IgAD dogs (Felsburg et al., 1985; Glickman et al., 1988; Moroff et al., 1986) and chickens (Luster et al., 1976), the molecular basis of these deficiencies has not been elucidated. However, owing to recent progress in the field of canine genetics, dogs may well be a suitable system for searching for immunodeficiency-associated genes (Karlsson and Lindblad-Toh, 2008; Wilbe et al., 2010).

There is not as yet a rodent model available that resembles the human disease, although knockout mice with a deleted J chain (Hendrickson et al., 1995), Iα region (Harriman et al., 1996), or Cα region (Harriman et al., 1999) have been described. In the J chain-deficient mice, only secretion of IgA is impaired, and serum levels of IgA are up to 30-fold higher than in normal wild-type mice. Interestingly, there may be a J chain-independent IgA transport in the intestinal, mammary,

and respiratory epithelial cells of these mice (Hendrickson et al., 1996), adding to the complexity of the "secretory" IgA machinery. Mice with an I-region deletion produce normal levels of IgA. This observation suggests that the I region as such is redundant and can be replaced by other gene sequences, thus suggesting that splicing of germline transcripts rather than transcription per se controls DNA rearrangement leading to class switch.

Mice with a targeted inactivation of the α heavy chain constant region gene as well as part of the Sα region have also been produced (Harriman et al., 1999). These mice are profoundly deficient in both systemic and secretory IgA and show a perturbed pattern of expression of immunoglobulins, manifested as an increased level of IgM and IgG (primarily IgG2) and decreased levels of IgG3 and IgE both in serum and secretions. These mice are, however, largely normal with respect to development of their lymphoid tissues and proliferative responses. Cytokine profiles in response to antigenic challenge (influenza virus) are, however, altered, with a downregulation of Th1-mediated immune responses (Zhang et al., 2002).

ACKNOWLEDGMENTS

This work was supported by the Swedish Research Council and the EU grant EURO-PADnet (grant 201549). I am indebted to Dr. David Webster at the Royal Free and University College Medical School, London, for kindly providing the figures presented in this chapter.

INTRODUCTION TO SYNDROMES OF IMMUNE DYSREGULATION AND AUTOIMMUNITY

Hans D. Ochs and Jennifer M. Puck

Immunodeficiency disorders have traditionally been thought of as conditions resulting from the inability to mount effective host responses to infectious agents. However, immune dysregulation and autoimmune phenomena are seen in many inherited and acquired immunodeficiency disorders. Particular alleles of the major histocompatibility complex (MHC) locus have long been associated with increased susceptibility to a variety of diseases with an autoimmune basis—for example, insulin-dependent diabetes mellitus and celiac disease (Bodmer, 1996; Hammer et al., 1997; Thorsby, 1997). The detailed mechanisms that allow tolerance to be broken so that immune reactions are directed against one's own tissues are becoming better understood. The composition of the lymphocyte antigen recognition repertoire and the potential for cross-reactivity between self antigens in host tissues and foreign antigens from the environment is defined in part by an individual's MHC haplotype. With improved understanding of the processes directing selection, expansion, and control of an appropriate lymphocyte repertoire, several non-MHC-linked heritable immune disorders are now recognized in which disruption of tolerance and/or regulatory functions is a predominant feature. The chapters in this section highlight how autoimmune phenomena are an important aspect of primary immunodeficiency disease (PIDD). The group of single-gene disorders discussed in Chapters 30 through 33 are characterized by susceptibility to immune dysregulation and autoimmunity. While the typical findings commonly listed for primary disorders of the immune system relate to recurrent or unusually severe infections, autoimmune complications are seen in many PIDD settings. Indeed, for patients with some of the known defects in adaptive or innate immunity, autoimmunity and immune dysregulation are the predominant findings.

Dysregulation of adaptive immune responses can interfere with the central and peripheral control of self-reactive T cells, resulting in severe, life-threatening autoimmune phenomena, independent of any known infection (Westerberg et al., 2008). Under normal conditions, autoreactive T cells, generated in the thymus, are eliminated by negative selection: when the T-cell receptor (TCR) of a newly formed thymic T cell strongly recognizes an MHC molecule loaded with a self-antigen peptide, such as insulin, this autoreactive T cell receives a death signal and is promptly deleted by apoptosis. This process is controlled by the autoimmune regulator (*AIRE*) gene, with codes for a transcription factor expressed in medullary thymic epithelial cells. AIRE induces mature thymic epithelial cells to express and present to nascent T cells a variety of tissue restricted antigens representing organs throughout the body. The resulting deletion of the autoreactive T cells is referred to as *central tolerance*. When *AIRE* is mutated, as in autoimmune polyglandular syndrome type 1 (APS1), also called autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED), this central tolerance is impaired, resulting in a diverse spectrum of autoimmune disorders (Chapter 31).

$CD4^+$ $CD25^+$ $FOXP3^+$ natural regulatory T cells (nTreg), although generated mainly in the thymus, eventually exit to the periphery and ensure that self-reactive T cells that have escaped the central tolerance control system in the thymus are nonetheless prevented from attacking one's own tissues (peripheral tolerance). If the transcription factor FOXP3, encoded on the X chromosome, is missing or defective, nTregs fail to develop, resulting in the syndrome known as immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) (Chapter 32).

It is not surprising that single-gene defects resulting in reduced numbers or decreased fitness of nTregs are associated

with syndromes characterized by autoimmunity. These disorders include deficiency of CD25 (Chapter 32), a component of the high-affinity IL-2 receptor that is expressed by Tregs; defective STAT5b (Chapter 32), a transcription factor involved in the regulation of FOXP3 expression; and impaired or absent Wiskott-Aldrich syndrome protein (WASp), a protein required for synapse formation between Tregs and effector T cells (Chapter 43).

A third group of T-cell deficiencies associated with autoimmunity are caused by defective T-cell development due to impaired VDJ rearrangement, in which limited diversity of TCR rearrangement in the thymus leads to clones of self-reactive T cells, as in DiGeorge and Omenn syndromes, the latter frequently caused by hypomorphic mutations in RAG1, RAG2, or other proteins (Artemis, Ligase4) required for TCR rearrangement (Chapter 13).

Autoantibodies are directly involved in the pathogenesis of antibody-mediated cytopenias and several other autoimmune diseases, indicating the importance of autoreactive B cells. Analogous to the establishment of T-cell tolerance in the thymus, early B-cell progenitors include a high proportion of self-reactive cells, which are effectively purged in the bone marrow and later in the periphery by receptor editing and other mechanisms that remove autoreactive B cells using central and peripheral B-cell tolerance checkpoints (Meffre and Wardemann, 2008).

Apoptosis is an important mechanism for elimination of autoreactive lymphocytes, and defective apoptosis due to dominant germline or somatic mutations in the apoptosis receptor Fas cause autoimmune lymphoproliferative syndrome (ALPS) (Chapter 30). Additional apoptosis mediators have likewise been implicated in conditions in which T cells fail to die when they should, leading to persistence of elevated numbers of $CD4^-CD8^-$ mature $CD3^+$ T cells (which express α,β T-cell receptors), autoimmune blood cytopenias and other autoimmune disorders, and elevated risk of developing lymphoma (Turbyville and Rao, 2010).

Patients with chronic granulomatous disease (CGD) are prone to autoimmune complications such as sarcoidosis and Crohn's disease (Chapter 52). This may be due to persistent inflammation caused by secretion of proinflammatory cytokines (TNFα, IL-1β, IL-6) and/or accumulation of microorganism-derived antigens in tissue macrophages. Defective apoptosis of CGD neutrophils, as suggested by diminished surface expression of phosphatidyl serine (PS), may contribute to the delayed removal of antigen-loaded neutrophils by macrophages and, as a consequence, the production of autoantibodies resulting in discoid or systemic lupus.

Finally, congenital defects in the early complement components (C1q, C1r/s, C4, and C2) (Chapter 55) are strongly associated with systemic lupus erythematosus, demonstrating the need for an intact classical complement pathway for the safe elimination of immune complexes and prevention of immune complex disease.

Inherited susceptibility to autoimmunity associated with immune deficiency poses diagnostic and therapeutic challenges, affects the patient's long-term prognosis, and has implications for family members who may be at risk themselves or may have an increased chance of having affected offspring.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Thomas A. Fleisher, Frederic Rieux-Laucat, and Jennifer M. Puck

Apoptosis, or programmed cell death, is a critical process for deleting lymphocytes with self-reactive potential, both during lymphocyte development and in the peripheral blood and tissues throughout life. After leaving the thymus, mature T cells normally undergo a life cycle of activation and effector responses followed by apoptosis. Apoptosis maintains immune homeostasis and serves as one mechanism to minimize potential reactions against self-antigens by limiting lymphocyte accumulation after appropriate expansion in response to antigenic challenge. It is not surprising that a process as important as apoptosis is tightly regulated by interactions among multiple components. Two major mechanisms for the death of lymphocytes after their stimulation are recognized (Lenardo et al., 1999). Passive (intrinsic) apoptosis mediated by mitochondrial mechanisms follows cytokine (e.g., interleukin [IL]-2) withdrawal after clearance of antigen, while active (extrinsic) apoptosis requires the engagement of specific cell-surface molecules, principally the FAS receptor, a member of the tumor necrosis factor receptor gene superfamily also known as CD95 or APO-1.

After lymphocytes have been stimulated and are proliferating, a second or prolonged encounter with antigen induces expression of both the transmembrane receptor FAS and its ligand, FAS ligand (FASL). Extracellular engagement of a trimer of FASL chains with homotrimeric Fas receptor triggers a cascade of intracellular molecular events leading to alterations in the cell membrane, DNA fragmentation, and ultimately the death of the cell. An animal model that reveals the in vivo importance of this pathway in maintaining lymphocyte homeostasis is illustrated by the lymphoproliferation, autoantibody formation, and autoimmune nephritis that develops in mice with *lpr* and *gld* mutations, genetic defects in Fas and FasL expression, respectively (Nagata and Goldstein, 1995). In these models there are factors beyond the primary mutation that modify disease as evidenced by differences in the severity of autoimmunity between various strains. The relevance of this apoptotic pathway to human disease was postulated in 1992 with a description of two children with massive, nonmalignant lymphoid hyperplasia and autoimmune disease (Sneller et al., 1992). Subsequently, Rieux-Laucat et al. (1995), from INSERM in Paris, and Fisher et al. (1995), from the U.S. National Institutes of Health (NIH), documented that this disorder, now called autoimmune lymphoproliferative syndrome (ALPS), is associated with inherited mutations in the gene encoding FAS, *FAS* (also called *TNFRSF6*, for tumor necrosis factor receptor superfamily member 6). Previous descriptions of patients with a clinical condition consistent with ALPS include pseudolymphoma and Canale-Smith syndrome (Canale and Smith, 1967; Rao et al., 1974). Further reports by these and other teams of investigators have enlarged the number of known patients with ALPS to over 500 and documented that the syndrome can be associated with a broad clinical spectrum and molecular defects in apoptosis pathway members other than the transmembrane FAS receptor. While the series of patients followed at NIH is currently the largest (Bleesing et al., 2001; Caminha et al., 2010; Jackson et al., 1999; Sneller et al., 1997, 2003), patients have been reported worldwide (Bettinardi et al., 1997; Drappa et al., 1996; Le Diest et al., 2003; Rieux-Laucat et al., 2003; Seif et al., 2010), providing an increasingly comprehensive picture of the clinical, genetic, and immunological features of ALPS and its consequences for a patient bearing this defect in lymphocyte apoptosis present over a period of decades.

Even among the cohorts of ALPS patients bearing *FAS* mutations, the story is a complex one. The majority of patients with ALPS have inherited germline, dominant, heterozygous *FAS* mutations, but compound heterozygous

Table 30.1 **DIAGNOSTIC CRITERIA FOR ALPS***

I. Required
Chronic (>6 months duration) nonmalignant, noninfectious lymphadenopathy and/or splenomegaly
Elevated numbers of $CD3^+$ $TCR\alpha/\beta^+$ $CD4^-$ $CD8^-$ DNT cells (≥1.5% of total lymphocytes or 2.5% of $CD3^+$ lymphocytes) in the setting of normal or elevated lymphocyte counts
II. Accessory
Primary
1. Defective lymphocyte apoptosis (in two separate assays)
2. Somatic or germline pathogenic mutation in *FAS*, *FASL*, or *CASP10*
Secondary
1. Elevated plasma sFASL levels (>200 pg/mL) OR elevated plasma IL-10 levels (>20 pg/mL) OR elevated serum or plasma vitamin B12 levels (>1,500 ng/L) OR elevated plasma IL-18 levels (>500 pg/mL)
2. Typical immunohistological findings as reviewed by an experienced hematopathologist
3. Autoimmune cytopenias (hemolytic anemia, thrombocytopenia, or neutropenia) AND elevated IgG levels (polyclonal hypergammaglobulinemia)
4. Family history of a nonmalignant, noninfectious lymphoproliferation with or without autoimmunity

Definitive diagnosis ALPS: both required criteria plus one primary accessory criterion

Probable diagnosis ALPS: both required criteria plus one secondary accessory criterion

or homozygous mutations have been found in a few severely affected patients with early-onset disease starting in infancy. In addition, somatic *FAS* mutations have now been identified as the second most commonly defined molecular basis of ALPS (Dowdell et al., 2010; Holzelova et al., 2004). Most of the mutant *FAS* alleles from patients with ALPS have a dominant negative effect on apoptosis by normal alleles co-expressed in the same cell. The relatives of ALPS patients who share the same FAS defects may have mild or undetectable lymphoproliferation and autoimmunity, or may be severely affected. Taken together, these findings suggest that factors in addition to heterozygous defects of FAS are required for the full clinical expression of ALPS, similar to observations in the murine models. In addition, individuals with inherited FAS defects are at increased risk of lymphoma and possibly other malignancies (Rao et al., 2010; Straus et al., 2001). Thus, as the first human immune disorder to be associated with defective lymphocyte apoptosis, ALPS clarifies the critical role of cell death in health and disease.

DIAGNOSTIC CRITERIA AND CLASSIFICATION BY GENOTYPE

ALPS is defined as an impairment of lymphocyte apoptosis that includes chronic, nonmalignant, noninfectious lymphadenopathy and/or splenomegaly, plus expansion of a normally rare subset of lymphocytes in the peripheral blood and tissues—$CD3^+$ T cells that express α/β T-cell receptors ($TCR\alpha/\beta^+$) but express neither CD4 nor CD8 co-receptors ($CD4^-$ $CD8^-$), cells that are referred to as double-negative T (DNT) cells. The recently revised case definition of ALPS (Table 30.1) requires nonmalignant, noninfectious lymphadenopathy and/or splenomegaly persistent for at least 6 months and DNT expansion along with either defective lymphocyte apoptosis as assayed in vitro (on at least two occasions) or a defined disease-associated mutation in *FAS*, *FASL* (also called *TNFSF6*) or *CASP10* (Oliveira et al., 2010). This classification system also includes a probable ALPS category that includes the two required findings noted above together with one associated abnormality: elevated ALPS biomarker levels (soluble FASL [sFASL], IL-10, IL-18, or vitamin B12), typical immunohistological findings on lymph node biopsy, autoimmune cytopenia with hyperglobulinemia, or a family history of a similar clinical condition (Oliveira et al., 2010). The original classification system for genotypes of ALPS established by the NIH group (Puck and Straus, 2004), with variations suggested by others (Holzelova et al., 2004; Rieux-Laucat et al., 2003), has recently been revised based on an international consensus conference (Oliveira et al., 2010). As shown in Table 30.2, ALPS-FAS includes the originally reported patients, in whom germline (homozygous or heterozygous) *FAS* mutations produce deleterious consequences for the expression or function of the FAS protein. This type accounts for two thirds to three quarters of all ALPS cases in various series, with the majority having dominant, heterozygous *FAS* mutations, but rare patients with compound heterozygous mutations and a patient with homozygous null mutation of *FAS* have been reported (Jackson et al., 1999; Rieux-Laucat et al., 1995; van der Burg et al., 2000). Patients with somatic mutations in *FAS* (Dowdell et al., 2010; Holzelova et al., 2005) are designated as ALPS-sFAS and are now known to represent the second largest ALPS patient group with a defined genetic basis for disease.

Patients who fulfill the case definition for ALPS based on an abnormal in vitro FAS-mediated apoptotic defect but who do not have a defined genetic mutation (including a somatic *FAS* mutation) are referred to as having ALPS-U (unknown). Patients with a defect in *FASL* as initially described in an adult patient with atypical lupus are defined

Table 30.2 REVISED CLASSIFICATION OF ALPS*

REVISED NOMENCLATURE	PREVIOUS NOMENCLATURE	GENE	DEFINITION
ALPS-FAS	ALPS type 0	*FAS*	Patients fulfill ALPS diagnostic criteria & have germline homozygous *FAS* mutation
ALPS-FAS	ALPS type 1a	*FAS*	Patients fulfill ALPS diagnostic criteria & have germline heterozygous *FAS* mutation
ALPS-sFAS	ALPS type 1m	*FAS*	Patients fulfill ALPS diagnostic criteria & have somatic *FAS* mutation
ALPS-FASL	ALPS type 1b	*FASL*	Patients fulfill ALPS diagnostic criteria & have germline *FASL* mutation
ALPS-CASP10	ALPS type IIa	*CASP10*	Patients fulfill ALPS diagnostic criteria & have germline *CASP10* mutation
ALPS-U	ALPS type III	Unknown	Patients fulfill ALPS diagnostic criteria but genetic defect is undetermined (no *FAS*, *FASL*, or *CASP10* defect)

* Oliveira et al., 2010

as having ALPS-FASL (Wu et al., 1996), and patients with a defect in *CASP10* are now classified as having ALPS-CASP10 (Wang et al., 1999; Zhu et al., 2006). Patients who meet the two primary clinical and laboratory criteria for ALPS without mutations in apoptosis pathway genes or a demonstrable apoptotic defect but in whom an additional supporting finding is present are now referred to as having probable ALPS (Oliveira et al., 2010).

Two siblings who presented with a phenotype that included certain ALPS features plus immunodeficiency that is associated with a defect in caspase 8 encoded by the *CASP8* gene are now classified as having an ALPS-related condition referred to as caspase 8 deficiency state (CEDS) (Table 30.3; Chun et al., 2002). Additional patients have been described who have some features of ALPS but no demonstrable in vitro defects of apoptosis or mutation in apoptosis pathway components; these patients are also included in the ALPS-related disorder category, with a designation of DALD (Dianzani-associated lymphoproliferative disorder) in Table 30.3 (Dianzani et al., 1997). Finally, more recently described patients have been identified with an ALPS-related disorder associated with a somatic gain of function mutation in either the *NRAS* or *KRAS* genes. This constellation of findings results in a defect affecting the intrinsic apoptotic pathway induced by cytokine withdrawal and is now categorized as RAS–associated autoimmune leukoproliferative disease (RALD) (Table 30.3; Niemela et al, 2010; Oliveira et al., 2007).

EPIDEMIOLOGY

ALPS has been diagnosed in both males and females of diverse racial backgrounds, but at this juncture no figures estimating incidence are available. However, patients with idiopathic lymphoproliferation and autoimmune phenomena, sometimes inherited as autosomal dominant traits, have appeared in multiple literature reports and clinical series from the 1960s onward (Canale and Smith, 1967; Cheng et al., 1980; Holimon and Madge, 1971; Randall et al., 1965; Rao et al., 1974). Some of these individuals are likely to have been suffering from ALPS, and in at least three cases ALPS has been proven in follow-up studies with the detection of mutations in *FAS* (Drappa et al., 1996; and NIH unpublished data). Patients with medical findings consistent with ALPS have been under the care of physicians in many specialties: hematologists, called upon to manage the thrombocytopenia and hemolytic anemia; oncologists, who have biopsied the enlarged lymph nodes and sometimes felt compelled to treat patients with persistent adenopathy as if they had lymphoma; and rheumatologists, who have evaluated and managed some of their autoimmune phenomena.

In patients with defined mutations of *FAS* it has been possible to recognize multiple relatives bearing identical mutations but with highly variable clinical penetrance. Similar mutations have not been detected in significant numbers of healthy individuals screened at random. In some

Table 30.3 REVISED CLASSIFICATION OF ALPS-RELATED DISORDERS*

REVISED NOMENCLATURE	PREVIOUS NOMENCLATURE	GENE	DEFINITION
Caspase 8 deficiency state (CEDS)	ALPS type IIb	*CASP8*	Patients present with lymphadenopathy and/or splenomegaly, DNT elevation, recurrent infections, and germline *CASP8* mutation
RAS-associated autoimmune leukoproliferative disorder (RALD)	ALPS type IV	*NRAS*	Patients present with autoimmunity, lymphadenopathy and/or splenomegaly, elevated or normal DNTs, and somatic *CASP8* mutation
Dianzani autoimmune lymphoproliferative disease (DALD)	DALD	Unknown	Patients present with autoimmunity, lymphadenopathy and/or splenomegaly, normal DNTs, and defective in vitro FAS-mediated apoptosis

Malignancy		
Lymphoma	9%	4%

*Proband, the first member of each family referred to NIH.

†While some relatives with *FAS* mutations meet the criteria for the full definition of ALPS, others do not due to reduced penetrance and variable expressivity.

ALPS families, most or all individuals with *FAS* mutations meet the strict criteria for ALPS, as listed in Table 30.1, while other genetically affected persons can be found with few or no clinical, immunological, or hematological manifestations.

CLINICAL MANIFESTATIONS OF ALPS

Clinical features of ALPS-FAS are listed in Table 30.4. The frequencies of each feature are given for probands, defined as unrelated individuals who were the first in their kindred to be referred to NIH, and their relatives who carry the same *FAS* mutations as the probands (Jackson et al., 1999; Sneller et al., 2003; and NIH unpublished data). Other series are similar in overall range and frequency of clinical features (Le Deist et al., 1996, Vaishnaw et al., 1999a). The presentation of probands with splenomegaly and adenopathy is most often in infancy or early childhood, with a mean age of 2 years; only rarely do patients present with adenopathy as late as 15 years. At least three children were clinically affected at birth (Bettinardi et al., 1997; Le Diest et al., 1996, 2003).

LYMPHOPROLIFERATION

Lymphoproliferation is the most dramatic and consistent clinical feature of ALPS (Table 30.4). In addition, patients almost always develop splenomegaly of moderate to massive proportions before age 5. Although the dimensions of the spleen may fluctuate over time in a given patient, palpable splenomegaly almost always persists. The spleen may extend only 2 to 4 cm below the left costal margin or past the umbilicus and into the pelvis with commensurate degrees of abdominal distention. Splenectomy, originally performed in the majority of patients to manage blood cytopenias, is now strongly discouraged unless severe hypersplenism is refractory to other measures due to the increased risk of systemic bacterial infection after splenectomy. Splenectomy has been necessitated in ALPS patients by traumatic rupture of their enlarged spleens.

Mild to moderate hepatomegaly is observed in most patients at some point in time. However, clinical signs of liver dysfunction are uncommon in the absence of hepatitis C virus infection, which has complicated the course of some patients who have received blood transfusions for management of severe hemolytic anemia.

Lymphadenopathy is a consistent feature of ALPS. Virtually all patients have experienced protracted periods of palpable, nontender lymph node enlargement, but the dimensions of the nodes can fluctuate, tending to become relatively less impressive through adolescence and adulthood. On the other hand, lymphadenopathy may be massive, distorting anatomical landmarks, as seen in the 5-year-old child depicted in Plate 30.I, in whom the lymphoid mass varied but did not abate through 10 years of serial clinical observations. The anterior, posterior cervical, and axillary chains in this patient were the primary sites of enlarged lymph nodes, but, as seen in the rear view, there was also enlargement of posterior nodes. Some patients have had enlargement of preauricular and submental nodes as well as nodes in the axillary, epitrochlear, and inguinal chains. Mediastinal and retroperitoneal adenopathy can be detected on imaging studies (Avila et al., 1999). Canale and Smith (1967) observed that intercurrent infections were associated with reductions in lymph node size, and patients followed at NIH have been observed to have similar paradoxical decreases in lymph nodes in a few, but not most, instances of documented infections.

AUTOIMMUNITY

Autoimmunity in ALPS is largely directed against blood cells. Direct Coombs-positive autoimmune hemolytic anemia (AIHA) is most common autoimmune complication (Table 30.4), immune-mediated thrombocytopenia (ITP) second, while autoimmune neutropenia has been proven less frequently, possibly due to a lack of sensitive standardized tests for antineutrophil antibodies. Episodes of hemolysis may be severe; many patients have experienced at least one occasion on which hemoglobin levels fell below 7 mg/dL. Similarly, platelet counts below 10,000/μL have been seen one or more times in almost half of the patients followed at NIH (Sneller et al., 1997).

In a small number of ALPS patients, glomerulonephritis with renal compromise has been severe enough to require dialysis, and Guillain-Barré polyneuroradiculitis has occurred without any recognized predisposing infectious illness (Rieux-Laucat et al., 2003; Sneller et al., 1997). Many ALPS patients suffer from recurring rashes, including urticaria and nonspecific cutaneous vasculitis. Other infrequently reported findings of unclear pathogenesis in ALPS patients have included arthralgia, arthritis, hepatitis, biliary cirrhosis, iridocyclitis or uveitis, mucosal ulcers, panniculitis, pulmonary infiltrates, seizures, and vasculitis (Rieux-Laucat et al., 2003; Sneller et al., 2003).

Autoimmunity is a hallmark in ALPS, but it can be difficult to document for three reasons. First, not all patients are tested for many recognized types of autoantibodies. Second, some patients manifest overt autoimmune phenomena only after many years of lymph node and spleen enlargement. For example, one patient seen at NIH first developed ITP at age 31, while another first manifested AIHA at age 54. Finally, in the absence of demonstrable antiplatelet, antineutrophil, or anti-red cell antibodies, one cannot diagnose with certainty an immune basis for blood cytopenias in a setting of ongoing hypersplenism. Additional patients such as those in the reports of Le Deist et al. (1996) and Bettinardi et al. (1997) who were recognized because of their more severely affected siblings are so far without overt autoimmune disease but do have circulating autoantibodies.

MALIGNANCY

In some patients with ALPS a diagnosis of lymphoreticular malignancy or premalignant state was made but later reversed upon review of the histology in lymph node biopsies. However, in one of the earliest reports of ALPS, Hodgkin's disease (HD) and non-Hodgkin's lymphoma (NHL) were confirmed in two young adult brothers with ALPS, one of whom died of this complication (Fisher et al., 1995). An unrelated ALPS patient treated for confirmed NHL had an affected cousin who developed HD at age 7, and another unrelated woman and her son with ALPS had HD (Infante et al., 1998). A multicenter study determined that in patients with ALPS-FAS (formerly ALPS type Ia) the risk of NHL was 14-fold and the risk of HD 51-fold above that of the general population (Straus et al., 2001). Lymphomas reported to date have been exclusively B-cell–derived and included various subtypes of HD, Burkitt's lymphoma, follicular B-cell lymphoma, and T-cell–rich B-cell lymphoma. The overall rate of lymphoma among ALPS-FAS patients followed at NIH has been 9 percent as of this writing (Table 30.4; Rao et al., 2010; Sneller et al., 2003). Lymphoma has been diagnosed in patients up to 51 years of age. As young patients are followed for increasing durations of time, the overall rate of lymphoma may increase.

Two older ALPS patients reported by Drappa et al. (1996) had malignancy. One, who died of hepatocellular carcinoma at age 43, had risk factors including hepatitis C and a history of prior cytotoxic chemotherapy for his adenopathy. The other had multiple thyroid and breast adenomas and two basal cell carcinomas, all occurring between the ages of 15 and 41. In addition, another ALPS patient developed a histiocytic sarcoma (Rao et al., 2010). Other solid organ malignancies have occurred in some of the older relatives of ALPS patients, but neither their frequency nor any distinctive features recognized to date clearly distinguish them from malignancies in the general population.

OVERLAP BETWEEN ALPS AND OTHER SYNDROMES

With increased awareness in the medical community, patients previously diagnosed with other conditions have been recognized to have ALPS. Evans syndrome is a hematological disorder of unknown etiology consisting of multiple autoimmune blood cytopenias, most commonly hemolytic anemia and thrombocytopenia. Enlargement of lymph nodes, spleen, and liver occur in over half of the cases. First described by Evans et al. (1951), this syndrome is clinically similar to ALPS. An initial examination of 12 patients with Evans syndrome identified ALPS in half of them (Teachey et al., 2005), and a multi-institutional study of 45 children with Evans syndrome confirmed 22 with a diagnosis of ALPS (Seif et al., 2010). These studies suggest consideration

of a diagnosis of ALPS and with initial screening by enumeration of αβ DNT cells in all cases of Evans syndrome.

Children with sinus histiocytosis with massive lymphadenopathy (SHML), also known as Rosai-Dorfman disease, share some clinical features with ALPS, including prominent adenopathy, hypergammaglobulinemia, and autoimmune phenomena in 10 to 15 percent of cases (Grabczynska et al., 2001; Rosai and Dorfman, 1969, 1972). Histological examination of tissues from 44 patients with confirmed ALPS-FAS (at the time categorized as ALPS Ia) revealed in 18 cases the characteristic SHML histiocytic proliferation with emperipolesis (enlarged histiocytes that have engulfed other blood cells) and prominent expression of the S-100 antigen that typifies Rosai-Dorfman syndrome (Maric et al., 2005). A preliminary report has also noted *FAS* mutations in DNA isolated from tissues of SHML patients (George et al., 2004).

Although the original mouse with Fas deficiency was developed as a model for human systemic lupus erythematosus (SLE), *FAS* mutations have not been found commonly in patients with SLE. Nonetheless, at least one patient each with ALPS-FAS, ALPS-FASL, and ALPS-CASP10 confirmed by mutation analysis has fulfilled the diagnostic criteria for SLE (Gill et al., 2003; Vaishnaw et al., 1999a; Wu et al., 1996; Zhu et al., 2006).

Finally, the recognition of increased risk of lymphoma in ALPS-FAS patients suggests that with other forms of ALPS, inherited mutations in the receptor-mediated apoptosis pathway may underlie a proportion of sporadic occurrences of this malignancy, and possibly a considerable proportion of familial lymphomas. Somatic mutations in *FAS* are already known to occur in some 10 percent of cases of B-cell lymphomas and leukemias. The demonstration of somatic mutations in ALPS (Dowdell et al., 2010; Holzelova et al., 2004) indicates that clinical features of autoimmunity and lymphoproliferation may long predate the actual emergence of clonal lymphoproliferation.

PATHOLOGICAL FEATURES OF ALPS

Histopathological analysis of lymph nodes of patients affected with ALPS shows characteristic pathological changes (Lim et al., 1998; Sneller et al., 1992), as seen in Plate 30.II. There is architectural preservation, but with a florid reactive follicular hyperplasia with immunoblasts and plasma cells and marked paracortical expansion. The features resemble those of viral lymphadenitis except for the conspicuous absence of histiocytes normally seen to contain apoptotic debris in infection-associated reactive nodes. The paracortical expansion is in some cases extensive enough to consider a differential diagnosis of immunoblastic lymphoma, with many cells expressing the Ki-67 antigen, indicative of active proliferation (Gerdes et al., 1984).

Analysis of splenic tissue from ALPS patients demonstrates lymphoid hyperplasia of the white pulp with histological features similar to those of the lymph nodes. B cells expand the lymphoid follicles while DNT cells accumulate in the paracortical areas. Bone marrow aspirates are generally unremarkable, although trilineage hematopoiesis is seen in patients with autoimmune cytopenias.

Although many of the T cells in both spleen and lymph nodes are $CD4^+$ or $CD8^+$, the remarkable and most characteristic feature of the lymphoid histology in ALPS is the large proportion of α/β TCR $CD4^-$ $CD8^-$ cells in the paracortical areas. Given the underlying defects in apoptosis in ALPS, it was surprising when histological analyses showed many splenic lymphocytes undergoing apoptosis (Le Deist et al., 1996). It is presumed that alternative pathways of lymphocyte apoptosis may be upregulated in an attempt to compensate for a defect in the FAS-mediated apoptosis pathway. As discussed above, histiocytic infiltrates and emperipolesis of lymphocytes and plasma cells, as seen in SHML, are found in biopsied lymph nodes of about 40 percent of ALPS cases. The enlarged histiocytes, located in paracortical areas and sinusoids, are strongly positive for the S-100 antigen (Maric et al., 2005).

In ALPS-CASP10, impairment of dendritic cell apoptosis was noted and associated in one patient with expansion of dendritic cells in lymph node biopsy (Wang et al., 1999).

LABORATORY FINDINGS IN ALPS

IMMUNOLOGICAL FINDINGS

Lymphocyte phenotyping provided the first clues as to the unique nature of ALPS. There is an increase of peripheral blood $CD3^+$ T cells that exceeds the sum of $CD4^+$ plus $CD8^+$ cells, indicating expansion of a normally minor $CD4^-$ $CD8^-$ T-cell or DNT-cell subset. Such cells can be found in the blood of some patients with malignancy, HIV infection, acute viral infections, and certain other inflammatory states. However, in these disorders, the expanded cell subpopulation typically bears γ/δ TCR. In contrast, the DNT-cell subpopulation that is increased in all patients with ALPS expresses the α/β TCR. This population is less than 2.5 percent of $CD3^+$ T cells (1.5 percent of lymphocytes) in normal controls and over 200 FAS-normal relatives of ALPS patients, while ALPS patients typically have 5 to 20 percent DNT cells, with a range from 1.5 to 68 percent (Bleesing et al., 2001; Oliveira et al., 2010). These cells are also generally $CD45RA^+$, $CD45RO^-$, $CD57^+$, and many of them have increased expression of HLA class II antigen, HLA-DR (Bleesing et al., 2001; Sneller et al., 1997). The DNT cells in ALPS express restricted V-beta TCR diversity and appear to be clonally related to $CD8^+$ T cells (Bristeau-Leprince et al., 2008). As distinct from $CD4^-$ $CD8^-$ immature thymocytes, the DNT cells of ALPS, when isolated and studied in vitro, are poorly responsive to mitogens and antigens and fail to produce cytokines such as IL-2 upon activation (Sneller et al., 1992). Rather than immature cells, they appear to be a population of aged T cells that have escaped elimination by apoptosis. They thus are a marker for the ALPS disease state, but their role in the evolution of autoimmunity remains unknown.

Patients with ALPS also show other abnormalities in their immunological profiles (Bleesing et al., 2001, 2002; Table 30.5). In addition to $CD4^+$ and $CD8^+$ T cells displaying

Table 30.5 LABORATORY FINDINGS IN ALPS

IMMUNOLOGY
Lymphocytes
Relative if not absolute lymphocytosis involving both B and T cells
Excess of $CD4^-/CD8^-$ T cells; specifically >1.5% α/β TCR $CD4^-/CD8^-$ cells
Increased proportions of HLA DR^+ and $CD57^+$ T cells
Decreased $CD4^+/CD25^+$ T cells
Decreased CD27 expression on B cells (with increased soluble CD27 in serum)
Decreased delayed-type hypersensitivity to skin test antigens
Granulocytes
Neutropenia
Eosinophilia
Immunoglobulins
Elevated levels of IgG, IgA, and/or IgM
Monoclonal IgG1 spike in one severely affected patient with homozygous Fas deficiency
Poor and/or unsustained specific antibody responses to polysaccharide antigens
Autoantibodies to
Erythrocytes (direct Coombs)
Platelets
Neutrophils
Phospholipids
Smooth muscle
Rheumatoid factor
Antinuclear
Cytokines
Elevated serum IL-10 (ALPS-FAS and ALPS-sFAS)
Elevated serum IL-18 (ALPS-FAS and ALPS-sFAS)
Elevated sFASL (ALPS-FAS and ALPS-sFAS)
Hematology
Anemia
Hypersplenism
Autoimmune hemolysis
Iron deficiency
Elevated vitamin B12 levels
Chemistry
Elevated aminotransferases or cholesterol seen uncommonly
Proteinuria (in cases of glomerulonephritis)

HLA-DR and CD57, ALPS patients average a 5-fold or greater expansion of B-cell numbers relative to normal subjects, and the B cells have a marked decrease in the expression of the memory marker CD27 (Bleesing and Fleisher, unpublished). Natural killer (NK) cell numbers are normal. ALPS patients have a characteristic TH2 T-helper-cell–oriented cytokine profile, with increased TH2 cytokines IL-4, IL-5, and IL-10 and reduced in vitro release of the TH1 cytokines IL-12, IL-2, and interferon-γ. Levels of IL-10 in serum are profoundly elevated in most patients with ALPS, particularly patients with *FAS* mutations, whereas they are usually undetectable in normal subjects and patients without ALPS, even those who have a variety of autoimmune disorders characterized by autoantibodies, such as SLE (Fuss et al., 1997). The TH2 cytokine profile is thought to promote the development of autoimmune features of ALPS.

Recently a pattern of biomarkers has been identified that correlates with a diagnosis of ALPS-FAS. These include marked elevations in serum IL-10, IL-18, and soluble FASL levels as well as increased serum vitamin B12 levels (Caminha et al., 2010; Magerus-Chatinet et al. 2009).

Despite a dramatic and at times alarming degree of lymphoid organ enlargement, immunity in ALPS is surprisingly intact unless disease complications are being treated with immunosuppressive medications. Except for frequent pneumococcal sepsis following splenectomy, ALPS-FAS patients have rarely experienced unusual or severe opportunistic infections. Nonetheless, abnormalities in both humoral and cellular immunity can be demonstrated. Of eight NIH patients tested, four failed to respond to a panel of three delayed-type hypersensitivity skin test recall antigens. Although antibody responses to T-dependent antigens appeared to be intact, patients with ALPS responded less to polysaccharide antigens, such as those in the 23 serotype pneumococcal polysaccharide vaccine. Moreover, several patients have failed to sustain initially protective antibody levels to pneumococcal polysaccharides following immunization, a concern in asplenic individuals who are susceptible to bacterial sepsis. Antibodies to the T-dependent antigen tetanus toxoid have also been noted to be poorly sustained. Immunoglobulin levels are usually elevated, with IgG concentrations as high as 8 g/dL. IgA or other isotypes may be elevated. The immunoglobulin is almost invariably polyclonal, but Rieux-Laucat et al. (1995) reported one child with a monoclonal IgG-1 spike.

Autoantibody production is very common in ALPS, with most antibodies directed against red cells or platelets. Antineutrophil antibodies and low titers of anti-smooth muscle, antiphospholipid, antinuclear antibodies, and rheumatoid factor can also be seen.

HEMATOLOGY

Most ALPS patients are anemic based on one or more of three mechanisms: hypersplenism, Coombs-positive hemolysis, and iron deficiency. Prior to splenectomy it is not uncommon for hemoglobin levels to average 7 to 8 mg/dL. Hemoglobin concentrations below 3 mg/dL can be seen in acute hemolytic crises. Red cell indices are mostly normocytic, but microcytosis is common, and red cell survival is short.

Platelet counts can be normal, but in the presence of hypersplenism they are typically low, and they are elevated

after splenectomy. Thrombocytopenic crises with bruising and epistaxis are frequent immune-mediated events.

Nearly all patients with ALPS sustain an absolute lymphocytosis ranging from 8,000 to 90,000 cells/μL or even higher, but averaging about 14,000 cells/μL after splenectomy. Granulocytosis can occur. On the other hand, an absolute neutropenia is common prior to splenectomy. Postsplenectomy immune-mediated neutropenia is well documented (Kwon et al., 2003). Most patients also exhibit a relative, if not absolute, eosinophilia ranging from 3 to 32 percent and averaging about 7 percent a finding that has been associated with abnormal Fas expression in a murine model (Simon et al., 1996).

CHEMISTRY

The blood chemistry profile in ALPS is largely normal, but occasional patients have persistently elevated aminotransferases in the range of 100 to 300 IU/mL. One individual in the NIH series had hypercholesterolemia associated with lymphocytic infiltration into the hepatic sinusoids and portal triads; liver transplantation was eventually required (S. E. Straus, unpublished). While this patient did not have any evidence of viral hepatitis, a patient with ALPS and hepatitis C developed hepatocellular carcinoma (Drappa et al., 1996).

MOLECULAR BASIS OF ALPS

The similarity between humans with ALPS and mice with *lpr* and *gld* mutations was postulated in 1992 in a report from NIH of two children with massive, nonmalignant lymphoid hyperplasia, autoimmune disease, and markedly elevated numbers of $CD4^-$ $CD8^-$ T cells (Sneller et al., 1992). The *lpr* mouse had been studied for many years as a model for immune complex diseases, particularly lupus, and was known to have lymphoid hyperplasia and expanded $CD4^-$ $CD8^-$ T cells as well as nephritis due to renal deposition of autoantibodies (Cohen and Eisenberg, 1991; Theofilopoulos et al., 1981). Shortly after the NIH patients were reported in 1992, the genetic cause of the murine *lpr* phenotype was discovered to be a homozygous autosomal recessive mutation causing extremely reduced levels of the protein designated Fas (for *F*S-7 cell line-associated surface antigen) (Watanabe-Fukunaga et al., 1992; Yonehara et al., 1989). The same protein was independently identified and named APO-1 (Dhein et al., 1992; Oehm et al., 1992; Trauth et al., 1989), and a third name, CD95, was subsequently assigned.

In both the Japanese group led by S. Yonehara and S. Nagata and the German group led by P. H. Krammer, monoclonal antibodies had been developed that induced apoptosis upon binding to the surface of cells (and the FS-7 cell line in particular). In addition to their effect of cross-linking a cell-surface apoptosis receptor, these antibodies were used to purify the FAS/APO-1/CD95 protein, which in turn was partially sequenced, leading to identification and isolation of the human cDNA for the apoptosis gene now officially designated *FAS* (*TNFSF6*, *CD95*, *APT1*). Furthermore, the same antibodies were used to demonstrate the absence of Fas on lymphocytes of the *lpr* mouse, indicating that defective lymphocyte apoptosis was the basis of the autoimmune phenotype of this mouse. In related studies, the defect in *gld* mice proved to be in the Fas ligand (FasL), which cross-links Fas under physiological conditions to induce apoptosis (Fig. 30.1; Takahashi et al., 1994). Both Rieux-Laucat et al. (1995) and Fisher et al. (1995) described defects in the human *FAS* gene in patients with autoimmunity, lymphoproliferation, and excess $CD4^-$ $CD8^-$ T cells, including one of the original NIH patients described by Sneller et al. (1992).

Fas and FasL are members of two superfamilies of receptors and ligands that are important in immune regulation (reviewed in Lenardo et al., 1999; Nagata and Goldstein, 1995). Fas is a member of the tumor necrosis factor receptor superfamily (TNFRSF), which includes TNFRSF1A (p55) and TNFRSF1B (p75); CD40, important in B-cell activation (see Chapter 26); CD30, found on Reed-Sternberg cells in Hodgkin's lymphoma; and several other receptors. These type 1 membrane-spanning proteins share up to 25 percent amino acid identity and contain variable numbers of conserved extracellular cysteine-rich domains (CRDs). Fas and TNFRSF1A share an intracellular region of homology as well, a 70 amino acid "death domain," around which is assembled a death-inducing signal complex (DISC) that propagates intracellular signals for apoptosis.

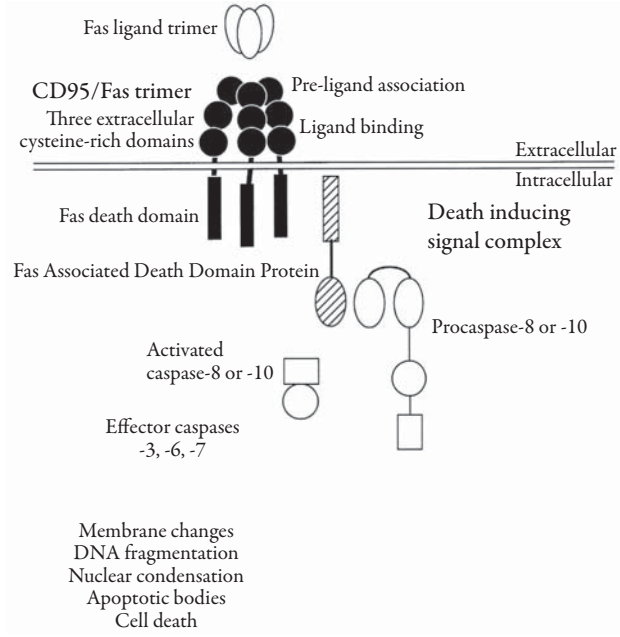

Figure 30.1 Lymphocyte apoptosis pathways (Nagata et al., 1997). After Fas, TNFR-1, and related apoptosis mediators (not shown) are linked by their trimeric ligands, their intracellular death domains transduce signals to cytoplasmic death domain-containing proteins, including FADD/MORT1, TRADD, and RIP. Caspase protease domains of FADD/MORT1 and FLICE/MACH1 cleave downstream proteases such as caspase 8, which in turn signal the activation of proteolytic enzymes and DNases. Some components of the apoptosis pathway such as RIP and TRAF-2 may have a regulatory role, inducing antiapoptotic survival factors via NF-κB activation.

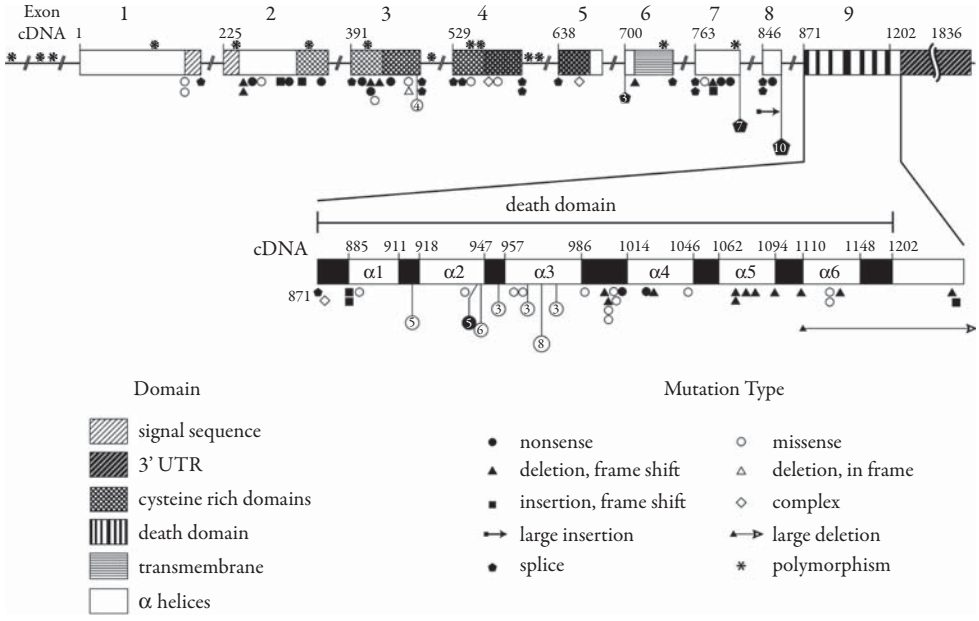

Figure 30.2 Diagram of the structure of the human *FAS* gene encoding the protein FAS/CD95/APO-1, showing mutations in patients with ALPS. CRD, cysteine-rich domain. (A) Two heterozygous alleles bearing missense mutations in three brothers with ALPS reported in Italy (Bettinardi et al., 1997). (B) Homozygous deletion resulting in undetectable cell surface Fas protein in a severely affected patient reported from France (Le Deist et al., 1996; Rieux-Laucat et al., 1995). Mutations in the top row are reported from Europe, those in the second row are from Cornell University Medical Center (Drappa et al., 1996), and the remaining mutations were detected at NIH (Fisher et al., 1995; Infante et al., 1998; Sneller et al., 1997; NIH group, unpublished). GenBank accession numbers X81335–X81342 (Behrman et al., 1994).

Protein structural studies indicate that FASL, which occurs in membrane-bound and secreted forms, self-associates into homotrimers with a conical configuration to become functionally active (Fig. 30.1). The FASL trimer engages a homotrimeric complex of Fas chains displayed on the surface of lymphocytes. FAS chains self-assemble at the cell surface by means of their pre-ligand association domains in the first CRD of the FAS molecules (Siegel et al., 2000). Upon ligand engagement, the extracellular projections of the Fas trimeric complex extend and embrace the FasL trimer. Disulfide bonds between the cysteine residues of the CRDs stabilize the conformation of the extracellular portion of Fas.

Extracellular binding of a FASL trimer to a FAS trimer results in the formation at the intracellular side of the cell membrane a DISC that consists of the trimeric FAS death domains, the Fas-associated death domain protein FADD (also called MORT1), TRADD, RIP, and associated partners that possess proteolytic ICE-like domains (named for their homology to IL-1β converting enzyme) (Enari et al., 1995; Hsu et al., 1995, 1996; Los et al., 1995). These ICE-like proteases, now collectively referred to as *caspases*, cleave proteins at specific amino acid recognition sites. Procaspase 8 (originally called FLICE and MACH by different independent groups of discoverers) and procaspase 10 can be cleaved by the proteolytic domain of FADD/MORT1. After cleavage, caspase 8 and caspase 10 themselves becomes active proteases that act on further proteases in a cascade, eventually leading to activation of effectors caspase 3 and caspase 9, which in turn bring about the cellular events that constitute the apoptosis program (Salmena et al, 2003). Characteristic lethal cellular events collectively known as apoptosis include early membrane permeabilization and exposure of proteins not normally detectable at the cell surface; DNA cleavage between nucleosome units into fragments of incremental sizes, visible on electrophoresis gels as "ladders;" condensation and segmentation of nuclei; and shedding of "apoptotic bodies," nuclear particles encased in membrane that are rapidly phagocytosed by macrophages (Lenardo, 1996; Nagata and Goldstein, 1995). Apoptosis, in contrast to necrosis, the other major physiological mechanism for removal of cells in the body, does not incite local inflammation.

Figure 30.2 shows the organization of the *FAS* gene encoding FAS; the gene has nine exons within a genomic span of about 25 kb on human chromosome 10q23 (Behrmann et al., 1994). The open reading frame, beginning in exon 2, encodes a signal peptide of 16 amino acids. After directing transmembrane expression this peptide is cleaved off the mature protein. Exons 2 through 5 encode the three extracellular CRD units of FAS; the sequences encoding the transmembrane domain lie within exon 6. The intracellular domain of *FAS* includes in exon 9 a death domain with homology to the intracellular portion of *TNFRSF1A*. A number of single nucleotide polymorphisms (SNPs) that do not alter amino acid sequence have been defined within the *FAS* gene (Neimela et al., 2006). Particularly common SNPs in exon 3 and exon 7 (Fiucci and Ruberti, 1994) make possible allotype assignment for family genetic studies. The FAS protein is expressed in heart and liver as well as in lymphocytes. Particularly high amounts are found in T cells activated by TCR engagement and IL-2.

MUTATION ANALYSIS AND GENOTYPE–PHENOTYPE CORRELATIONS IN ALPS-FAS

To date, over 500 patients with ALPS have been identified (Jackson et al., 1999; Kasahara et al., 1998; Le Deist et al., 2003; Oliveira et al., 2010; Puck, 2005; Vaishnaw et al., 1999a, 1999b). Among these, *FAS* gene mutations causing ALPS-FAS have been found in over 200 families, and several families have more than one affected member (Bettinardi et al., 1997; Drappa et al., 1996; Infante et al., 1998; Le Deist et al., 1996; Oliveira et al., 2010; Puck, 2005; Sneller et al., 1997). A website that lists many curated mutations in *FAS* is the Leiden Open Variation (LOVD) Database installation at the National Center for Biotechnology (NCBI) at NIH (http://www.ncbi.nlm.nih.gov/lovd/home.php?select_db = FAS). The above mutations, other than the polymorphisms mentioned above and other SNPs that do not alter the predicted amino acid sequence of the FAS protein, have not been detected upon screening over 200 alleles of chromosome 10 from unrelated healthy individuals.

Nearly all of the mutations causing ALPS-FAS to date are changes of a single nucleotide or a few nucleotides in *FAS*. Exceptions are a 331-bp insertion 5′ of exon 8 that disrupts splicing and a 290-bp terminal deletion in exon 9 (Fig. 30.2). The latter deletion was found in homozygosity in a very severely affected daughter of consanguineous parents (Le Deist et al., 1996; Rieux-Laucat et al., 1995). The infant had massive lymphoproliferation at birth, evidenced by hydrops fetalis with massive hepatosplenomegaly. The spleen had to be removed at the age of 2 months, at which time it weighed 1.8 kg. Other findings were pulmonary infiltrates, intra-abdominal lymph node enlargement as shown by CT scan examination, and lymphocytosis up to 150,000/μL. Although a *FAS* mRNA signal of reduced length was detected by Northern analysis in this patient, consistent with deletion of the 3′ end of the gene, FAS protein was not detectable by cell-surface staining with anti-FAS antibody, suggesting a defect either in protein synthesis or in stability or transport to the cell membrane. The heterozygous parents of this patient were healthy, and their lymphocytes had normal FAS-mediated apoptosis by the in vitro testing method employed (Le Deist et al., 1996). Thus, this human null mutation was most reminiscent of the *lpr* mouse mutation in that it resulted in nonexpression of FAS and a recessive, severe disease phenotype.

The three brothers with striking lymphoproliferation characteristic of ALPS reported by Bettinardi et al. (1997) were compound heterozygotes for two missense mutations, one in the extracellular CRD2 domain and the other at the proximal end of the intracellular death domain. One brother had autoimmune thrombocytopenia and hemolytic anemia, while the others had no overt autoimmune disease but did have autoantibodies. Interestingly, their parents, each a heterozygous carrier with one wild-type *FAS* allele, were reported to be healthy and without elevated DNT cells or defective apoptosis. The mechanism by which the two mutations in these brothers might combine to produce ALPS with recessive phenotype is not clear.

By far the majority of ALPS-FAS cases are associated with heterozygous *FAS* mutations; ALPS is inherited in an autosomal dominant fashion along with FAS defects in most kindreds. Patients with this form of ALPS have one mutant and one normal, functional *FAS* allele. As shown in Figure 30.2, the most common region of the *FAS* gene to be mutated in ALPS-FAS is the intracellular death domain in exon 9, expanded in the figure to show the large number of mutations clustered within it. The heterozygous death domain mutations occur in and around the six α-helical regions of the peptide structure (Huang et al., 1996). These mutations are predicted to result in either early termination of protein synthesis (frameshifting insertions and deletions; amino acids changed to stop codons) or single amino acid substitutions (missense mutations), as shown in Figure 30.2. They occur in portions of the death domain that are highly conserved in other death domain proteins in other species such as the mouse. For example, a point mutation in murine Fas in the lpr^{cg} mouse strain has been identified and found to predispose to lymphoproliferation and autoimmune disease similar to that in mice with the *lpr* and *gld* mutations (Kimura and Matsuzawa, 1994; Watanabe-Fukunaga et al., 1992). This missense point mutation in the lpr^{cg} mouse introduces a nonconserved asparagine residue corresponding to human FAS amino acid 238, between the second and third α-helices. Immediately adjacent to the position of this mouse mutation, three human missense mutations, G237V, G237S, and G237D, have been identified in patients with ALPS. The heterozygous death domain substitution mutations are compatible with expression of mRNA and protein, suggesting that mutant protein molecules may inhibit apoptosis by normal FAS expressed concurrently. Ultrastructural studies have indicated disruption of the death domain architecture by some mutations, whereas others appear to affect contact points between FAS and FADD (Huang et al., 1996).

Many other mutations in the extracellular domains of *FAS* as well as in the more proximal intracellular regions result in clinical and immunological presentations similar to those of ALPS patients with death domain mutations, but often of milder clinical severity. As an example, one patient with a splice mutation immediately following exon 3 was shown to make in-frame abnormal mRNA and protein that skipped exon 3 (Fisher et al., 1995; this individual is pictured in Plate 30.I). Two other patients had mutations within exon 3, a nonsense mutation and a single base deletion with a frameshift. Curiously, unlike the splice mutation described above, analysis of cDNA clones showed that these mutant alleles were not associated with exon 3 skipping (Jackson et al., 1999; Puck, unpublished). If translated, they would produce truncated proteins corresponding only to the first CRD. Splice mutations of exons encoding intracellular domains have also been found, in some cases producing a shortened mRNA and protein terminating immediately after the transmembrane region, but without intracellular charged amino acids to anchor it (Fisher et al., 1995). The possibility that some mutations encode shortened FAS proteins that are secreted from the cell needs to be explored. These mutations may cause disease through the mechanism of haploinsufficiency (Hsu

et al, 2012; Kuehn et al, 2011). Expression and function of mutant alleles must be addressed experimentally to determine whether and by what mechanism it is deleterious.

Satisfactory correlations between the *FAS* genotype and the clinical presentation or phenotype of each individual are complicated by several factors. First, as indicated above, ALPS may be recessive, but it is more often a dominant disorder associated with heterozygous mutations; the mode of inheritance is at least in part dependent on the type of mutation itself, with homozygous or compound heterozygous mutations expected to produce more severe, recessive disease. Second, penetrance and expressivity of phenotypes associated with heterozygous *FAS* mutations are also variable, in that mutation-bearing relatives of ALPS probands may have all of the defining criteria for ALPS or may instead have milder or even completely undetectable clinical and immunological abnormalities (Infante et al., 1998; Jackson et al., 1999; Vaishnaw et al., 1999b).

FUNCTIONAL ASPECTS: IN VITRO ASSAY OF APOPTOSIS

Defective apoptosis is the hallmark of peripheral blood lymphocytes of patients with ALPS. Activated, cultured T cells from ALPS patients exhibit reduced rates of apoptotic death when stimulated through the FAS pathway (Fig. 30.3A). To assay apoptosis, peripheral blood mononuclear cells in vitro are initially exposed to a strong activating stimulus such as phytohemagglutinin; then the activated T cells from these cultures are maintained and expanded in IL-2; and after 5 to 20 days, the cells are subjected to trimerized FAS ligand or an anti-FAS monoclonal antibody, such as CH11 or Apo-1 (Fisher et al., 1995). Apoptosis can be quantitated by a variety of means, perhaps most directly by measuring loss of viable cells in culture wells exposed to antibody versus no antibody for 24 hours. As shown in Figure 30.3A, after cross-linking activated cultures of lymphocytes from four ALPS patients exhibited rates of cell loss averaging only 7 percent, compared to an average of 50 percent for cultures from three healthy control subjects. Other methods of demonstrating apoptosis include staining free DNA ends that result from DNA fragmentation and demonstrating characteristic membrane changes. Recently an alternative assay called the FasT Kill Assay that is performed on fresh PBMCs and yields reproducible results within hours (Lo et al, 2013). Assay conditions and normal ranges for all apoptosis tests must be established and monitored in each laboratory.

Lymphocytes from all ALPS patients with deleterious germline *FAS* mutations have defective FAS-specific apoptosis. ALPS patient B-cell lines transformed with Epstein-Barr virus likewise show defective apoptosis after anti-FAS exposure, indicating that both B and T lymphocytes express the defect in FAS-mediated programmed cell death (Sneller et al., 1997). In addition, mutation-bearing family members, even those with no clinical abnormalities and no elevations of $CD4^-$ $CD8^-$ T cells, demonstrate defective apoptosis in vitro. Thus the impairment in cellular apoptosis associated with *FAS* mutation is inherited as a dominant trait.

The NIH group (Fisher et al., 1995) studied the mechanism by which a heterozygous mutant *FAS* allele can exert a dominant inhibition of apoptosis by using an in vitro transfection system (Fig. 30.3B). *FAS* cDNA in an expression plasmid introduced into a FAS-negative mouse thymoma cell line by electroporation achieved measurable cell-surface expression of mutant or normal FAS in about 50 percent of the target cells (Fig. 30.3B, white bars). When the human-specific CH11 anti-FAS monoclonal antibody was added (black bars), 50 percent of cells treated with 10 μg of normal *FAS* plasmid were killed; thus virtually all of the FAS-expressing cells died. When thymoma cells were transfected with *FAS* cDNA bearing the death domain mutation T225P found in an ALPS patient, protein was expressed at the cell surface, but there was no apoptotic cell loss after treatment with CH11. As shown on the right of the figure, when mixtures of normal and mutant *FAS* cDNA were transfected together, the mutant allele inhibited transmission of a death signal by the normal, wild type allele (Fig. 30.3, asterisks). With equal amounts of wild-type and mutated *FAS* cDNA, apoptosis was almost completely interrupted; this dominant inhibitory effect was still seen with a 3:1 ratio of wild type to mutant.

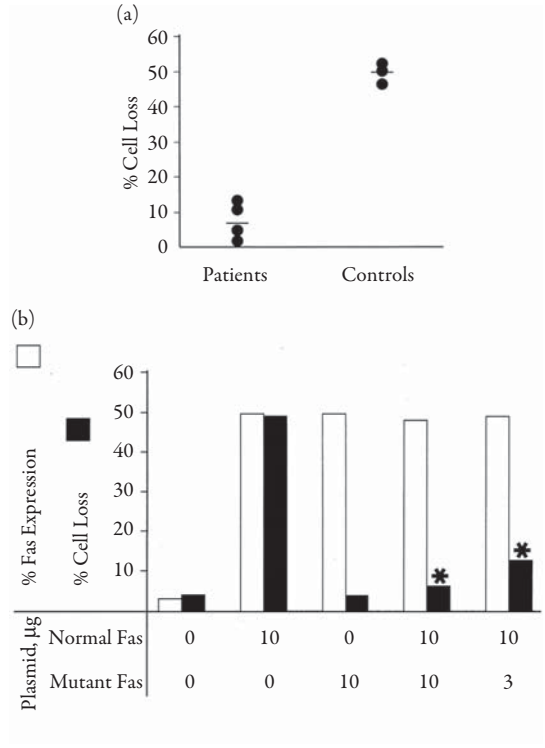

Figure 30.3 FAS-mediated apoptosis. (A) FAS-mediated killing of activated, IL-2–dependent T cells derived from ALPS patients versus normal controls. The percent cell loss reflects the difference between cells exposed to an anti-FAS monoclonal antibody compared to cells not exposed to the antibody (Fisher et al., 1995). (B) Expression (*open bars*) and apoptosis (*black bars*) in cells transfected in vitro with *FAS* cDNA constructs, followed by exposure to anti-FAS antibody to induce cell loss. Transfection with normal *FAS* leads to killing of all cells expressing FAS, while essentially no cell loss occurs with mutant FAS. Transfection with mixtures of normal and mutant *FAS* show the dominant negative inhibition of apoptosis by mutated FAS (*) despite the presence of normal FAS.

The dominant-interfering effect on apoptosis of FAS proteins with a death domain mutation is consistent with the model of FAS as a functional trimer (Fisher et al., 1995). Three FAS molecules form a trimeric complex to interact with a FASL trimer at the cell surface, and the intracellular death domains of the FAS molecules must interact properly with downstream mediators in the DISC to accomplish cell killing. If there is equal expression of normal and mutant FAS mRNA, normal and defective protein chains are expected to be synthesized and expressed equally at the cell surface. Assembly of these FAS monomer chains into trimers at random will yield only one out of every eight trimer complexes with three normal FAS subunits. Following this model, the presence of one, two, or three defective FAS molecules in a complex is predicted to render that complex nonfunctional. Thus, heterozygous interfering mutations are expected to have a profound inhibitory effect on apoptosis, as is actually observed.

Some FAS proteins with mutations outside of the death domain may also have a dominant inhibitory effect (Fisher et al., 1995; Jackson et al., 1999). Similarly, truncated FAS protein molecules terminating before or within the death domain may impair apoptosis in a dominant negative fashion (Jackson et al., 1999; Rieux-Laucat et al., 1999; Vaishnaw et al., 1999b). On the other hand, certain mutations, and indeed some splice variants of normal FAS, produce a protein that lacks the transmembrane region and thus may be secreted rather than membrane-bound (Cheng et al., 1994; Papoff et al., 1996; Ruberti et al., 1996). In vitro studies by some investigators indicate that peptides containing the first 49 amino acids of FAS are sufficient to inhibit apoptosis in cultured cells (Papoff et al., 1996). However, the pathophysiological role of secreted FAS in ALPS or in other autoimmune disorders, whether produced by mutant alleles or splice variants, remains unclear. Furthermore, some *FAS* mutations, such as termination codons at the far 5′ end of the gene are null, resulting in loss of function rather than dominant interference (Jackson et al., 1999; Vaishnaw et al., 1999b). These mutations appear to cause ALPS by producing haploinsufficiency, implying that the amount of FAS at the cell surface is a critical parameter for induction of apoptosis in physiological conditions (Hsu et al., 2012; Kuehn et al., 2011).

ALPS DUE TO SOMATIC MUTATIONS OF FAS

Holzelova et al. (2004) initially reported a group of six children presenting by 2 years of age with typical clinical features of ALPS, including lymphadenopathy, splenomegaly, elevated DNT cells, hypergammaglobulinemia, and, in four of six cases, autoimmune disease. Interestingly, none of the patients had affected relatives; moreover, they lacked demonstrable defects in lymphocyte FAS-mediated apoptosis and did not have germline mutations of *FAS*. The DNT cells of these patients were isolated by flow cytometric sorting, and DNA prepared from this cell subset was subjected to *FAS* sequence analysis. In all six DNT samples, deleterious *FAS* mutations either identical to or having the same effects as previously known dominant-interfering mutations were found. T cells from these patients that had been activated in vitro and cultured in IL-2 did not harbor the mutations, nor did the patients' buccal mucosal cells, indicating that the FAS defects had arisen by somatic mutation and were subject to positive selective pressure because of their resistance to physiological apoptosis signals in vivo. ALPS due to FAS defects arising by somatic mutation in T-cell precursors, common lymphoid progenitors, or hematopoietic progenitors is designated ALPS-sFAS (somatic mutant) (Table 30.2). A recent evaluation of 32 patients from the NIH cohort without germline mutations in *FAS* identified 50 percent of these individuals with a somatic mutation in *FAS* (Dowdell et al., 2010), and these findings establish somatic mutations in *FAS* as the currently second most common genetic basis for ALPS.

ALPS-LIKE ILLNESSES WITHOUT FAS DEFECTS

Both children and adults have been observed who have autoimmune lymphoproliferation but no mutations in *FAS*. Some of these individuals have modestly expanded numbers of DNT cells. Among this group are patients with impaired in vitro apoptosis via the FAS pathway; normal apoptosis after anti-FAS antibody exposure but impairment of apoptosis by TCR restimulation; impairment of apoptosis associated with cytokine (IL-2) withdrawal (with normal FAS-mediated cell death); and also patients with no demonstrable apoptosis defects (Dianzani et al., 1997; Oliveira et al., 2007; Sneller et al., 1997; S. E. Straus and J. M. Puck, unpublished observations; J. P. Villartay, unpublished observations). Additional patients with clinical findings similar to those of ALPS patients have failed to show elevations of DNT cells, although not all have been studied over long time periods with consistent staining protocols. A variety of patients with autoimmune blood cytopenias have splenomegaly with or without adenopathy; they are not considered to have ALPS unless the required features in Table 30.1 are fully met.

Of probands (the first subject enrolled in each kindred) in the NIH cohort who met the criteria for ALPS in Table 30.1, ~70 percent have either germline or somatic FAS defects (ALPS-FAS and ALPS-sFAS), as shown in Table 30.2. The remaining patients, however, had normal *FAS* gene sequences and were thus investigated for mutations in other components of lymphocyte apoptosis pathways, many of which are depicted in Figure 30.1. A single patient had a mutation in FASL, similar to the patient reported by Wu et al. (1996), and is now designated as having ALPS-FASL (Bi et al., 2001; Oliveira et al., 2010). No human cases to date have been published with absence of FADD, consistent with the finding that mice with targeted disruptions of this gene are nonviable.

Two heterozygous, dominant-interfering caspase 10 mutations have been found to cause ALPS-CASP10 in three families (Table 30.2; Wang et al., 1999; Zhu et al., 2006). The missense mutations are L285F, located in the proximal portion of the p17 protease domain, and I406L, very near the active site made up of conserved amino acids QACQG at

399–403. An additional mutation, V410I, was initially noted in homozygosity in a subject with recurrent fevers, noninfectious lymphocytic meningitis, optic neuritis, and no FAS defect (Wang et al., 1999). However, the patient's disease may have been in part caused by a subsequently identified TNF receptor-associated periodic fever mutation (see Chapter 33). Furthermore, the V410I variant of caspase 10 is now known to be a polymorphism in healthy populations, with an allele frequency of 6.8 percent in Danish, 3.4 percent in U.S. Caucasian, and 0.5 percent in African American unrelated individuals (Gronbaek et al., 2000; Zhu et al., 2006). Zhu et al. also confirmed that individuals with caspase 10 V410I, including homozygotes, are healthy and even found statistical evidence that caspase 10 V410I may have a protective effect against severe disease in subjects with *FAS* mutations that can cause ALPS-FAS. Zhu et al. further reported another caspase 10 population variant, Y446C, present in 1.6 percent of Caucasian alleles, for which no functional role has been demonstrated.

A single family has been found in which a son and daughter of a consanguineous marriage were homozygous for the caspase 8 mutation R248W, a nonconserved amino acid substitution in the proximal p18 protease subunit. Both children had features of ALPS, including adenopathy, mildly or intermittently increased DNTs, autoantibodies, and impaired lymphocyte apoptosis, while heterozygous relatives were unaffected. Moreover, unlike other ALPS cases, these children also manifested T- and B-cell immunodeficiency with growth retardation, recurrent sinopulmonary and herpes simplex virus infections, eczema, and poor responses to immunizations. The *CASP8* mutation they carried in homozygosity not only abrogated the cleavage activity of experimental protease substrates and failed to mediate apoptosis when transfected into epithelial cell lines; it also rendered the patients' lymphocytes refractory to activation in vitro (Chun et al., 2002). Further studies confirmed a requirement for full-length caspase 8 in the NF-κB activation phase of normal T-, B-, and NK-cell responses (Su et al., 2005). Thus caspase 8 has dual functions, in both apoptotic and cell activation pathways, and this is categorized as an ALPS-related disorder with specific designation of caspase 8 deficiency state (CEDS) (Oliveira et al., 2010).

ALPS-U patients are those who meet the two major criteria for ALPS as well as have one of the minor secondary criteria but do not have a defined genetic defect or a demonstrable in vitro FAS-mediated defect in cell death. It is possible that the majority of the patients described by Dianzani et al. (1997), who had ALPS with FAS pathway apoptosis defects but normal *FAS* gene sequences, also carry as-yet-unidentified mutations in other apoptosis pathway genes.

One patient within the NIH cohort who presented with findings suggestive of ALPS, but in whom the in vitro FAS-mediated cytotoxicity assay proved to be normal, was recently found to have a defect in cytokine (IL-2) withdrawal-mediated T-cell apoptosis. This finding was associated with decreased BCL-2 interacting mediator of apoptosis (BIM) levels and was ultimately identified as resulting from a somatic gain of function mutation in *NRAS* (Oliverira et al., 2007). Since this original description additional patients have been identified with similar findings including patients who had somatic gain of function mutations in *KRAS*, rather than *NRAS*, collectively these patients are now categorized as having RAS-associated autoimmune leukoproliferative disorder (RALD) (Oliveira et al., 2010, Niemela et al, 2011).

STRATEGIES FOR DIAGNOSIS

Unexplained splenomegaly and lymphadenopathy of early onset, particularly when accompanied by overt autoimmune disease and/or a positive family history, are the clinical features that lead to a suspicion of ALPS. More than 1.5 percent of α/β TCR $CD4^-$ $CD8^-$ T cells (among all lymphocytes, or 2.5 percent of T cells) are a defining characteristic of ALPS, but may not be counted correctly if only CD4, CD8, and CD3 are quantified, because several more common conditions are associated with increased γ/δ T cells lacking CD4 and CD8. Hypergammaglobulinemia, elevated numbers of B cells, and the presence of autoantibodies are further important clues and are more widely assayed. Since FAS membrane expression is absent only in rare patients with null mutations in both alleles, its assessment is of little help in diagnosis. Histological examination of enlarged lymph node biopsies yields a fairly characteristic appearance in ALPS, especially in cases associated with *FAS* mutations, and special stains revealing DNT cells can be diagnostic even in subjects who are not available to provide fresh blood samples (Lim et al., 1998). In vitro evaluation of lymphocyte apoptosis as triggered by agonistic FAS-specific antibodies can help establish the diagnosis.

Abnormal FAS-mediated apoptosis should lead first to investigation for causative mutations in the *FAS* gene transcript and sequence. Exon 9, the most frequently mutated portion of the gene, can be sequenced first, with subsequent attention to the remaining eight exons if no deleterious mutation is found. Special attention should be given to establishing the significance of missense mutations. SNPs in *FAS* have been delineated that are not associated with ALPS (Niemela et al., 2006). For previously unreported changes a panel of 100 chromosomes from 50 unrelated, healthy individuals helps to suggest that a missense mutation is not merely a polymorphism without functional consequences. However, functional assays of apoptosis should be combined with sequence abnormalities to prove the deleterious nature of any *FAS* mutation.

In a patient with clinical and immunological features of ALPS, a constitutional *FAS* mutation associated with defective FAS and impaired lymphocyte apoptosis would confirm the diagnosis of ALPS-FAS. Patients with FAS defects only in a sublineage of their hematopoietic cells, designated ALPS-sFAS, can be diagnosed on the basis of deleterious *FAS* mutations in isolated DNT cells (Dowdell et al., 2010; Holtzelova et al., 2004). If the sequence of both *FAS* alleles is normal, deleterious mutations in the genes encoding caspase 10 (ALPS-CASP10) can be sought, as well as FASL (ALPS-FASL) if apoptosis in response to anti-FAS stimulation is intact. Remaining patients without defined defects receive a diagnosis of ALPS-U.

It is not yet clear to what extent defects in FAS or other lymphocyte apoptosis mediators, particularly caspase 8, contribute to common variable immunodeficiency (CVID) (see Chapter 24) or autosomal hyper-IgM syndrome (see Chapter 21), both syndromes representing collections of defects with diverse genetic etiologies. Up to one third of CVID and autosomal hyper-IgM patients may experience chronic lymphadenopathy and/or splenomegaly, and autoimmune features are commonly present in both conditions. However, it is not common for CVID to be diagnosed as early in life as ALPS, and CVID frequently becomes more severe in the teen years to adulthood, when the findings of ALPS, if anything, tend to regress. Nonetheless, potential overlap between several features of ALPS and other primary immunodeficiency syndromes is an area for further investigation.

The differential diagnosis of ALPS versus malignancy and the apparent increased risk of lymphomas in ALPS remain major concerns for patients presenting with enlarged lymphoid organs or those who exhibit significant new lymph node enlargement. Biopsy of consistently large or rapidly growing nodes should reveal the characteristic histological features of ALPS (Plate 30.II), while in lymphoma a homogenous monoclonal cell population disrupts the normal architecture. Study of clonality of immunoglobulin or TCR gene rearrangements and cytogenetic investigation for chromosomal translocations must be done to identify true lymphomas in patients with a history of prolonged adenopathy.

FINDINGS IN RELATIVES OF ALPS PROBANDS

Studies of family members of ALPS-FAS (previously referred to as ALPS Ia) probands have been undertaken to find additional individuals who might carry the same mutations as ALPS probands (Bettinardi et al., 1997; Drappa et al., 1996; Fisher et al., 1995; Infante et al., 1998; Jackson et al., 1999; Rieux-Laucat et al., 1995, 1999; Sneller et al., 1997; Vaishnaw et al., 1999b). In some instances newly occurring *FAS* germline mutations have been found in probands whose healthy parents had normal *FAS* gene sequences (Sneller et al., 1997). In the rest of the families, whether the mode of inheritance was recessive or dominant, relatives with a mutated *FAS* allele have been identified. Some of these relatives proved completely free of symptoms and signs of ALPS, while others met the diagnostic criteria for ALPS (Table 30.1). Still other mutation-bearing relatives had some but not all of the features of ALPS, such as episodes of significant adenopathy or an enlarged spleen without autoimmune disease. For example, in the family of one ALPS patient followed by the NIH group, four relatives in addition to the patient were found to share the same mutation on one *FAS* allele. All had defective in vitro lymphocyte apoptosis. However, none of the relatives experienced any clinical manifestations of ALPS and none had autoantibodies or any other laboratory abnormalities except for one individual with minimally increased (1.7 percent) DNT cells.

In contrast, a large kindred was studied in which 12 individuals from four generations were followed for over 30 years with a variety of findings, including splenomegaly, adenopathy, and Coombs-positive anemia; affected subjects were recently proven to have a heterozygous mutation changing an aspartic acid to valine at position 244 (D244V) in the death domain of FAS (Fig. 30.4) (Infante et al., 1998). The diagnosis of ALPS was first confirmed in individual IV-5, who at age 2 was in general good health but had adenopathy and splenomegaly, Coombs-positive anemia, 2.1 percent DNT cells, and a plasma IgG of 2,355 mg/dL. All of the surviving mutation-bearing members of this kindred (black upper right quadrants of pedigree symbols) had impaired lymphocyte apoptosis. Furthermore, as shown, each of these individuals had features of ALPS in at least one category—lymphoproliferation, evidenced by splenomegaly and or adenopathy (lower right quadrant); 1.5 percent or more DNT cells (lower left quadrant); and autoimmunity, with either overt manifestations such as hemolytic anemia or ITP, or significant titers of autoantibodies (upper left quadrant). By late adolescence or

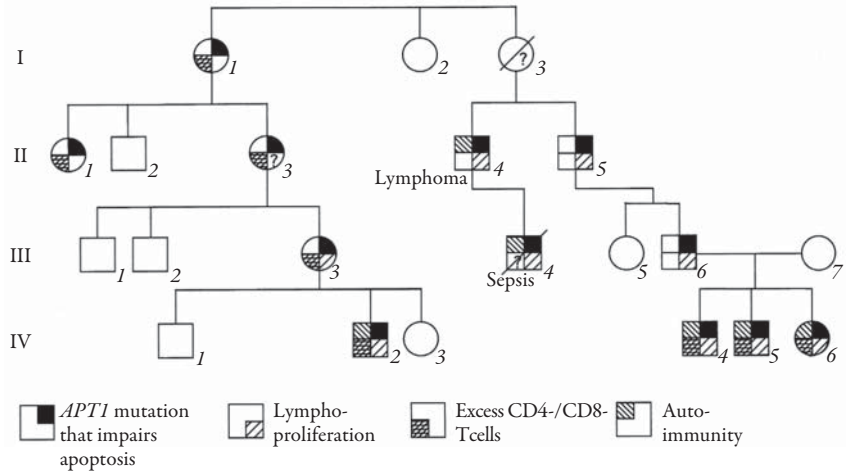

Figure 30.4 Dominant inheritance of *FAS* mutation and features of ALPS in a large kindred (adapted from Infante et al., 1998). Squares, males; circles, females; slash, deceased; ?, could not be ascertained.

adulthood, lymphoproliferation and autoimmune manifestations tended to abate, and the only premature death in the family was due to postsplenectomy sepsis at age 9 in individual III-4. However, the occurrence of NHL in individual II-4 at age 50, his development of ITP at age 23, and hemolytic anemia at age 54 demonstrate the lifelong risk of malignancy and the unpredictable course in this and many other families with FAS defects. Since this kindred was reported, Hodgkin's lymphoma was diagnosed in individual IV-4 at age 7 years.

Only limited family studies have been conducted in ALPS-CASP10, which, however, seems to have variable penetrance and severity similar to ALPS-FAS (Zhu et al., 2006). Prenatal diagnosis has not been published either by mutational analysis of *FAS* or by assessment of lymphocyte surface markers in fetal blood. The prenatal hydramnios of the severely affected recessive case reported by Le Deist et al. (1996) indicates that, at least in this patient, lymphoproliferation was ongoing before birth.

PROGNOSIS AND TREATMENT

Growing experience with ALPS indicates that patients can achieve a normal lifespan. Patient histories suggest that adenopathy may diminish with age; but while the most severe autoimmune disease appears to occur in early childhood, as indicated above, episodes can recur or in fact arise unpredictably at any age. In older individuals now recognized to have a longstanding history of ALPS, splenectomy was common, but recognition of the risks of infection in asplenic subjects has made this a treatment of last resort in current practice. Nonetheless, splenectomy has been performed in many of our patients with ALPS in order to manage their severe hypersplenism, severe hemolysis, or refractory thrombocytopenia. Splenectomy has also been performed following splenic rupture and in some cases when lymphoma was suspected. Fatal postsplenectomy sepsis has been documented in multiple patients despite prior administration of polysaccharide vaccines and prescription of prophylactic antibiotics. The current recommendation is to avoid splenectomy in ALPS patients if at all possible based on the observation that of 87 splenectomized patients followed at NIH, 5 have died. Two children had fatal sepsis due to *Streptococcus pneumoniae*, while three other patients developed opportunistic infections associated with multidrug immunosuppressive therapy for aggressive, infiltrative polyclonal lymphoproliferation (Rao et al., 2005).

Based on studies suggesting efficacy in *lpr* mice with an ALPS-like phenotype (Mountz et al., 1987), one patient received sequential therapeutic trials of prednisone, interferon-α, IL-2, and cyclosporine-A for treatment of her disease (Sneller et al., 1997). Therapy with high-dose prednisone resulted in a transient decrease of lymphadenopathy, but the lymph nodes returned to their original size following reduction of the dose. None of the other treatments resulted in a change in the degree of lymphadenopathy or clinical status. Many patients with ALPS suffer severe episodes of autoimmune hemolytic anemia, thrombocytopenia, and neutropenia requiring immunosuppressive therapy even after splenectomy. Most episodes of ITP and some hemolytic crises respond to short courses of high-dose steroids, such as 1 mg/kg of prednisone daily. In these patients lymph node size transiently decreases to some degree during treatment but increases in size after therapy. In several patients, multiple courses of high-dose steroid pulses, or prolonged daily steroid plus intravenous immunoglobulin therapy, have been used in an attempt to control the autoimmune disease. Attempts to treat patients with refractory autoimmunity using vincristine, azathioprine, methotrexate, and cyclophosphamide have not resulted in any clear indication that these agents are effective. Additional efforts to avoid the complications of chronic steroids and immunosuppressive regimens in children with ALPS have led to investigation of alternative agents.

The antimalarial drug combination of pyrimethamine and sulfadoxine (Fansidar) was reported to be effective in a preliminary study of seven ALPS patients, two with ALPS-FAS and five with ALPS-U (van der Werff Ten Bosch et al., 2002). However, experience with pyrimethamine (a component of Fansidar) in a study involving NIH patients did not substantiate the effectiveness of this agent in managing ALPS-related autoimmunity (Rao et al., 2007).

Mycophenolate mofetil (MMF) was evaluated in a group of NIH patients as a potential steroid-sparing immunosuppressive agent. MMF is a prodrug of mycophenolic acid, which inhibits a key enzyme in the purine synthetic pathway, an especially active pathway in T and B lymphocytes. MMF, previously shown to be effective in immune-mediated cytopenias (Hou et al., 2003; Howard et al., 2002), was used to treat autoimmune cytopenias in 13 ALPS patients who were steroid-dependent (Rao et al., 2005). Twelve of 13 responded, making possible reduction or termination of steroid treatment and in some cases avoidance of splenectomy, and a second report of successful MMF therapy confirmed its utility (Kossiva et al., 2006).

More recently rituximab was used in 12 ALPS patients with autoantibodies to red cells and/or platelets associated with refractory cytopenias. Seven of nine adult patients responded, but none of the three children who were treated showed improvement with this regimen (Rao et al., 2009). Finally, based on the effectiveness of rapamycin therapy in the murine model of ALPS (Teachey et al., 2006), four ALPS patients were treated with rapamycin, and in three of four patients there was resolution of the autoimmune cytopenias as well as decreased lymphadenopathy and DNT cells (Teachy at al., 2009). These encouraging results await additional experience to confirm the utility of rapamycin therapy in ALPS.

Most ALPS patients can be weaned from treatment after an acute episode of an autoimmune cytopenia, and the rate of recurrence and severity of autoimmune attacks may diminish as patients enter adolescence. Adults with ALPS may cease to experience autoimmune complications, but conversely, new onset of ITP has occurred in adulthood (Drappa et al., 1996; Infante et al., 1998).

In a patient with complete FAS deficiency, ALPS manifestations were so severe that several courses of antithymocyte globulin and then chemotherapy were given to reduce the lymphocyte burden (Le Deist et al., 1996). This treatment

proved to be only transiently beneficial, so ultimately a T-cell–depleted, parental haploidentical bone marrow transplantation (BMT) was undertaken. A first attempt of BMT led to early rejection. However, a second transplant using T-cell–depleted marrow from the second HLA haploidentical parent was successful. There was no recurrence of lymphoproliferation or of autoimmunity, although $CD4^-$ $CD8^-$ T cells were detected in the child's blood for over 2 years. This child was well 3 years after the second BMT attempt (Benkerrou et al., 1997). Clearly, the role of BMT is not well defined in ALPS, and this treatment should be considered only for the rare patient in whom life-threatening complications prove refractory to more conservative measures.

ANIMAL MODELS

The MRL *lpr* mouse pointed the way to the discovery of FAS defects in humans. This spontaneous mouse mutant strain has increased autoimmunity compared to the MRL parent strain; it was discovered to have high numbers of $CD4^-$ $CD8^-$ lymphocytes and defective apoptosis and was subsequently demonstrated to be Fas-deficient (Nagata and Goldstein, 1995; Watanabe-Fukunaga et al., 1992). Originally described as having a lupus phenotype, the MRL *lpr* mouse actually lacks some of the more typical features of human lupus such as anti-DNA antibodies and frequent arthritis. However, these mice regularly develop antinuclear antibodies, hypergammaglobulinemia, adenopathy, and nephritis. Additional spontaneous mutant mouse strains with similar phenotype are *gld*, found to have recessive defect of Fas ligand, and lpr^{cg}, a strain with a death domain point mutation causing a change in a conserved amino acid of Fas. Transgenic mice expressing dominant negative mutations in Fas corresponding to the mutations found in humans with ALPS had apoptosis defects and developed hepatosplenomegaly and lymphocytic liver infiltration (Choi et al., 1999).

Like the human, the phenotype in mice with *lpr* mutation is highly strain-dependent. For example, C57BL6 mice with the *lpr* mutation have much less severe disease than MRL*lpr* mice. Furthermore, the MRL strain is autoimmune-prone even without defective apoptosis conferred by the *lpr* Fas defect, in part due to a hypoactive variant of IL-2 (Choi et al., 2002). Both class I and class II major histocompatibility complex (MHC) determinants are important in development of autoimmunity in Fas-deficient mice (Christianson et al., 1996; Creech et al., 1996).

The range of autoimmune findings in *lpr*, *gld*, and lpr^{cg} mice is not identical to that seen in humans with ALPS; for example, nephritis is uncommon in patients, although isolated cases have been seen. While FASL defects are not a frequent cause of human ALPS, an adult male with atypical lupus and adenopathy was reported to have a dominant heterozygous *FASL* mutation (Wu et al.; 1996), an ALPS patient in the NIH series had a FASL defect (Bi et al., 2001) and recently an additional ALPS patient was described with a homozygous null FASL mutation (Magerus-Chatinet et al., 2013).

Although the mouse is an excellent model system in which to evaluate relationships between Fas apoptosis and other modulators of immune responses, differences between species need to be recognized. For example, the mouse lacks caspase 10, which in the human genome is located adjacent to caspase 8 and probably arose by gene duplication. Thus the relative roles of these caspases in the Fas apoptosis pathway cannot readily be dissected in mice. Mice with targeted disruptions of caspase 8 have cardiac and hematopoietic defects and do not survive (Varfolomeev et al., 1998), while humans lacking caspase 8 activity have features of both ALPS and combined immunodeficiency.

FUTURE DIRECTIONS AND CHALLENGES

MOLECULAR EVENTS CONTROLLING APOPTOSIS

The importance of programmed cell death in diverse physiological processes involving dividing cells is widely recognized. We now understand that apoptosis is critical for maintenance of immune-cell homeostasis, both by terminating an appropriate immune response and by preventing runaway responses by mature lymphocytes with cross-reactivity to self-antigens. However, all of the molecular events that deliver an apoptotic signal, the process of cell death itself, and the regulation of every step of the process are not yet fully understood (Chinnaiyan and Dixit, 1997; Nagata, 1997). Added insights into these processes have been garnered with extensive studies driven by the availability of cells with FAS defects and of increasingly sophisticated in vitro technologies. For example, the redistribution of FAS into lipid rafts at the cell surface has been highlighted as an important mechanism for making lymphocytes more sensitive to apoptosis (Muppidi and Siegel, 2004). The transmembrane molecules TNFR-1 and FAS interact with their ligands as trimers and share intracellular death domain regions. Both the TNFR-1 pathway and the FAS pathway are expressed in mature lymphocytes (Zheng et al., 1995). The TNFR-1 pathway involves some genes with restricted specificity, such as TNFR-1 itself, TRADD, and TRAF-2, but some of the other death domain interacting genes and perhaps certain caspases and final nuclear effectors of apoptosis may be shared with the FAS pathway. An additional apoptosis pathway through a distinct receptor DR3 (death receptor 3) has been identified in lymphocytes, and additional receptors DR4 and DR5 have been isolated (Chinnaiyan et al., 1996). Other intracellular signal transducers are also involved. The pivotal molecule NF-κB can be activated and appears to have an antiapoptotic effect by upregulating cellular survival factors, but its relationship with caspase 8 in cell activation is also essential. It is not entirely clear how mitochondrial apoptosis pathways interact with pathways of apoptosis involving TNFR family members, and defects in these pathways underlie some cases of ALPS-U as well as other clinical syndromes involving inflammation, lymphoproliferation, and immune dysregulation.

MODIFIERS OF THE ALPS PHENOTYPE

Even among ALPS patients with a well-defined FAS defect, the clinical phenotype can be highly variable, as appreciated early in the course of work in the field, suggesting that additional genetic and/or environmental factors must be required to interact with FAS defects to produce overt lymphoproliferation and autoimmunity. These putative ALPS-modifying factors might include other members of the FAS apoptosis pathway or related pathways, many of which are continuing to be identified. An existing model for severe disease produced by complementation between two apoptosis pathway mutations is the mouse doubly heterozygous for *gld* and *lpr*^{cg} defects of FasL and Fas, respectively. Identification of critical intracellular signaling mediators in the caspase protease cascade provides additional candidate genes for modifiers of the ALPS phenotype. Moreover, a large number of gene products regulating lymphocyte signaling networks have been implicated in lymphoproliferation and autoimmunity in mice; many of these could be exacerbated by further impairment of apoptosis and therefore may also be candidates for second mutations in ALPS.

The MHC locus is a major modifier of risk for many autoimmune conditions, and preliminary studies indicate that HLA B44 may be protective against severe disease in individuals with ALPS-FAS (Vacek et al., 2006). The caspase 10 variant V410I appears to be protective (Zhu et al., 2006). In contrast to many autoimmune diseases, ALPS appears to affect males equally or even to a greater degree than females. Identifying and understanding the mechanisms whereby these and other factors modify risk promises to clarify the genetic etiologies of further autoimmune syndromes, and perhaps to provide new therapeutic approaches for autoimmune disorders.

ACKNOWLEDGMENTS

The authors thank members of ALPS research teams at NIH: Michael Lenardo, V. Koneti Rao, Joie Davis, Joao Bosco Oliveira, Julie Niemela, Hyesun Kuehn, Susan Price, Amy Hsu, Elaine Jaffe, and the late Stephen Straus; and at INSERM and Hôpital Necker: Alain Fischer, J. P. de Villartay, J. F. Emiel, and N. Brousse. They also thank the families and their referring physicians who have participated in our studies. 31.

AUTOIMMUNE POLYGLANDULAR SYNDROME TYPE 1

Maureen A. Su and Mark S. Anderson

Autoimmune diseases arise from a breakdown in immune tolerance to self, and there are numerous genes and pathways that play a role in autoimmune susceptibility (Rioux and Abbas, 2005). Most autoimmune diseases arise from a complex interplay between environmental and genetic factors, but recent work on monogenic forms of autoimmunity has been particularly enlightening in expanding our understanding of how these diseases arise (Sakaguchi et al., 2008; Su and Anderson, 2009). Among these monogenic disorders is autoimmune polyglandular syndrome type 1 (APS1) or autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED), which is manifested by a pattern of autoimmunity that usually involves multiple organs. In this review, we will highlight key aspects of the clinical features and update the latest in our understanding of the underlying pathogenesis of this syndrome.

CLINICAL MANIFESTATIONS

APS1 is a rare autosomal recessive disorder that was originally described in a case report by Thorpe and Handley in 1929 (Thorpe and Handley, 1929); later on, the strong familial inheritance of the syndrome was recognized (Whitaker et al., 1956). The disorder has been found in many different populations and genetic backgrounds, but there are isolated areas/populations where the disease is more frequently observed, particularly in Finland, Sardinia, and Iranian Jews, with prevalence estimates of 1/25,000, 1/9,000, and 1/14,000 respectively (Ahonen et al., 1990, Rosatelli et al., 1998, Zlotogora and Shapiro, 1992). The clinical manifestations of APS1 are somewhat variable even within families, but prominent features include the triad of hypoparathyroidism, Addison's disease, and susceptibility to mucocutaneous candidiasis (Plate 31.I, 31.II). The presence of two of these three features, in fact, is considered by many to be diagnostic of the disorder (Perheentupa, 2006). However, there are also affected patients who do not manifest two of these features (Buzi et al., 2003). In addition to these major features, a wide number of autoimmune diseases have been described in APS1 patients, including autoimmune hepatitis, vitiligo Plate 31.III, alopecia Plate 31.III, premature gonadal failure, hypothyroidism, type 1 diabetes, autoimmune gastritis, uveitis Plate 31.IV, Sjögren syndrome, and autoimmune hepatitis (Betterle et al., 1998, Perheentupa, 2002, Ahonen, 1985). In addition to these autoimmune features, patients also develop other clinical findings that may or may not be autoimmune sequelae, including dental enamel hypoplasia Plate 31.IV, tympanic membrane calcification, pitted nail dystrophy (Plate 31.I Plate 31.IV) and intestinal malabsorption. We have summarized many of the clinical disorders described in these patients in Table 31.1 and organized them by their overall penetrance in relation to descriptions in the literature. Generally, it appears that many of the manifestations of the syndrome involve an organ-specific autoimmune attack rather than systemic autoimmunity, as descriptions of systemic lupus erythematosus and rheumatoid arthritis in these patients are exceedingly rare. There is also a relative pattern to the timing of when the disease features arise in these patients, with onset of one of the defining features often in early childhood; however, some patients do not manifest until early adulthood (Betterle et al., 1998; Perheentupa, 2006). Typically, candidal infection is the first manifestation, followed by hypoparathyroidism, and then Addison's disease, but again there can be wide variation in the timing and order. Given the wide variety of potential features associated with this syndrome, the clinical care and workup of these patients is complex and laborious. Perheentupa et al. have some of the most extensive experience in the expert care of these patients and have written a number of excellent reviews with extensive detail on the phenotypes, markers, and clinical care issues

Table 31.1 CLINICAL MANIFESTATIONS OF APS1

PENETRANCE		
HIGH	INTERMEDIATE	RARE BUT DESCRIBED
Candidiasis	Uveitis	Asplenia
Hypoparathyroidism	Ovarian failure	Pituitary insufficiency
Addison's disease	Type 1 diabetes	Hyperthyroidism
	Hypothyroidism	Autoimmune hemolytic anemia
	Alopecia	Sjögren syndrome
	Vitiligo	Nephritis
	Pernicious anemia/gastritis	Retinal degeneration
	Autoimmune hepatitis	Lymphocytic myocarditis
	Diarrhea/malabsorption	Interstitial lung disease
	Enamel hypoplasia	Autoimmune peripheral neuropathy
	Tympanic membrane calcification	

Although a number of extensive features are listed, it is by no means a complete listing for all APS1 features.

REFERENCES: Alimohammadi et al., 2009; Betterle et al., 1998; Perheentupa, 2002, 2006; Valenzise et al., 2009.

(Perheentupa, 2002, 2006). Here we highlight a few details of the major features of the disorder.

Susceptibility to candidiasis is one of the most prominent features of the disease, and it most often presents with oral/pharyngeal infection in these subjects (Perheentupa, 2002). Candidal infection involving the gastrointestinal tract, including perianal involvement, has been described. Postpubertal candidal vulvovaginitis is also quite common. Some subjects can also demonstrate infection of the digits of both the hands and feet. Despite this remarkable susceptibility pattern to *Candida*, it is important to note that these patients do not generally demonstrate susceptibility to systemic candidal infections. Treatment of candidal involvement typically involves courses of oral or topical antifungal agents, and patients usually show a response to this approach. Occasionally patients may require systemic antifungal treatment with persistent infections. No clear diagnostic testing is currently available to determine the cause of this susceptibility or to identify subjects with increased susceptibility, but there are descriptions of anergic skin testing to candidal antigens in APS1 subjects (Chilgren et al., 1967; Tomar et al., 1979). Finally, it is important to note that it is likely that the chronic oral involvement by *Candida* is likely carcinogenic, as an association with epithelial carcinoma of the oral mucosa has been noted (Perheentupa, 2006).

Hypoparathyroidism is also a common feature observed in APS1. Typically patients present with a vague clinical course that may include episodes of tetany or even grand mal seizures. Serum testing usually reveals a low serum calcium level and hyperphosphatemia in the setting of a low or inappropriately normal parathyroid hormone level. Treatment is calcium replacement along with vitamin D supplements. Care must be taken not to allow the serum calcium level to become too high, as this can often precipitate nephrolithiasis due to poor calcium reabsorption from the lack of parathyroid hormone. Although there have been reports of autoantibodies to the calcium-sensing receptor as a marker of this disease phenotype, data have been conflicting (Alimohammadi et al., 2008; Gavalas et al., 2007; Soderbergh et al., 2004). There has been recent identification of a novel autoantigen, NALP5, that may be a marker of this disorder (see discussion below) (Alimohammadi et al., 2008).

Addison's disease or autoimmune adrenal failure is a common feature in these subjects that also has an occult clinical course. Patients can present with malaise, fatigue, salt wasting, and hypotension as the disease progresses. Diagnosis is usually made by clinical suspicion and failure to secrete increased cortisol after stimulation with ACTH (Cortrosyn). In addition, autoantibodies to 21-hydroxylase (CYP450c21), an established marker of autoimmune adrenal failure, are usually present in these patients. This marker also appears before patients progress to adrenal insufficiency and is likely to be predictive for progression to adrenal failure within months to several years (Perheentupa, 2002). Affected patients are usually treated with cortisol and mineralocorticoid replacement, with instructions for stress dosing of cortisol during times of infection and additional stress.

Although less prevalent, APS1 patients develop a number of other endocrine deficiencies, particularly type 1 diabetes, hypothyroidism, and premature ovarian failure. The incidence of type 1 diabetes in APS1 cohorts is variable but reported to be as high as 18 percent, supporting that these patients have an increased susceptibility (Perheentupa, 2002). Interestingly, it appears that a much larger number of APS1 patients harbor autoantibodies to the type 1 diabetes autoantigen glutamic acid decarboxylase (GAD) than in isolated type 1 diabetes. Hypothyroidism is moderately apparent in these patients and is also associated with the typical marker autoantibodies to thyroid peroxidase and thyroglobulin. Finally, it is worth noting that many female patients develop premature ovarian failure, which is usually associated with low estrogen levels in the setting of high gonadotropin levels.

One potential manifestation of the disorder that requires particular attention is autoimmune hepatitis. This is because it is one of the few features of the disease that is treated with systemic immunosuppression with good clinical efficacy, and if

left untreated subjects can progress to fulminant liver failure. Abnormal liver function test results should raise suspicion, and the diagnosis is usually confirmed by needle biopsy of the liver. Patients do manifest autoantibodies seen in a subset of autoimmune hepatitis patients, particularly antibodies to liver microsomal antigen (Obermayer-Straub et al., 2001).

Overall, as mentioned above, the care of these patients is complex and involves rigorous surveillance for many of the potential features of the disease. Typically, treatment involves hormone replacement for endocrine deficiencies and immunosuppression if autoimmune hepatitis develops. Long-term data on these patients suggest that they do have increased mortality even under expert care, and there is likely a significant risk for depression and suicide beyond the autoimmune manifestations of the disorder.

GENETICS OF APS1 AND THE AIRE PROTEIN

APS1 is rare among autoimmune diseases in that it appeared to be inherited in a monogenic, autosomal recessive fashion. In 1997, using large family collections, two groups independently identified the *A*uto*i*mmune *Re*gulator (Aire) as the defective gene responsible for APS1 (Finnish-German APECED Consortium, 1997; Nagamine et al., 1997). This gene encodes a 545 amino acid, 58 kDa protein and is located on chromosome 21q22.3. Aire was an intriguing candidate in that its expression pattern predominantly in the thymus (and to a lesser extent in the lymph node and spleen) was highly suggestive of a role in immune function.

Additionally, a number of features suggest a role for Aire as a transcription factor. First, endogenous Aire protein is located in the nucleus in mouse thymi (Liston et al., 2004). The Aire protein contains a nuclear localization signal (NLS) that is sufficient to target the Aire protein to the nucleus (Pitkanen et al., 2001), and the recently described caspase-recruitment domain (CARD) also appears to have a role in a nuclear localization (Ferguson et al., 2008; Fig. 31.1).

Second, Aire contains a number of domains that suggest a role in transcriptional regulation (Fig. 31.1), including two plant homeodomains (PHDs) domains and a SAND (Sp100, Aire-1, Nucp41/75, and DEAF-1) domain. The PHDs have been described in a large number of transcription factors and have recently been implicated in the binding of nucleosomal histones. For example, the PHD in the bromodomain PHD finger transcription factor (BPTF) and inhibitor of growth family, member 2 (ING2) proteins has been shown to bind to histone H3 trimethylated at lysine 4 (H3K4me3) (Li et al., 2006; Shi et al., 2006). As discussed later, the PHD domain of Aire itself binds to histone H3 unmethylated at lysine 4 (H3K4me0) (Koh et al., 2008, Org et al., 2008).

In the Sp100b and glucocorticoid modulatory element binding protein 1 (GMEB) proteins, the SAND domain binds directly to DNA via the KDWK motif (Bottomley et al., 2001; Surdo et al., 2003). The Aire SAND domain, however, does not contain this KDWK motif, suggesting that the SAND domain of Aire may have a different function. Although there have been a small number of reports of Aire's direct binding to DNA (Kumar et al., 2001; Purohit et al., 2005; Ruan et al., 2007), these findings have not been widely replicated. Thus, the role of the SAND domain of Aire remains to be further studied.

Intriguingly, a point mutation in the Aire SAND domain that changes glycine 228 (in humans) to a tryptophan has been shown in both humans and mice to result in an autosomal dominant form of autoimmunity (Cetani et al., 2001; Su, 2008). This autoimmunity is phenotypically distinct from that seen with homozygous null mutations in Aire, resulting in largely autoimmune thyroiditis in humans. This mutation appears to act in a dominant negative fashion, preventing transcriptional transactivation by wild-type Aire in in vitro assays. These findings raise the possibility that some autoimmune diseases that do not appear to be APS1 may result from Aire mutations.

PATHOPHYSIOLOGY

Much of the pathophysiology of APS1 has been worked out in mouse models of this disease. In recent years, several different lines of Aire knockout mice have been independently generated (Anderson et al., 2002; Hubert et al., 2009; Kuroda et al., 2005; Ramsey et al., 2002). Like humans with homozygous

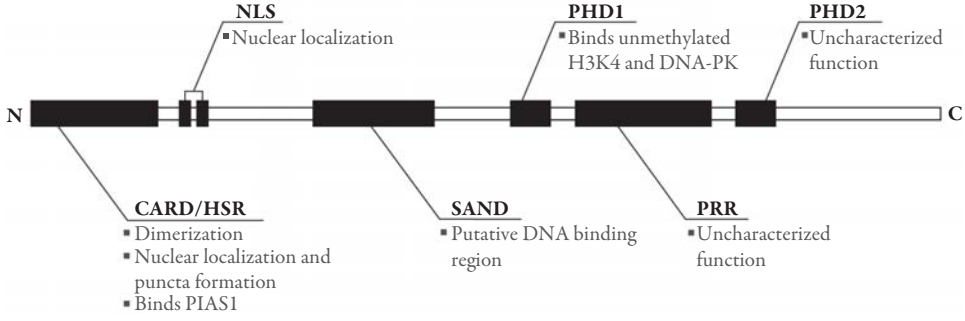

Figure 31.1 *Schematic of the Aire protein and its domains.* Black text indicates domain name, with gray text underneath highlighting known or potential function roles. NLS, nuclear localization signal; PRR, proline-rich region; HSR, homogeneous staining region; CARD, caspase-recruitment domain; SAND, Sp100, Aire-1, Nucp41/75, and DEAF-1; PHD, plant homeodomain.

mutations in Aire, these knockout mice develop spontaneous, organ-specific autoimmunity.

A clue into how Aire works came from its predominant expression pattern in the thymus. In particular, Aire appeared to be expressed in a subset of stromal cells in the thymus termed medullary thymic epithelial cells (mTECs) (Halonen et al., 2001; Heino et al., 1999; Zuklys et al., 2000). mTECs have been described to play a major role in the negative selection of self-reactive T cells in the thymus (reviewed in Kyewski and Klein, 2006). mTECs have the extraordinary property of expressing a number of tissue-specific antigens, including insulin and thyroglobulin (Smith et al., 1997). These antigens classically have been thought to be expressed only in an organ-specific manner (i.e., insulin in the pancreas and thyroglobulin in the thyroid). The "promiscuous" expression of these antigens in mTECs has been proposed to allow developing T cells in the thymus to sample self-antigens and allow self-reactive T cells to be eliminated.

Because Aire appeared to be a transcription factor, its expression pattern in mTECs led to the hypothesis that Aire was important in upregulating the expression of tissue-specific antigens in mTECs (Fig. 31.2A). Thus, loss of Aire would result in decreased expression of these antigens in mTECs and allow self-reactive T cells to escape negative selection in the thymus and potentially cause autoimmune disease (Fig. 31.2B). This hypothesis was validated in the Aire knockout mouse system, where isolated mTECs from these mice showed decreased expression of a number of tissue-specific antigens, including insulin (Anderson et al., 2002). Consistent with this hypothesis, loss of expression of a single eye-specific antigen in mTECs has been shown to result in autoimmune uveitis in mice (Devoss et al., 2006). Additionally, using transgenic mouse lines that allow the tracking of antigen-specific T cells, Aire-deficient mice appear to have a failure in negative selection of developing thymocytes that react against self-antigens (Anderson et al., 2005; Liston et al., 2003).

Interestingly, Aire is also expressed in secondary lymphoid organs, including bone marrow and spleen (Gardner et al., 2008). Like mTECS, these extrathymic Aire-expressing cells (eTACs) also express a number of tissue-specific antigens. The overlap of these antigens with those expressed by mTECs is surprisingly small, suggesting that these cells may play a nonredundant function in maintaining self-tolerance. For example, desmoglein, the antigen important in pemphigus foliaceus, is expressed in eTACS but not in mTECs. However, the physiological role of these cells in preventing autoimmunity remains to be tested.

How Aire is seemingly able to upregulate the expression of a large array of genes has been the subject of much interest. It has been proposed that Aire-regulated genes appear to be physically clustered on chromosomes (Derbinski et al., 2005; Johnnidis et al., 2005), which may perhaps facilitate their regulation as a group by Aire. These clusters of Aire-regulated genes, however, are often interspersed with Aire-independent genes, suggesting a more complex mechanism by which Aire is acting.

On a subcellular level, Aire is closely associated with nuclear speckles (Su et al., 2008). These nuclear speckles contain

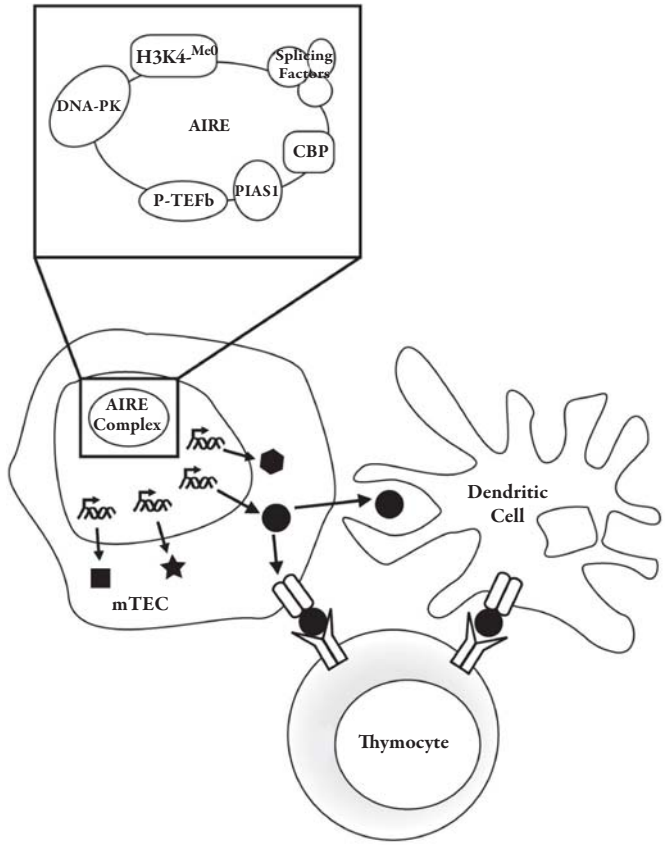

Figure 31.2 *Functional activity of Aire in thymic medullary epithelial cells (mTECs).* Aire likely works in a complex with an array of other nuclear proteins (including DNA-PK, P-TEFb, PIAS1, CBP, and other splicing factors) to drive the expression of a wide array of tissue-specific antigens (indicated by circle and star) within mTECs. These tissue-specific antigens can be processed and displayed in a MHC/self-antigen complex on the surface of mTECs or alternatively passed on to nearby dendritic cells for MHC/self-antigen complex formation. This MHC/self-antigen complex is then displayed to developing thymocytes to negatively select out those that are autoreactive. DNA-PK, DNA protein kinase; P-TEFb, positive transcription elongation factor b; PIAS1, protein inhibitor of activated STAT 1; CBP, CREB binding protein.

proteins important in transcription, including small nuclear ribonuclear proteins (snRPs), RNA polymerases, and splicing factors (Lamond and Spector, 2003). Additionally, Aire contains two PHD domains, which have been shown in other proteins to interact with chromatin (reviewed in Peterson et al., 2008). These zinc-finger–containing domains specifically seem to interact with histone H3, a core nucleosome protein that is subject to epigenetic modifications with methyl groups. Aire appears to bind to demethylated histone H3 (H3K4me0) via the PHD1 domain (Koh et al., 2008; Org et al., 2008).

In addition to demethylated histone H3, a number of other binding partners for Aire have also been described. These binding partners include positive transcription elongation factor b (pTEFb) (Oven et al., 2007), CREB binding protein (CBP) (Pitkanen et al., 2000), protein inhibitor of activated STAT 1 (PIAS1) (Ilmarinen et al., 2008), and DNA-dependent protein kinase (DNA-PK) (Liiv et al., 2008; Fig. 31.2). The mechanism by which Aire acts as a transcriptional regulator is the subject of much investigation at this point, and much

of how these binding partners may participate in Aire function remains to be determined. Nevertheless, all of these binding partners have potential roles in transcription (reviewed in Peterson et al., 2008). The pTEFb complex phosphorylates RNA polymerase II, allowing for the polymerase to convert to the elongating form and for transcription to proceed. CBP is a cofactor for a number of different transcription factors and is involved in transcription regulation. PIAS1 and DNA-PK bind to DNA sequences in the nuclear matrix, which may be an important site for chromatin assembly.

The tissues targeted in Aire-deficient mice appear to be dependent on mouse strain, pointing to a role for modifier genes in determining the disease phenotype (Jiang et al., 2005; Niki et al., 2006). Modifier genes also appear to play an important role in determining disease phenotype in humans, since the major histocompatibility complex (MHC) locus appears to have an effect on expression of disease (Gylling et al., 2000; Halonen et al., 2002). While some of the MHC associations overlap with those seen with the isolated autoimmune disease, others do not. For example, the risk alleles that confer susceptibility to type 1 diabetes do not appear to increase the likelihood of type 1 diabetes in APS1 patients.

In addition to upregulating transcription of a variety of tissue-specific antigens, Aire has also been proposed to have additional roles. These roles include regulating antigen presentation on the cell surface of mTECS (Anderson et al., 2005), regulating B-cell responses (Lindh et al., 2008), and in the differentiation of mTECs (Gillard et al., 2007). These roles for Aire remain to be further defined.

RECENT ADVANCES IN THE EVALUATION OF APS1

As discussed above, the classic triad of APS1 consists of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis. Mucocutaneous candidiasis is a highly penetrant finding, with all adult patients in a cohort of 91 Finnish patients having manifested this disease (Perheentupa, 2006). Hypoparathyroidism and adrenal failure were also quite penetrant, with 88 percent and 84 percent of APS1 patients affected, respectively. In addition, a number of other endocrine and nonendocrine manifestations are present at variable frequency. It is important to note that in this cohort as well as others, there was great variability in the disease presentation of APS1 even among siblings.

In patients suspected of having APS1 by clinical findings, a number of laboratory evaluations can be useful adjuncts. First, DNA sequencing of the Aire locus can confirm the diagnosis. The most common mutations described are the R257X mutation and a 13 base pair deletion in exon 8. Importantly, however, approximately 60 mutations have been described throughout the Aire gene (Peterson et al., 2008). Thus, if the most common mutations are not found in a patient suspected of having APS1, sequencing of the entire gene may be necessary.

Second, autoantibody testing may be useful in helping to determine organs affected or at risk for being affected. Much effort has recently been focused on identifying the particular antigens important in autoimmune pathogenesis in APS1. Recently, autoantibodies against the NALP5 {NACHT [*NA*IP (neuronal apoptosis inhibitory protein), *C*IITA (MHC class II transcription activator), *H*ET-E (incompatibility locus protein from *Podospora anserina*), and *T*P1 (telomerase-associated protein)] leucine-rich-repeat and pyrin protein 5} antigen have been identified as a potential clinically useful marker for identifying APS1 patients with autoimmune hypoparathyroidism (Alimohammadi et al., 2008). NALP5 autoantibodies appear to be specific for APS1 patients with hypoparathyroidism, since none of the patients with isolated hypoparathyroidism appeared to have these autoantibodies. Interestingly, autoantibodies against calcium-sensing receptor were negative in all APS1 patients with hypoparathyroidism in this study.

Additional headway toward antigen identification has been made in Aire-deficient mice. As noted earlier, the expression of the IRBP (interphotoreceptor retinoid-binding protein) eye antigen in the thymus was shown to be sufficient in preventing eye-specific autoimmunity (Devoss et al., 2006). These mice develop autoantibodies against IRBP, suggesting that these autoantibodies may be a useful marker of uveitis in patients. These studies in APS1 patients with uveitis remain to be performed. Additional antigens identified in Aire-deficient mice include SVS2 (seminal vesicle secretory protein 2) in autoimmune prostatitis (Hou et al., 2009) and mucin in autoimmune gastritis (Gavanescu et al., 2007).

Third, antibodies directed against type 1 interferons have been shown to associate strongly with having mutations in Aire. In five separate studies, almost all patients with Aire mutations appear to have type 1 interferon autoantibodies (Meager et al., 2006; Meloni et al., 2008; Wolff et al., 2007; Zhang et al., 2007). Although the pathogenesis and consequences of these antibodies are not clear, testing for these antibodies may be a useful tool in diagnosing APS1. These antibodies may, for example, help to diagnose a suspected patient for whom one or both Aire mutations are not found. It must be noted, however, that these antibodies are not specific only to APS1, and patients with diseases like myasthenia gravis with thymoma may also have type 1 interferon autoantibodies (Meager et al., 2003).

TREATMENT FOR APS1

At this point in time, treatment for APS1 is largely supportive for the endocrine dysfunction seen in APS1. This includes hormone replacement for endocrinopathies, including adrenal failure, type 1 diabetes, hypothyroidism, and growth hormone deficiency; and vitamin D, calcium, and potentially magnesium supplementation for hypoparathyroidism. Dr. Perheentupa has noted in his extensive clinical experience in Finland that treatments for hypoparathyroidism, adrenal failure, and diabetes mellitus can interact with each other, complicating the management of APS1 patients (Perheentupa, 2006). Immunosuppression has been used to treat the nonendocrine manifestations of APS1, including autoimmune hepatitis.

Importantly, the mucocutaneous candidiasis seen in APS1 is a significant cause of morbidity and mortality and should

be treated aggressively. In a cohort of 91 Finnish patients, mucocutaneous candidiasis resulted in a number of complications, including esophageal strictures, candidal abscesses, and squamous cell carcinoma of the mouth and esophagus (Perheentupa, 2006).

In mouse models of disease, attempts have been made to try to alter the immune function in Aire-deficient animals as a way of curing the disease. In mice, both anti-CD4 antibody (Devoss et al., 2008) and anti-CD20 (Gavanescu et al., 2008) treatments have been used to prevent disease progression. As far as immunotherapy in patients, there are sparse data as to the efficacy of immunotherapeutic approaches toward the disease as a whole. In one case report, a 13-year-old patient with APS1 appears to have responded to an 8-month course of oral cyclosporine, with improvement in exocrine pancreatitis, keratoconjunctivitis, alopecia, and hepatitis (Ward et al., 1999). Without a systematic, controlled trial, however, it is difficult to assess if this treatment actually prevented or ameliorated disease. Importantly, side effects of the treatment included hypomagnesemia, hyperuricemia, and decreased glomerular filtration rate. Given the rarity of APS1, however, systematic trials of immunotherapies may be difficult to carry out.

AREAS FOR FUTURE STUDY

APS1 has classically been thought of as an autoimmune disorder. However, given the predisposition of patients to mucocutaneous candidiasis, APS1 can also be thought of as a state of immune deficiency. Thus, like many syndromes with immune manifestations (either autoimmunity or immune deficiency), APS1 should perhaps be thought of most accurately as a syndrome of immune *dysregulation*.

Much of the pathophysiology of APS1 has been recently unraveled. However, a number of areas remain open for further study: how the findings in mice translate to humans; the mechanism by which Aire is influencing the gene transcription of a large number of tissue-restricted antigens; and the pathophysiology underlying the immune deficiency and non-autoimmune manifestations are just some of the areas that will be unraveled in future studies.

32.

IMMUNE DYSREGULATION, POLYENDOCRINOPATHY, ENTEROPATHY, AND X-LINKED INHERITANCE

Troy R. Torgerson, Eleonora Gambineri, and Hans D. Ochs

In 1982, Powell et al. reported on a large family with multiple affected males in a five-generation pedigree (Fig. 32.1). Affected males presented early in life with multiple endocrinopathies, severe chronic enteropathy, dermatitis, autoimmune hemolytic anemia, and antibody-induced neutropenia and thrombocytopenia. The syndrome was named IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked). Most of the affected boys died before the age of 3 years due to malabsorption, failure to thrive, infections, or other complications. Characteristic findings at autopsy of these and subsequently identified patients included lymphocytic infiltrates in the lungs and endocrine organs, particularly the pancreas and thyroid, and increased lymphoid elements in lymph nodes and spleen (Powell et al., 1982; Wildin et al., 2001). Symptomatic therapy with immunosuppressive drugs provided limited beneficial effects (Seidman et al., 1990).

Some 20 years before the initial description of this syndrome, a spontaneously occurring mutant mouse strain called *scurfy* was identified at the Oakridge National Laboratory (Russell et al., 1959). Affected mice have many phenotypic similarities to IPEX, including X-linked inheritance, dermatitis, and a wasting syndrome caused by enteropathy. Death occurs invariably during the first 3 to 4 weeks of life.

In humans, the gene responsible for IPEX was mapped to Xp11.23–Xq13.3 by linkage analysis (Bennett et al., 2000; Ferguson et al., 2000)., Shortly thereafter, the gene responsible for the scurfy syndrome in mice was identified by positional cloning as a transcription factor belonging to the forkhead/winged helix family and designated *Foxp3* (Brunkow et al., 2001). The human ortholog, *FOXP*3, was subsequently recognized as the causative gene for IPEX syndrome (Bennett et al., 2001b; Chatila et al., 2000; Wildin et al., 2001). Following this discovery, additional families with mutations in *FOXP*3 were identified and the full extent of the clinical phenotype of IPEX (OMIM304930) began to be clearer (An et al., 2011; Bae et al., 2011; Fuchizawa et al., 2007; Gambineri et al., 2003; Halabi-Tawil et al., 2009; Harbuz et al., 2010; Hashimura et al., 2009; Kobayashi et al., 2001; McGinness et al., 2006; McMurchy et al., 2010; Moes et al., 2010; Moraes-Vasconcelos et al., 2008; Nieves et al., 2004; Ochs et al., 2007; Ohshima et al., 2009; Otsubo et al., 2011; Owen et al., 2003; Torgerson et al., 2007; Wildin et al., 2002).

Finally, using the scurfy mouse model, three independent groups demonstrated that Foxp3 plays an essential role in generating $CD4^+CD25^+$ regulatory T cells (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003), providing convincing evidence that the lack of regulatory T cells is the direct cause of the early-onset autoimmunity observed in scurfy mice and patients with the IPEX phenotype.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

INCIDENCE, ONSET OF SYMPTOMS, AND AGE AT DIAGNOSIS

Because there is no broad-based screening program for IPEX, the true incidence of this disease is unknown. Following the discovery of the genetic defect in IPEX, more than 100 unrelated families have been identified, 52 in our laboratory. The triad of severe diarrhea associated with villous atrophy and failure to thrive, an eczematous dermatitis, and early-onset diabetes is highly suggestive of classic IPEX. As one would expect, there are milder, less characteristic phenotypes not readily recognized as IPEX. The oldest described case in which a de novo diagnosis of IPEX was considered and confirmed by mutation analysis is a 19-year-old (Tourangeau et al., 2011). A positive

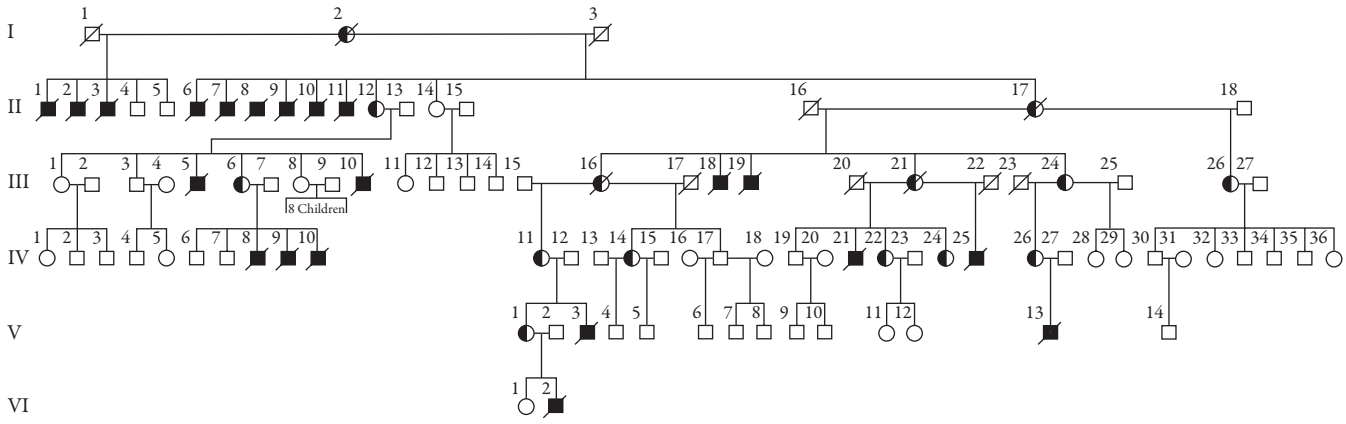

Figure 32.1 Updated pedigree of the IPEX kindred originally described by Powell et al. (1982), demonstrating X-linked inheritance and high mortality (half-filled circle, carrier female; filled square with slash, affected deceased male).

family history supports early recognition and prenatal diagnosis is possible if the *FOXP3* mutation is known for a given family.

GASTROINTESTINAL SYMPTOMS AND FAILURE TO THRIVE

Early-onset diarrhea associated with villous atrophy and lymphocytic infiltrates in the small bowel mucosa are the most prominent clinical findings in patients with the IPEX phenotype (An et al., 2011; Baud et al., 2001; Bennett et al., 2001b; Chatila et al., 2000; Cilio et al., 2000; Di Rocco and Marta, 1996; Ellis et al., 1982; Ferguson et al., 2000; Finel et al., 1996; Gambineri et al., 2008; Halabi-Tawil et al., 2009; Harbuz et al., 2010; Hattevig et al., 1982; Jonas et al., 1991; Kobayashi et al., 1998; Levy-Lahad and Wildin 2001; McMurchy et al., 2010; Meyer et al., 1970; Moes et al., 2010; Moraes-Vasconcelos et al., 2008; Peake et al., 1996; Powell et al., 1982; Roberts and Searle, 1995; Rubio-Cabezas et al., 2009; Satake et al., 1993; Savage et al., 1982; Seidman et al., 1990; Torgerson et al., 2007; Walker-Smith et al., 1982; Wildin et al., 2002; Zeller et al., 1994). With two exceptions, all patients in our series of 52 families with IPEX or those with IPEX-like phenotype presented with gastrointestinal symptoms of watery or mucoid-bloody diarrhea that does not respond to dietary manipulation (Table 32.1). Total parenteral nutrition (TPN) is often required to prevent failure to thrive. Severe villous atrophy and mucosal erosion with lymphocytic infiltrates of the submucosa or lamina propria are frequently observed in small bowel biopsies, often leading to a diagnosis of autoimmune enteropathy and occasionally of Crohn's disease or ulcerative colitis. In rare cases, gastrointestinal symptoms occur at a later age, possibly resulting from a less severe mutation of *FOXP*3 or, in some cases, non-FOXP3-related mechanisms. Treatment with immunosuppressive drugs may lead to temporary improvement of gastrointestinal symptoms.

AUTOIMMUNE ENDOCRINOPATHY

Early-onset, sometimes neonatal or congenital insulin-dependent type 1 diabetes is a frequent initial finding (Bae et al., 2011; Bennett et al., 2001a; Cilio et al., 2000; Di Rocco and Marta, 1996; Dodge and Laurence, 1977; Ferguson et al., 2000; Finel et al., 1996; Gambineri et al., 2008; Halabi-Tawil et al., 2009; Hattevig et al., 1982; Jonas et al., 1991; Levy-Lahad and Wildin 2001; Meyer et al., 1970; McMurchy et al., 2010; Moes et al., 2010; Moraes-Vasconcelos et al., 2008; Nieves et al., 2004; Peake et al., 1996; Powell et al., 1982; Roberts and Searle 1995; Satake et al., 1993; Wildin et al., 2002; Zeller et al., 1994). IPEX patients with diabetes lack sufficient insulin and often have anti–islet cell antibodies. At autopsy, chronic inflammation with lymphocytic infiltrates in the pancreas and absence of islet cells is a characteristic finding. Thyroid disease, initially presenting as either hypo- or hyperthyroidism, is a common complication (Gambineri et al., 2008; Halabi-Tawil et al., 2009; Moes et al., 2010; Moraes-Vasconcelos et al., 2008; Nieves et al., 2004; Ochs et al., 2007; Powell et al., 1982; Satake et al., 1993; Wildin et al., 2001, 2002) and may be associated with elevated thyrotropin levels or anti-thyroid microsomal antibodies (Kobayashi et al., 1998; Savage et al., 1982; Wildin et al., 2002).

In our own clinical survey of IPEX patients, type 1 diabetes was present in 55 percent and thyroid disease in 33 percent of patients with a *FOXP*3 mutation. Interestingly, only 1 of 52 IPEX patients had adrenal insufficiency.

AUTOIMMUNE HEMATOLOGICAL DISORDERS

Coombs-positive hemolytic anemia, autoimmune thrombocytopenia, or neutropenia are frequent complications (Baud et al., 2001; Di Rocco and Marta, 1996; Gambineri et al., 2008; Levy-Lahad and Wildin 2001; Nieves et al., 2004; Ochs et al., 2007; Powell et al., 1982; Roberts and Searle, 1995; Satake et al., 1993; Wildin et al., 2002). Specific autoantibodies (anti-red blood cell, antiplatelet, or antineutrophil antibodies) are frequently present in the circulation.

AUTOIMMUNE HEPATITIS

Hepatitis is a frequent complication observed in IPEX patients (Gambineri et al., 2008). In our own series, 22 percent of IPEX

patients with mutations in FOXP3 have a history of hepatitis. In some patients, the liver disease is associated with the presence of high titers of anti-liver/kidney microsomal antibody (LKM1 type 2), or antimitochondrial antibody, autoantibodies associated with autoimmune hepatitis or primary biliary cirrhosis (PBC), respectively (Lopez et al., 2011; Tsuda et al., 2010).

DERMATOLOGICAL ABNORMALITIES

Dermatitis is one of the most consistent clinical findings in IPEX (Baud et al., 2001; Chatila et al., 2000; Di Rocco and Marta, 1996; Ellis et al., 1982; Ferguson et al., 2000; Gambineri et al., 2008; Halabi-Tawil et al., 2009; Levy-Lahad and Wildin, 2001; McGinness et al., 2006; Moes et al., 2010; Moraes-Vasconcelos et al., 2008; Nieves et al., 2004; Peake et al., 1996; Powell et al., 1982; Roberts and Searle, 1995; Zeller et al., 1994). Eczema is by far the most common skin manifestation observed in patients of all ages with IPEX (Fig. 32.2 and Color Plate 32.I), but erythroderma has been reported in a few infants with the disease. In older patients, severe localized psoriasiform dermatitis (Fig. 32.3 and Color Plate 32.IIA), alopecia universalis, and pemphigoid nodularis have been described (McGinness et al., 2006; Nieves et al., 2004). The psoriasiform lesions show irregular hyperplasia of the epidermis with overlying parakeratosis and lymphocytic infiltrates (Fig. 32.4 and Color Plate 32.IIB). Autoantibodies recognizing skin antigens, including Keratin 14, have been identified in the blood of scurfy mice and IPEX patients (Huter et al., 2010). The usual eczematous dermatitis of IPEX is responsive to T-cell–directed immunosuppression (tacrolimus, etc.) and topical therapy with steroid ointment and hydration. Pemphigoid nodularis observed in a 14-year-old boy with autoantibodies to the 180 Kd bullous pemphigoid antigen was responsive to B-cell–depletion therapy with monoclonal anti-CD20 antibody (McGinness et al., 2006).

INFECTIONS

It is unclear whether IPEX patients have a significantly increased susceptibility to infections as a function of their genetic defect, as was suspected by Powell et al. (1982), or whether this susceptibility is secondary to other clinical features, such as decreased barrier function of the skin and gut, or to immunosuppressive therapy. In a large cohort of patients with the IPEX phenotype, 62 percent had serious infection, including sepsis, meningitis, pneumonia, and osteomyelitis, with many of these infections occurring prior to the initiation of immunosuppressive therapy (Ochs and Torgerson, 2007). Sepsis due to line infection is a common complication. Autoimmune neutropenia, if present, likely contributes to the increased incidence of infections in those patients with this feature. The most common pathogens identified were *Enterococcus* and *Staphylococcus* species, cytomegalovirus, and *Candida* (Ferguson et al., 2000; Gambineri et al., 2008; Halabi-Tawil et al., 2009; Jonas et al., 1991; Kobayashi et al., 1998; Levy-Lahad and Wildin, 2001; Moraes-Vasconcelos et al., 2008; Ochs and Torgerson, 2007; Peake et al., 1996; Roberts and Searle, 1995). Opportunistic infections such as *Pneumocystis jiroveci* are rare and are most likely a consequence of immunosuppressive therapy (Torgerson et al., 2007).

Figure 32.2 Chronic eczema in a 14-year-old male IPEX patient. (See Color Plate.)

Figure 32.3 Psoriasiform dermatitis in a patient with IPEX due to an amino acid substitution in FOXP3 (p.A384T). Chronic scaly, erythematous plaques are present on the patient's legs. (See Color Plate.)

OTHER CLINICAL MANIFESTATIONS

Severe, acute reactions to routine immunizations have been reported (Powell et al., 1982). Such reactions suggest that FOXP3 and regulatory T cells are necessary to keep immune responses to foreign antigens under control and prevent the potential of "horror autotoxicus" or autoimmunity, a term introduced by Paul Ehrlich more than 100 years ago (Ehrlich, 1900).

Renal disease, described as glomerulonephropathy, interstitial nephritis (Bae et al., 2011; Ellis et al., 1982; Kobayashi et al., 1998; Powell et al., 1982; Zeller et al., 1994), or minimal-change nephritic syndrome (Hashimura et al., 2009; Rubio-Cabezas et al., 2009) has been observed frequently in IPEX patients. In our own IPEX series, 29 percent of patients with *FOXP*3 mutation had renal abnormalities. In some instances, renal disease may be directly caused or worsened by treatment with calcineurin inhibitors; however, renal disease has been described in patients not receiving any immunosuppressive drugs.

Other features include neurological problems, including seizures and developmental delay, in almost 25 percent of the patients in our cohort. In addition, hepatosplenomegaly and lymphadenopathy due to extensive lymphocytic infiltrates have been reported in patients at autopsy (Levy-Lahad and Wildin, 2001; Peake et al., 1996; Roberts and Searle, 1995; Wildin et al., 2002).

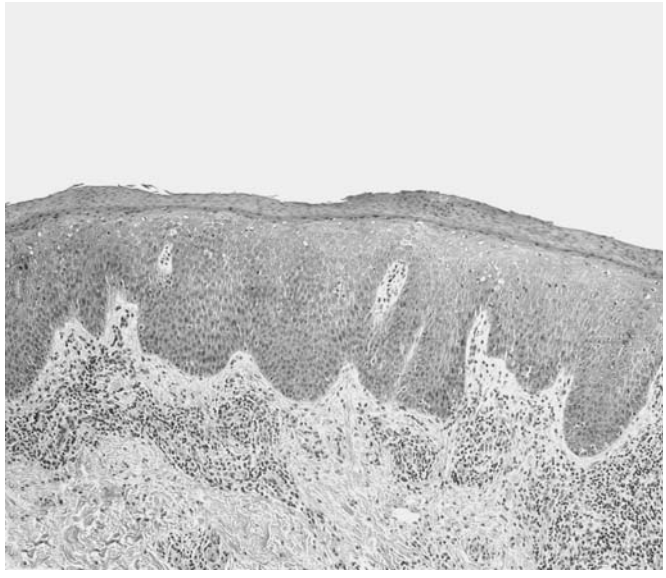

Figure 32.4 A skin biopsy of a new skin lesion of the same patient shows irregular psoriasiform hyperplasia of the epidermis with overlying parakeratosis. Cell infiltrates consist mainly of T lymphocytes (CD8>CD4) (hematoxylin-eosin, ×10). (From Nieves et al., *Arch Dermatol* 2004;140:466–472, with permission.) (See Color Plate.)

LABORATORY FINDINGS

The immunological evaluation of IPEX patients is unremarkable except for elevated serum levels of IgE and IgA and marked eosinophilia. IgG and IgM levels, absolute lymphocyte counts, and subset numbers are typically within the normal range, and in vitro proliferation of lymphocytes in response to mitogens and specific antigens is normal (Gambineri et al., 2008). In our series, greater than 90 percent of IPEX patients had significantly elevated IgE levels and 67 percent had elevated IgA levels.

With only rare exceptions, patients with IPEX have normal antibody responses to immunization with protein and polysaccharide antigens (for review, see Wildin et al., 2002). In those patients who do not respond, it may be a result of systemic immunosuppressive therapy at the time of immunization and testing. The presence of autoantibodies is a hallmark of this syndrome (Gambineri et al., 2008; Huter et al., 2010; Tsuda et al., 2010). Most patients with insulin-dependent diabetes have autoantibodies against pancreatic islet cells (Baud et al., 2001; Ferguson et al., 2000; Finel et al., 1996; Gambineri et al., 2008; Jonas et al., 1991; McMurchy et al., 2010; Peake et al., 1996; Roberts and Searle, 1995; Wildin et al., 2002). Anti-insulin and anti-glutamic acid decarboxylase (GAD) antibodies are also common (Baud et al., 2001; Cilio et al., 2000; Gambineri et al., 2008; McMurchy et al., 2010). In addition, antimicrosomal/antithyroglobulin antibodies, antibodies against smooth muscle, mitochondrial antigens, and antinuclear antibodies have been demonstrated (Baud et al., 2001; Di Rocco and Marta, 1996; Ferguson et al., 2000; Finel et al., 1996; Gambineri et al., 2008; Powell et al., 1982; Satake et al., 1993; Savage et al., 1982; Seidman et al., 1990; Tsuda et al., 2010). Antibodies against human intestinal tissue (anti-enterocyte) and an autoantibody specific for a 75kDa gut- and kidney-specific antigen (AIE-75) have been observed (Gambineri et al., 2008; Kobayashi et al., 1998, 1999; McMurchy et al., 2010; Satake et al., 1993; Walker-Smith et al., 1982). Studies of scurfy mice and patients with IPEX demonstrated the presence of autoantibodies that target keratins (Huter et al., 2010).

While $CD4^{+}CD25^{high}$ lymphocytes are present in the peripheral blood of IPEX patients with mutations in FOXP3, most, but not all, have low percentages of

$CD4^+CD25^{high}FOXP3^+$ Treg cells in the circulation (Gambineri et al., 2008; Gavin et al., 2006). It is unlikely that the $FOXP3^+$ cells that are present exhibit significant suppressive activity. Due to the volume of blood required to perform the routine in vitro suppression assays to evaluate Treg function and the fact that most patients are small and clinically unstable, this cannot be formally evaluated in most patients at the present time. Flow cytometry testing to evaluate Treg number and percentage is therefore the recommended screening test. CD4, CD25, and FOXP3 are generally considered to be the basic markers needed to identify Tregs by flow cytometry. This can however be further refined by using additional markers, including low-level expression of CD127 (the α-chain of the interleukin [IL]-7 receptor), CTLA-4, GITR, and Helios. A number of studies have demonstrated that CD127 expression on Tregs inversely correlates with FOXP3 expression and the suppressive function of Treg cells, making it a particularly useful cell-surface marker in combination with CD4 and CD25 for isolation of viable $CD4^+CD25^+CD127^{low}FOXP3^+$ Treg cells (Hartigan-O'Connor et al., 2007; Liu et al., 2006; Shen et al., 2009; Smith et al., 2008; Otsubo K, et al. 2011; Venken et al., 2008).

MOLECULAR BASIS OF IPEX

Following the identification of a 2bp insertion in the *Foxp*3 gene of mice with the scurfy phenotype (Brunkow et al., 2001), three laboratories reported that symptomatic males of families with X-linked IPEX had mutations of the human *FOXP*3 gene (Bennett et al., 2001b; Chatila et al., 2000; Wildin et al., 2001). The human *FOXP*3 gene, located on the short arm of the X chromosome (Xp11.23), consists of 11 translated exons that encode a protein of 431 amino acids (429 amino acids for the murine Foxp3). The two proteins, human and murine, have 86 percent sequence identity. The gene is expressed predominantly in lymphoid tissues (thymus, spleen, and lymph nodes), particularly in $CD4^+CD25^{bright}$ T cells (Roncador et al., 2005). Human $CD4^+CD25^-$ and $CD8^+$ T cells can inducibly express FOXP3 upon activation, although typically at lower levels than in Treg cells (Cosmi et al., 2003; Roncador et al., 2005; Walker et al., 2003; Xystrakis et al., 2004). In mice, Foxp3 is expressed at low levels in $CD4^+CD25^-$ but not at significant levels in CD8+ cells (Brunkow et al., 2001; Fontenot et al., 2005; Hori et al., 2003).

The Forkhead (FKH) BOX protein FOXP3 is a member of the P subfamily of Fox transcription factors, which as a group are characterized by the presence of a highly conserved winged helix/forkhead DNA binding domain. Proteins bearing a forkhead DNA-binding motif represent a large family of related transcriptional regulators that play diverse roles in enhancing or suppressing transcription of particular genes. Studies in model organisms such as *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Mus musculus* have demonstrated a pivotal role for Fox family transcription factors in embryonic patterning, development and organogenesis, and regulation of metabolism (Benayoun et al., 2011; Carlsson and Mahlapuu, 2002; Gajiwala and Burley, 2000; Jackson et al., 2010). A subset of Fox transcription factor family members has been shown to play a role in the development and maintenance of normal immune responses and thymic development (Foxn1, see Chapter 21), in lineage commitment (Foxp3; e.g., $CD4^+CD25^+$ regulatory T cells), and in the function of lymphocytes (Foxj1 and Foxo3).

The FOXP3 protein has a number of characteristic structural features, including an amino-terminal proline-rich domain required for the gene repression activity of FOXP3 (Lopes et al., 2006), a centrally located C2H2 zinc-finger and leucine zipper (both conserved structural motifs involved in protein–protein interaction and the latter involved in dimerization of FOXP3), and carboxy-terminal forkhead DNA-binding domain (Fig. 32.5). There is a putative nuclear localization signal at the C-terminal portion of the forkhead domain (Lopes et al., 2006). Human Tregs co-express equal amounts of two splice isoforms of FOXP3, one encoded by the full-length mRNA and the other lacking the sequence encoded by exon 2 (FOXP3Δ2). At present, the function of FOXP3Δ2 is not fully understood (Allan et al., 2005).

FUNCTION OF FOXP3

For transcription factors such as FOXP3 to modulate gene transcription, they need to be imported to the nucleus of the cell, where they typically interact with a number of binding partners to either upregulate or downregulate transcription from a number of gene promoters. FOXP3 is no exception. Studies using N-terminal green fluorescent protein (GFP)-tagged FOXP3 suggest that it constitutively traffics to the nucleus (Fig. 32.6; Lopes et al., 2006). Studies using a combination of gene expression analysis and genome-wide chromatin immunoprecipitation to evaluate promoter occupancy have demonstrated that FOXP3 binds to more than 700 promoters and can act either as a transcriptional repressor or as a transcriptional activator, depending on the promoter to which it is bound (Zheng et al., 2007). Recent mouse data have demonstrated that on DNA, Foxp3 interacts with a network of other transcription factors to mediate its effects (Fu et al., 2012; Rudra et al., 2012). Specifically, when bound to the IL-2 promoter, crystal structure analysis suggests that the FOXP3 forkhead domain forms a ternary complex with the DNA-binding domain of the transcription factor NFAT1 (Bandukwala et al., 2011). The unique feature of this structure is that FOXP3 forms a domain-swapped dimer that bridges two molecules of DNA. Some IPEX-associated mutations, including the F373A mutation observed in one patient with a severe IPEX phenotype (Bacchetta et al., 2006; Otsubo et al., 2011; Wildin et al., 2002), are located in this domain swap interface of FOXP3, disrupting dimer formation by the Forkhead domain without affecting DNA binding; this defect in dimer formation was associated with loss of suppressor function (Bandukwala et al., 2011).

FOXP3 ACTS AS A TRANSCRIPTIONAL REPRESSOR OF CYTOKINE PROMOTERS

Among the important genes regulated by Foxp3 are a number of cytokine genes, including those encoding IL-2, IL-4,

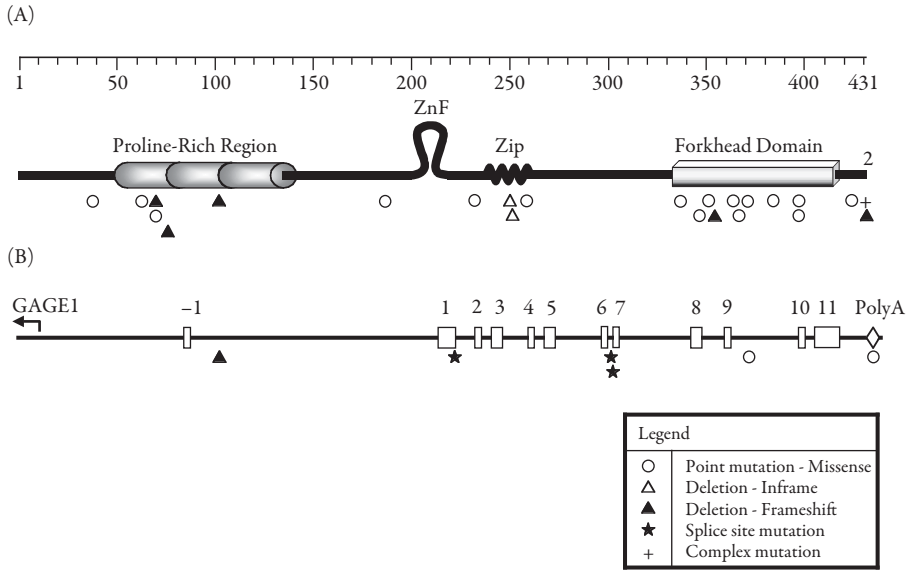

Figure 32.5 FOXP3 structure. (A) Schematic representation of the FOXP3 protein, highlighting the proline-rich region at the N terminus, followed by a C2H2 zinc-finger domain (ZnF), a leucine zipper (Zip), and the DNA-binding forkhead domain at the C terminus. (B) Genomic organization of the FOXP3 gene. There are 11 coding exons, a Poly A region located 878–883 bp downstream of the FOXP3 stop codon, and the adjacent (upstream) gene (*GAGE1*). The location and type of FOXP3 mutations identified to date are indicated by specific symbols. Nucleotide 1 is the first nucleotide of exon 1.

and interferon-γ (Bettelli et al., 2005; Schubert et al., 2001). Downregulation of gene transcription by Foxp3 on these promoters is thought to be the reason that Treg cells do not express these cytokines upon activation. Foxp3, but not Foxp1 or Foxp2, physically associates and functionally interacts with NF-κB and NFAT protein, and as a result inhibits IL-2, IL-4, and IFN-γ production by Foxp3-transduced $CD4^+$ effector cells. T cells from scurfy mice have a substantial increase in NFAT and NF-κB transcriptional activity compared with T cells derived from wild-type mice. This overexpression of NFAT and NF-κB is reduced to normal levels by complementation with Foxp3 in scurfy-derived T cells (Bettelli et al., 2005).

In addition to direct interactions on cytokine promoters, FOXP3 has been proposed to have a second effect caused by binding to and repressing transcription of the gene encoding the inducible form of NFAT (NFAT2) in T cells. In this way, FOXP3 functions not only to suppress the first wave of NFAT-mediated transcriptional responses mediated by NFAT1 as a result of direct interactions on cytokine promoters but also affects sustained NFAT-mediated inflammatory gene expression through suppression of inducible NFAT2 transcription (Torgerson et al., 2009). In addition, FOXP3 binds to intergenic regions, suggesting that FOXP3 also regulates noncoding RNA, such as miR-155, a miRNA associated with c-myc upregulation, pre-B-cell proliferation, and tumorigenesis (Zheng et al., 2007).

FOXP3 AS A RHEOSTAT OF THE IMMUNE RESPONSE

The generation of transgenic mice expressing multiple copies of the *Foxp*3 gene results in a dramatic suppression of immune responses. Transgenic mice have markedly decreased numbers of $CD4^+$ T cells in the peripheral blood and decreased cellularity in lymph nodes and spleen. In contrast to scurfy T cells, those derived from Foxp3 transgenic mice were hyporesponsive

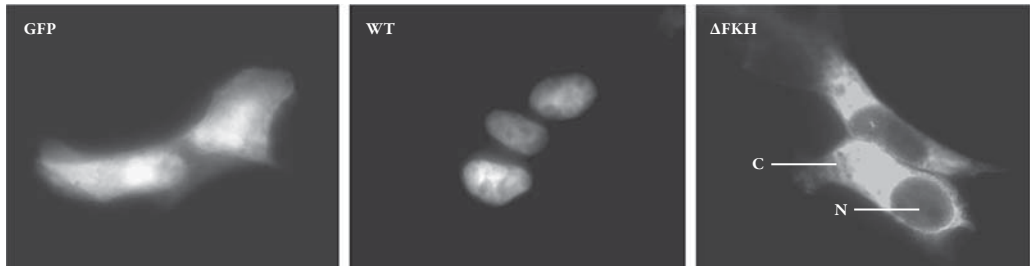

Figure 32.6 Nuclear import of FOXP3. The forkhead domain of FOXP3 is required for nuclear import. Constructs encoding N-terminal green florescent protein (GFP), GFP-FOXP3 (WT), or GFP-FOXP3 lacking the forkhead (ΔFKH) domain were transiently transfected into HEK 293 cells and evaluated by standard fluorescence microscopy for the ability to translocate to the nucleus. GFP by itself is below the size-exclusion limit for the nuclear pore complex and therefore is present throughout the cell. WT FOXP3 is located entirely in the nucleus; if the forkhead domain is deleted (ΔFKH-FOXP3), the protein is excluded from the nucleus (N) and remains in the cytoplasm (C).

to stimulation both in vivo and in vitro. The suppressive effect was shown to be entirely dependent on peripheral T cells, as overexpression of wild-type Foxp3 in the thymus did not affect peripheral-blood T-cell numbers or functions (Khattri et al., 2001). In this model, Foxp3 functions as a rheostat of the immune system, with activation responses being inversely proportional to the amount of Foxp3 protein expressed by $CD4^+$ T cells. Combined with the findings reported by Bettelli et al. (2005, vide supra), this hypothesis postulates that Foxp3 has an important function in peripheral $CD4^+$ T cells, in addition to its role in generating regulatory T cells in the thymus. If, as suggested by experimental evidence (Bettelli et al., 2005; Schubert et al., 2001; Torgerson et al., 2009), Foxp3 directly interacts with NF-κB and NFAT, it is possible that this physical association recruits Foxp3 to the promoters of cytokine genes. Being a potent transcriptional repressor, the recruitment of Foxp3 to these promoters would downmodulate transcriptional activity. Such a mechanism would explain the fact that scurfy T cells are hyperresponsive to T-cell receptor (TCR) stimulation with anti-CD3 (Clark et al., 1999). The observation that myelin proteolipid protein-specific autoreactive T cells transduced with Foxp3 are no longer able to mediate experimental autoimmune encephalomyelitis supports the notion that Foxp3 suppresses the effector function of autoreactive T cells (Bettelli et al., 2005). A similar suppression of experimental allergic encephalomyelitis by Foxp3-positive regulatory T cells was reported by Yu et al. (2005). Using a hemophilia A mouse model in which all T cells overexpressed FOXP3 (HemA/Foxp3-Tg), the transfer of factor VIII (FVIII) plasmid no longer induced the production of neutralizing anti-FVIII antibody in these HemA/Foxp3-Tg mice, resulting in permanent cure of hemophilia A (Miao et al., 2009). $CD4^+Foxp3^+$ T cells from these tolerized mice suppressed proliferation of FVIII-stimulated effector cells and could be adoptively transferred into plasmid-treated HemA mice, significantly suppressing the production of neutralizing antibody titers.

$CD4^+CD25^+FOXP3^+$ REGULATORY T CELLS

Some 10 years ago, Sakaguchi et al. described a small subset of $CD4^+$ T cells expressing the high-affinity IL-2 receptor α-chain (CD25) that was associated with antigen-specific suppression of T-cell responses (Sakaguchi et al., 2001). These $CD4^+CD25^+$ "regulatory" T cells (Tregs) are anergic in vitro but upon activation suppress proliferation and IL-2 production by naïve and memory $CD4^+$ T cells through a contact-dependent, cytokine-independent mechanism (Itoh et al., 1999; Shevach 2001). This type of "dominant tolerance" exerted by dedicated regulatory T cells is in contrast to the "recessive tolerance" mediated by negative selection of autoreactive T-cell clones in the thymus or autoreactive B-cell clones in the bone marrow or the periphery (see Chapters 30 and 31).

Regulatory T cells have been recognized as lead actors in the control of chronic human diseases. They play a major role in transplantation tolerance (Wood and Sakaguchi, 2003) and are numerically low in patients with chronic graft-versus-host disease following bone marrow transplantation (Zorn et al., 2005). Similarly, decreased numbers of regulatory T cells have been associated with autoimmune diseases in both humans and mice (Loser et al., 2005; Marinaki et al., 2005; Wei et al., 2004; Yu et al., 2005). Treatment strategies to increase Treg function have improved transplantation tolerance and autoimmune symptoms in experimental models (Bettelli et al., 2005; Liu et al., 2011; Loser et al., 2005). Conversely, an increase in the number and activation of Tregs has been associated with tumor progression (Berger et al., 2005; Karube et al., 2004; Ormandy et al., 2005; Unitt et al., 2005; Viguier et al., 2004), and therapeutic regimens are being explored to reduce Treg activity during cancer therapy (Beyer et al., 2005; Sharma et al., 2005; Wei et al., 2004).

Although the precise molecular events that lead to the production and regulation of regulatory T cells are unknown, it was shown independently by three groups that Foxp3 plays a crucial role in the generation of Tregs in mice (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003). Foxp3 is preferentially expressed in the $CD4^+CD25^+$ pool of cells, and mice that lack Foxp3 (scurfy or Foxp3 knockout mice) fail to generate functional Tregs. Ectopic expression of FOXP3 in human or murine $CD4^+CD25^-$ T cells is sufficient to convert these cells to a Treg-like phenotype regardless of CD25 expression, enabling the transduced T cells to suppress the proliferation of bystander cells in vitro and limit the effector functions of autoreactive T cells in vivo (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003; Yagi et al., 2004). Murine $CD4^+CD25^-$ cells, if activated in vitro by cross-linking CD3, do not express Foxp3 and do not acquire suppressor activity, despite strong expression of CD25 on the cell surface (Fontenot et al., 2003; Khattri et al., 2003). However, human $CD4^+CD25^-$ cells readily induce expression of FOXP3 when activated in vitro and develop some regulatory function, although not as potently as natural Treg cells (Walker et al., 2003; Yagi et al., 2004).

Although it is generally accepted that Foxp3 is indispensable for the differentiation and suppressive function of Tregs, it is unclear how $CD4^+CD25^+FOXP3^+$ regulatory T cells exert their potent suppressive effect on target cells to control immune responses to infectious agents and self-antigens, thus preventing autoimmunity. Most IPEX patients with known FOXP3 mutations (even those with missense mutations that allow expression of a mutant protein) lack a normal population of FOXP3-expressing $CD4^+CD25^+$ Tregs (Fig 32.7 and Color Plate 32.III) (Fuchizawa et al., 2007; Gavin et al., 2006). There are, however, IPEX patients with mutations in FOXP3 who have normal percentages of FOXP3+ T cells, but with impaired suppressive function (Bacchetta et al., 2006; Bandukwala et al., 2011; Gambineri et al., 2008).

Although the Treg story is still in flux, several key facts are generally accepted: Naturally arising $CD4^+CD25^+FOXP3^+$ Tregs are generated in the thymus of both mice and humans (Itoh et al., 1999; Papiernik et al., 1998; Stephens and Mason 2000; Roncador et al., 2005). These $CD4^+CD25^+FOXP3^+$ thymocytes are capable of suppression in adoptive transfer models and in in vitro suppression assays (Itoh et al., 1999). Furthermore, the generation of Tregs in the thymus requires TCR signaling during thymocyte development (Hsieh and Rudensky, 2005). In this model of regulatory T-cell lineage commitment, intermediate-avidity TCR–self-peptide–MHC interactions take

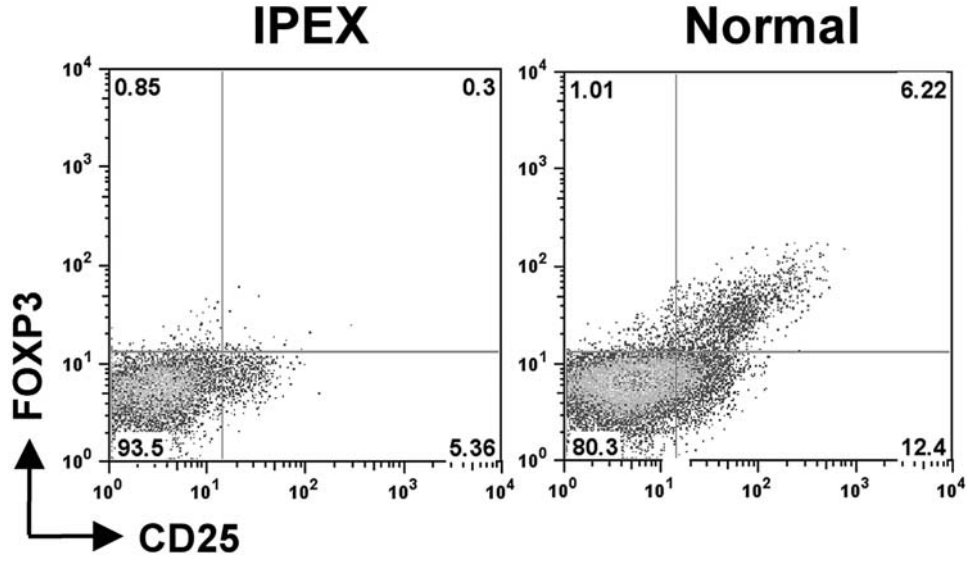

Figure 32.7 Regulatory T cells (Tregs) in human peripheral blood. Peripheral blood mononuclear cells were stained for CD4, CD25, and FOXP3 using fluorescently labeled monoclonal antibodies and evaluated by flow cytometry. A subset of CD4+ T cells (5–7 percent in normal individuals) are $CD4^+CD25^{bright}FOXP3^+$ and constitute the naturally arising regulatory T-cell population. This subset of $CD4^+CD25^{bright}FOXP3^+$ Treg cells is absent in the peripheral blood of a patient with IPEX. (See Color Plate.)

place in the thymus, augmented by CD28 signaling and signals sent via common γ-chain-containing cytokine receptors (and perhaps additional, unidentified signals) to induce Foxp3 expression and Treg cell differentiation. While Foxp3 is crucial for development of Treg cells in the murine thymus, its continuous expression is equally important for the maintenance of Treg cell function. Induced excision of a conditional (loxP-flanked) Foxp3 allele in mature peripheral murine Treg cells resulted in the loss of Foxp3 protein and ablation of suppressor function while gaining the ability to produce IL-2, IFN-γ, and TNF (Williams and Rudensky, 2007). Similar results were observed when wild-type mice harboring Treg cells that could be deleted at will were generated by inserting cDNA encoding GFP fused to the diphtheria toxin receptor into the 3′ UTR of the Foxp3 locus. Since all Foxp3 Treg cells of these mice express the diphtheria toxin receptor, diphtheria toxin treatment results in rapid and complete elimination of Treg cells in these unmanipulated disease-free mice. Following chronic ablation of Treg cells, both neonatal and adult mice developed rapidly progressing terminal autoimmune disease and died within 10 to 24 days after diphtheria toxin exposure (Kim et al., 2007). In addition to controlling T-cell self-reactivity, an important role for Tregs in maintaining human B-cell tolerance has recently been demonstrated (Kinnunen et al., 2013). While new emigrant/transitional B cells from IPEX patients produced antibodies with reactivities similar to those generated by the same cell populations obtained from normal controls, mature "naïve" B cells from IPEX patients often expressed autoreactive antibodies. These studies demonstrate that Tregs represent a dedicated T-cell lineage capable of controlling both T- and B-cell self-reactivity, thereby preventing autoimmune disorders. The role of Foxp3, therefore, is that of being the most important lineage specification factor for Treg cells (Fontenot and Rudensky, 2005).

MUTATION ANALYSIS

In an effort to define the clinical and immunological phenotype of IPEX and to explore a possible genotype–phenotype correlation, we have identified FOX3 mutations in 70 patients from 52 families living in North or South America, Europe, or Asia with a clinical phenotype compatible with IPEX. To date, we have identified 32 unique FOXP3 mutations (Fig. 32.5), in addition to mutations reported previously by others (An et al., 2011; Bacchetta et al., 2006; Bae et al., 2011; Chatila et al., 2000; Gambineri et al., 2008; Halabi-Tawil et al., 2009; Harbuz et al., 2010; McMurchy et al., 2010; Moes et al., 2010; Otsubo et al., 2011; Owen et al., 2003; Rubio-Cabezas et al., 2009; Tsuda et al., 2010; Wildin et al., 2001, 2002). These naturally occurring mutations have been invaluable for understanding the relative importance of each structural domain of FOXP3. The missense mutations identified thus far cluster in three specific functional domains: the N-terminal proline-rich domain, the central leucine zipper, and the C-terminal forkhead domain (Fig. 32.5). No missense mutations have been discovered in the zinc-finger domain, which suggests that it may not play a critical role in FOXP3 function. Other mutations identified include nonsense mutations, deletions, and splice-site mutations. In one family with multiple affected members, we found a large deletion upstream of exon 1 resulting in failure to initiate splicing (Moes et al., 2010). The family initially described by Powell in 1982 has a point mutation affecting the first canonical polyadenylation signal (AAUAAA→AAUGAA), which resides 878–883 bp downstream of the *FOXP*3 stop codon (Bennett et al., 2001a). This mutation may result in a somewhat milder phenotype, permissive of longer survival in some patients. However, except for one successfully transplanted infant, all affected members of that family eventually succumbed to this disease (Fig. 32.1). Not all patients who present with the IPEX phenotype have detectable

mutations in FOXP3. Of more than 400 patients with symptoms compatible with IPEX referred to our laboratory for sequencing, only 70 had identifiable mutations in *FOXP*3. Among the patients who had IPEX symptoms but lacked FOXP3 mutations (termed IPEX-like), approximately half were found to have low FOXP3 expression levels based on flow cytometry and quantitative polymerase chain reaction (PCR) testing. This suggests that at least some IPEX-like patients may have mutations involving regulatory sequences of the *FOXP*3 gene such as promoter or enhancer regions. Alternatively, there may be other genes or gene products that are directly or indirectly involved in the activation of FOXP3 itself.

STRATEGIES FOR DIAGNOSIS

Because of the wide spectrum of clinical findings, the diagnosis of IPEX should be considered in male patients presenting with intractable diarrhea, villous atrophy, and failure to thrive. The presence of an erythematous/eczematoid rash or a psoriasiform dermatitis supports the diagnosis (Figs. 32.2 and 32.3, Color Plates 32.I and 32.IIA). Early-onset type 1 insulin-dependent diabetes and/or hypothyroidism in a patient with gastrointestinal symptoms and eczema is almost pathognomonic for IPEX. Autoimmune hemolytic anemia, thrombocytopenia, and neutropenia are quite common. The diagnosis of IPEX is strongly suggested by demonstrating the absence of $CD4^+CD25^+FOXP3^+$ regulatory T cells (Fig. 32.7 and Color Plate 32.III) (Bacchetta et al., 2006; Fuchizawa et al., 2007; Gambineri et al., 2008; Gavin et al., 2006; Otsubo et al., 2011) and confirmed by mutation analysis of *FOXP*3.

DIFFERENTIAL DIAGNOSIS

Other single-gene defects in either humans or mice found to cause clinical phenotypes with significant immune dysregulation include the following (Table 32.1):

CD25 deficiency. CD25 (α-chain of the IL-2 receptor) was found to be deficient in three infants from two unrelated families. Clinical features resemble those of both IPEX and SCID. Like IPEX, CD25-deficient infants presented with severe, chronic diarrhea and villous atrophy at an early age (Caudy et al., 2007; Sharfe et al., 1997). One patient presented with early-onset insulin-dependent diabetes and eczema (Caudy et al., 2007), and all subsequently developed autoantibodies, hepatosplenomegaly, lymphadenopathy, and lymphocytic infiltrates in the lung, gut, and liver (Aoki et al., 2006; Caudy et al., 2007; Sharfe et al., 1997). In addition to autoimmune symptoms, the patients had infectious complications more commonly observed in patients with SCID, including recurrent cytomegaloviral pneumonitis, persistent thrush, candidal esophagitis, and Epstein-Barr virus infection. One patient underwent successful bone marrow transplantation from a matched sibling (Aoki et al., 2006). CD25-deficient mice develop early autoimmunity with massive lymphocytic infiltrates in lungs and liver. Tregs from these mice have decreased competitive fitness relative to Tregs from normal mice (Boone et al., 2003; Sharma et al., 2009).

STAT5b deficiency. Signal transducer and activator of transcription 5b (STAT5b) is the transcription factor that mediates signaling from the IL-2, IL-7, and IL-15 receptors. As such, patients with STAT5b deficiency have moderate T- and NK-cell lymphopenia and are susceptible to chronic viral infections. Patients also have markedly decreased $CD4^+CD25^+FOXP3^+$ T cells and present with diarrhea, chronic lymphocytic interstitial pneumonitis (LIP), eczematous rash, and autoimmunity (Kofoed et al., 2003). Autoantibodies are present in half of the patients (Nadeau et al., 2011). In addition to cytokine signaling, STAT5b also plays an essential role in signaling from the growth factor receptor, so patients typically suffer from severe growth failure due to lack of IGF1 (insulin-like growth factor 1) that is not responsive to growth hormone therapy (Nadeau et al., 2011). STAT5a/5b double-deficient mice develop lymphocytic infiltrates of the bone marrow, colon, liver, and kidneys, resulting in early death. These mice have a quantitative reduction of Treg cells (Snow et al., 2003).

FAS/APO-1 (CD95) deficiency. FAS/APO-1 is a transmembrane receptor belonging to the tumor necrosis factor (TNF) receptor superfamily. Engagement of FAS/APO-1 by its ligand, FASL, induces programmed cell death in a variety of cell lines, including lymphocytes (Nagata 1997). Programmed cell death is an important mechanism of regulating the immune response by deleting autoreactive lymphocyte clones in the thymus and from the peripheral lymphocyte pool. Mutations in FAS or FASL cause a rare autosomal dominant syndrome known as autoimmune lymphoproliferative syndrome (ALPS) or Canale-Smith syndrome, which presents in the first 1 to 2 years of life and is characterized by massive lymphadenopathy and splenomegaly caused by nonmalignant lymphocytic infiltrates with an expansion of double-negative ($CD4^-CD8^-$) $\alpha\beta CD3^+$ T cells. Almost all patients present with autoimmune hemolytic anemia and thrombocytopenia, and some may have other autoimmune phenomena (Drappa et al., 1996; Fisher et al., 1995; ; Rieux-Laucat et al., 1995; see Chapter 30). Patients with ALPS survive well into adulthood and, as they age, continue to have autoimmune manifestations. Although the lymphoproliferative component of the syndrome often resolves with age, ALPS patients have a high incidence of B-cell lymphoma. Mice with inactivating mutations in either Fas or FasL show dramatic lymphocytic proliferation and infiltration of multiple organs. Fas/FasL mutant mice develop autoantibodies, including IgM rheumatoid factor and antichromatin antibodies (Takahashi et al., 1994; Watanabe-Fukunaga et al., 1992; Weintraub et al., 1998).

AIRE1 deficiency. Autoimmune regulator (AIRE) is a DNA-binding protein encoded by the *AIRE* gene located on chromosome 21 (Bjorses et al., 1998). AIRE is expressed in lymph nodes, spleen, testis, and thymus, particularly in the thymic medullary epithelial cells of the murine thymus (Heino et al., 2000). Mutations in this gene cause the rare autosomal recessive human syndrome of autoimmune polyendocrinopathy, chronic mucocutaneous candidiasis (CMC), ectodermal dysplasia (APECED) (see Chapter 31). The three most common characteristics of this disease are mucocutaneous

candidiasis, hypoparathyroidism, and adrenocortical insufficiency. Patients may develop a variety of other symptoms, including type 1 diabetes, Hashimoto's thyroiditis, vitiligo, and hemolytic anemia. The onset of APECED is less fulminant than that of IPEX, typically starting with candidiasis by age 5, hypoparathyroidism by age 10, and Addison's disease by age 15 (Vogel et al., 2002). Most APECED patients with CMC have high titers of neutralizing autoantibodies to IL-17A, IL-17F, and/or IL-22 (Kisand et al., 2010; Puel et al., 2010), strongly suggesting that the immune deficiency underlying CMC in APECED patients is caused by an autoimmune process. *Aire*-deficient mice, generated by targeted gene disruption, develop many of the typical APECED features (Anderson et al., 2002; Ramsey et al., 2002). Affected mice are born and develop normally but have lymphocytic infiltrates in the liver and atrophy of the adrenals and gonadal tissue. *Aire*-deficient mice often develop autoantibodies to the liver, exocrine pancreas, testis, and adrenal glands. Analysis of these deficient mice revealed that Aire is required for the expression of self-antigens by antigen-presenting thymic dendritic cells (Anderson et al., 2002). Following presentation of self-antigens to autoreactive T-cell clones, they are eliminated by negative selection (Su and Anderson, 2004). Thus, Aire provides a mechanism for the deletion of functional autoreactive T cells in the thymus, contributing substantially to immune tolerance.

Omenn syndrome. Omenn syndrome is a clinically defined disorder characterized by early-onset, generalized erythematous rash, combined immune deficiency, elevated serum IgE levels, and eosinophilia (see Chapter 13). Most patients with Omenn syndrome have normal numbers of (oligoclonal) T cells and low or absent circulating B-cell numbers. Because of severe gastrointestinal symptoms and failure to thrive, TPN is often required and line infection is a frequent complication. Hypomorphic mutations of *Rag*1 and *Rag*2 are frequently associated with Omenn syndrome, but mutations in Artemis, adenosine deaminase, common γ chain, RMRP, DNA-Ligase IV, or IL-7Rα have been reported in association with this clinical phenotype.

WAS deficiency. Patients with the Wiskott-Aldrich syndrome (WAS), caused by mutations in the *WAS* gene, frequently present during early infancy with bloody diarrhea, bacterial and viral infections, eczema, and bleeding due to congenital thrombocytopenia (see Chapter 43). Patients with WAS may develop autoimmune hemolytic anemia or thrombocytopenia, and neutropenia. Circulating CD4+CD25+FOXP3+ Tregs are normal in number but have impaired suppressive function. As in IPEX, the inheritance is X-linked.

ITCH deficiency. Mutations in the E3 ubiquitin ligase *ITCH/AIP4* have recently been observed in a large Amish kindred with 10 affected family members (Lohr et al., 2010). The clinical features include dysmorphic facial features, failure to thrive, developmental delay, and autoimmunity/immune dysregulation that is characterized by chronic interstitial pneumonitis (LIP), thyroiditis, type 1 diabetes, enteropathy, and hepatitis. Itch catalyzes the transfer of ubiquitin to a number of signaling proteins (PLCγ1, protein kinase Cθ, notch), a process that can lead to altered function or degradation of these proteins. Absence of Itch can affect T-cell anergy (Venuprasad 2010) or result in defective FOXP3 expression (Venuprasad et al., 2008). A radiation-induced loss-of-function mutation at the mouse agouti locus results in the non-agouti-lethal 18H mouse, also known as the itchy mouse (Perry et al., 1998). These Itch-deficient mice die at 4 to 6 months of age of chronic interstitial pneumonitis, gastroenteritis, lymphoid hyperplasia, and epidermal inflammation. Immunologically they demonstrate marked Th2 skewing within the T-cell population.

STAT1 Gain-of-Function Mutations. Heterozygous mutations in the transcriptional regulator Signal Transducer and Activator of Transcription 1 (STAT1) were recently identified in patients with chronic mucocutaneous candidiasis (CMC) (van de Veerdonk et al., 2011; Liu et al., 2011). These mutations within the coiled-coil and DNA-binding domains of the protein lead to hyperphosphorylation of STAT1 in response to cytokines such as IFNγ. Subsequent screening of a cohort of patients with IPEX-like symptoms who also had mucocutaneous fungal infections, found STAT1 gain-of-function mutations in a subset of these patients as well. Their clinical characteristics included enteropathy with villus atrophy, Type I diabetes (60%), thyroiditis (60%), mild-moderate eczema (100%), and a variety of other features including short stature (60%), delayed puberty, vascular aneurysms (20%), and viral infections. Interestingly, FOXP3+TREG numbers are within the normal range and have normal suppressive function as measured by in vitro assays (Uzel et al., 2013). The mechanism by which STAT1 gain-of-function patients develop severe autoimmunity is therefore unknown although it has been hypothesized that effector cells may be less responsive to suppression as a result of excessive STAT1 activity.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

If the mutation in a given family is known, a suspected carrier female can be identified by mutation analysis. Similarly, prenatal diagnosis of a male fetus at risk can be determined by DNA analysis with chorionic villus biopsy or cultured amniocytes as a DNA source.

TREATMENT AND PROGNOSIS

Early, aggressive therapy is of utmost importance in treating IPEX patients. By the time most patients are diagnosed, they typically demonstrate profound failure to thrive and malnutrition. They may also have diabetes and thyroid disease. The initial goal of therapy is to stabilize the patient in preparation for more definitive therapy. TPN is often necessary to ensure adequate caloric intake. This may require placement of a central venous catheter, which increases risks for line infection and sepsis. It is unclear if early immunosuppressive therapy can prevent the onset of type 1 diabetes. Long-term immunosuppression has been moderately effective in some patients, but over time, the effectiveness tends to diminish. Cyclosporin A or tacrolimus (FK506), sometimes in combination with steroids, is the most commonly used regimen (Baud et al.,

2001; Di Rocco and Marta, 1996; Ferguson et al., 2000; Finel et al., 1996; Kobayashi et al., 1995; Levy-Lahad and Wildin 2001; Satake et al., 1993; Seidman et al., 1990; Wildin et al., 2002). Sirolimus (rapamycin) has also been used with some success and seems to be less nephrotoxic (Bindl et al., 2005). Rituximab has been effective in situations where there is clearly autoantibody-mediated disease (pemphigoid nodularis, autoimmune hemolytic anemia, autoimmune thrombocytopenia, etc.; McGinness et al., 2006). A variety of immunosuppressive medications, including methotrexate, corticosteroids, mycophenolate mofetil, azathioprine, infliximab, and others, have been tried but with mixed success. Chronic immunosuppressive therapy may facilitate opportunistic infections.

Hematopoietic stem cell transplantation is currently the only effective cure for IPEX, and many patients have achieved complete remission of symptoms following myeloablative (Baud et al., 2001; Mazzolari et al., 2005) or nonmyeloablative hematopoietic stem cell transplantation (Burroughs et al., 2010; Dorsey et al., 2009; Kasow et al., 2011; Rao et al., 2007; Seidel et al., 2009; Zhan et al., 2008). While many transplanted patients have achieved complete donor engraftment, several hematopoietic stem cell recipients had reduced donor T-cell engraftment ranging from 70 percent to as low as 5 to 10 percent (Baud et al., 2001; Mazzolari et al., 2005; Seidel et al., 2009). In the latter patient, despite total T-cell donor chimerism ranging from 5 to 10 percent, donor chimerism of the Treg cell population ranged between 53 and 91 percent. Importantly, this demonstrates that Tregs have a tremendous selective growth advantage in vivo and that long-term remission can be achieved with a minimal donor population of $CD4^+CD25^+CD127^{low}FOXP3^+$ Treg cells (Seidel et al., 2009). However, the overall long-term outcome of transplantation for IPEX is difficult to estimate since the number of reported transplants is relatively small and some transplanted patients have died of late complications after transplant (Baud et al., 2001; Wildin et al., 2002). The degree of symptomatic remission following stem cell transplantation depends on the transplant being initiated prior to irreversible damage that may have occurred to target organs such as the pancreas and thyroid. Interestingly, the patient reported by Baud et al. had complete symptomatic remission, including reversion of type 1 diabetes, during the conditioning regimen that consisted of anti–T-lymphocyte globulin, busulfan, and cyclophosphamide. This result raises the possibility that cytotoxic or biological agents that target T cells may be an effective treatment in patients who have failed to respond to other therapies. In general, the prognosis of IPEX is poor without stem cell transplantation. Untreated, most patients die at an early age. Patients with certain point mutations or unusual mutations, such as those affecting the mRNA polyadenylation signal, may present with a somewhat milder initial clinical course, but one that still leads to premature death. Treatment with potent immunosuppressive agents that target T cells can make a difference in these patients, but because of toxicity and increased susceptibility to infection, these agents do not guarantee long-term amelioration of symptoms. Hematopoietic stem cell transplantation should be performed early in the course of the disease, before pancreatic islet cells and other target organs have been irreversibly damaged.

ANIMAL MODELS

THE *SCURFY* MUTATION, A MOUSE MODEL FOR IPEX

The *Scurfy (sf)* mutation arose spontaneously in a partially inbred strain of mice at the Oakridge National Laboratory (Russell et al., 1959). Shortly after birth, affected male mice develop a scaly rash most evident on the ears and tail (Fig. 32.8 and Color Plate 32.IV), and they develop severe runting secondary to chronic diarrhea and malabsorption. Characteristically, the affected males also exhibit lymphadenopathy, splenomegaly, and massive lymphocytic infiltrates in the skin, liver, and lungs and develop hemolytic anemia associated with a positive Coombs test, suggesting that the *sf* mutation causes a "generalized autoimmune-like syndrome" (Godfrey et al., 1991b).

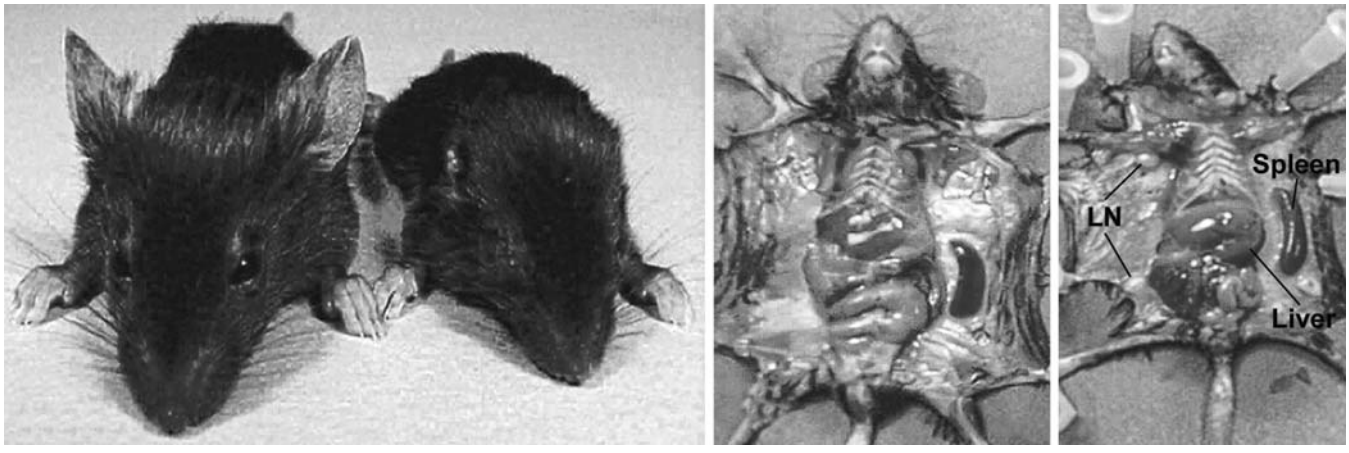

Figure 32.8 (Left panel) Wild-type (*left*) and scurfy (*right*) littermates, age 21 days. Note the small size of the scurfy mouse, the small and thickened ears, and the scaling of the feet. Compared to the wild-type mouse (middle panel), the scurfy mouse (right panel) has hepatosplenomegaly and enlarged lymph nodes (LN). Scurfy mice are deficient in FOXP3. (See Color Plate.)

IMMUNOLOGICAL FINDINGS

After a systematic study of these mice, Godfrey et al. suggested that "the scurfy disease may be the result of immune dysfunction rather than being a classic immune deficiency" (Godfrey et al., 1991b). This was supported by the observation that the thymus of young *sf* mice, although small, is densely populated with lymphocytes and has a distinct cortex and medulla. As the disease progresses, the thymic cortex is rapidly depleted of lymphocytes, and in mice older than 25 days, the thymus is a "shrunken stromal remnant lacking any corticomedullary distinction" (Godfrey et al., 1991b). The lymph nodes, spleen, and liver, however, are markedly enlarged from extramedullary hematopoiesis and cellular infiltrates. Transfer experiments demonstrated that the scurfy phenotype is mediated by T cells (Godfrey et al., 1994). T-cell subset depletion procedures strongly suggested that $CD4^+$ T cells are critical mediators of the lymphoproliferative disease in the scurfy mouse (Blair et al., 1994). Serum IgG and IgM are markedly elevated; IgA, which is absent in young normal mice, is demonstrable in male pups with the *sf* mutation (Godfrey et al., 1991a). Flow cytometric analysis of cell suspensions from the spleen or lymph nodes of *sf* mice reveal a characteristic increase in Mac-1^+ monocytic cells and a decrease in $B220^+$ cells; the latter population shows increased expression of B7.1 and B7.2 co-stimulatory molecules, suggesting a state of activation (Clark et al., 1999). The activity of *sf* T cells appears upregulated in vivo, as suggested by the spontaneous expression of CD69, CD25, CD80 (B7.1) and CD86 (B7.2). Although *sf* T cells are hyperresponsive to TCR ligation, they still require co-stimulation through CD28, albeit at decreased intensity (Clark et al., 1999). Following activation, $CD4^+$ T cells produce large amounts of granulocyte-macrophage colony-stimulating factor (>1,000-fold higher than wild-type $CD4^+$) as well as a number of other cytokines, including IL-2, IL-5, IL-6, IL-7, IL10, IFN-γ, and TNF-α (Clark et al., 1999; Kanangat et al., 1996). Interestingly, this hyperresponsiveness is resistant to suppression by inhibitors of tyrosine kinases, such as genistein and herbimycin A, and cyclosporin A (Clark et al., 1999). These observations suggest that the *sf* mutation interferes with the physiological downregulation of T-cell activation and may have implications for the immunosuppressive therapy of IPEX patients.

TRANSFER EXPERIMENTS IN *SF* MICE

The effect of transplantation of lymphoid organs and cell suspensions from *sf* (or wild-type) mice into athymic nude or severe combined immunodeficiency disease (SCID) mice (Blair et al., 1994; Godfrey et al., 1994) can be summarized as follows. First, transplanted *sf* thymus transfers the *sf* phenotype to nude and SCID mice. Second, euthymic (immunological competent) recipients of congenic *sf* thymus grafts remain clinically normal, as do all SCID and nude recipients of normal thymic transplants. Third, single-cell suspensions of thymus, lymph node, or spleen from *sf* mice transferred into histocompatible nude or SCID mice by intraperitoneal injection result in an *sf* phenotype in all recipients. Additional transfer experiments have demonstrated that the primary driver of the *sf* phenotype is the $CD4^+CD8^-$ T-cell population; $CD4^+$ but not $CD8^+$ lymph node T cells from *sf* mice transfer the disease to syngeneic host nude mice (Blair et al., 1994). Finally, if normal $CD4^+$ T cells are added to the $CD4^+$ *sf* T cells, the host nude mice do not develop the *sf* phenotype. These in vivo experiments suggest that *sf* is the result of dysregulated $CD4^+$ T cells, which express activation markers, excrete large quantities of cytokines, and are capable of inducing autoimmune disorders.

MUTATIONS AFFECTING THE *FOXP3* GENE ARE THE CAUSE OF *SF*

The *sf* locus was originally mapped to a 1.7 Cm interval between *DXWas70* and *Otc* in the proximal region of the mouse X chromosome (Kanangat et al., 1996; Lyon et al., 1990). Through combining high-resolution genetic and physical mapping with large-scale sequence analysis, the gene responsible for the *sf* mutation was identified and designated as Foxp3 (Brunkow et al., 2001). The protein encoded by *Foxp3* is a member of the forkhead winged-helix family of transcriptional regulators and is highly conserved in different mammalian species. The spontaneous mutation of *Foxp3* in *sf* mice is a 2bp insertion in exon 8, resulting in a frameshift that leads to a truncated protein lacking the carboxy-terminal forkhead domain (Brunkow et al., 2001).

FOXP3 TRANSGENIC MICE

To examine the in vivo consequences of Foxp3 overexpression, several different Foxp3-transgenic mouse lines have been established, each with differing levels of transgene expression (Brunkow et al., 2001; Khattri et al., 2001). Each of these lines, when bred onto an otherwise wild-type background, resulted in a reduction of lymph node size and cellularity. The extent of this reduction correlated with transgene copy number and expression, with higher Foxp3 levels resulting in a greater reduction in lymph node and splenic cellularity. Both $CD4^+$ and $CD8^+$ lymphocytes were reduced in number, while thymic cellularity was unaffected. A transgenic line with 16 copies of the transgene and an expression level of Foxp3 that was approximately threefold higher than in normal controls had a 50 percent reduction in the number of peripheral blood $CD4^+$ T cells and a 75 percent reduction in $CD8^+$ T cells. Histologically, peripheral lymphoid organs lacked follicular structure and were without margins between follicular and interfollicular regions. Purified $CD4^+$ T cells from this transgenic line displayed reduced proliferative responses when activated in vitro and lacked IL-2 production. Thus, Foxp3 is capable of regulating the ability of $CD4^+$ T cells to respond to TCR-mediated signals. As a direct consequence, T-helper function is severely impaired in Foxp3 transgenic mice, resulting in failure to respond to T-dependent antigens (Kasprowicz et al., 2003).

Finally, the *sf* mouse model was instrumental in defining the characteristics of the regulatory T-cell lineage (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003; see "FOXP3

and $CD4^+CD25^+$ Regulatory T Cells," above) and thus played a major role in understanding the immunological basis of IPEX. Using Foxp3-negative gene-targeted mice and a GFP-Foxp3 fusion–protein–reporter knock-in allele, it could be shown that expression of Foxp3 was highly restricted to αβ $CD4^+$ T cells and, irrespective of CD25 expression, correlated with suppressor activity (Fontenot et al., 2005).

CTLA-4- AND TGF-β1-DEFICIENT MICE

Two mouse models, neither with a human counterpart, show many similarities to the scurfy mouse. Ctla-4-deficient mice develop a lymphoproliferative syndrome similar to that of scurfy mice; however, the lymphocytic infiltrates tend to be more widespread, with accumulation of activated T cells in the heart, lungs, lymph nodes, thymus, spleen, liver, bone marrow, and pancreas. Mice are well until 2 weeks of age, then become ill and die by 3 to 4 weeks of age, probably of myocardial infarction due to massive lymphocytic infiltrates in the heart muscle (Tivol et al., 1995; Waterhouse et al., 1995). Ctla-4 is a cell-surface molecule expressed by activated T cells. When engaged by its ligand B7.1 or B7.2, Ctla-4 has an inhibitory effect on T-cell activation responses, including proliferation, cytokine secretion, and cell-surface protein expression (Chambers and Allison, 1999). Although there is no identified human syndrome caused by mutations of CTLA-4, it has been suggested that specific polymorphisms may increase the risk of developing Graves disease or autoimmune diabetes (Cosentino et al., 2002; Yung et al., 2002).

Transforming growth factor β1 (TGF-β1) belongs to a family of related growth factors that play diverse roles in cellular processes, including wound healing, hematopoiesis, and immune regulation. Tgf-β1-deficient mice develop normally until 2 weeks of age, when they begin to waste, and die by 3 to 4 weeks of age. Deficient mice also develop lymphocytic infiltrates into major organs, particularly the heart, lungs, and salivary glands, and die of cardiopulmonary symptoms secondary to massive lymphocytic infiltrates (Christ et al., 1994; Kulkarni et al., 1995; Shull et al., 1992). Tgf-β1 knockout mice develop high autoantibody titers to several nuclear antigens, including single- and double-stranded DNA (Yaswen et al., 1996). Mice conditionally lacking the transforming growth factor beta type II receptor (Tgf-βRII), one of the two cell-surface receptors for the TGF-β family of growth factors, also have a phenotype of lymphocytic infiltration and autoimmunity, but with a less fulminant course (Leveen et al., 2002).

CONCLUSION AND FUTURE DIRECTIONS

FOXP3 is the key mediator of regulatory T-cell development and function. Naturally occurring mutations in *FOXP*3 interfere with this process, resulting in the generation of unregulated autoaggressive T-lymphocyte clones and autoreactive antibody-producing B cells that are directly responsible for IPEX in humans and scurfy in mice, both lethal diseases. T-cell–directed immune suppression and aggressive supportive care are essential for stabilizing acutely ill patients, but at present hematopoietic stem cell transplantation is the only cure for patients with IPEX. Over the coming years, it is anticipated that careful evaluation of patients with IPEX and exploitation of animal models such as scurfy will lead to insights that not only answer important questions related to the care and treatment of IPEX but address more basic questions, including how FOXP3 expression and function are regulated, which FOXP3-regulated genes mediate the suppressive activity of regulatory T cells, and most importantly how Tregs functionally suppress target cells. These studies will have implications not only for patients with IPEX but also for those suffering from IPEX-like phenotypes, autoimmune diseases, graft-versus-host disease, or cancer.

RECURRENT FEVER SYNDROMES

Lori Broderick, Daniel L. Kastner, and Hal M. Hoffman

INTRODUCTION

The periodic fever syndromes are a heterogeneous group of disorders characterized by recurrent episodes of fever and localized inflammation, most commonly affecting the serosal membranes, joints, and skin (Table 33.1). Molecular genetic studies have revealed that these syndromes represent dysregulation of innate immunity. Consequently, the term "autoinflammatory disorders" has been used to describe this unique group (Doherty et al., 2011; Galon et al., 2000; Goldbach-Mansky et al., 2009; Hull et al., 2003; Masters et al., 2009; McDermott et al., 1999). In contrast to autoimmune disorders (e.g., systemic lupus erythematosus), autoinflammatory disorders notably lack high-titer autoantibodies and antigen-specific T cells. The predominance of monocytes and neutrophils as effector cells, rather than lymphocytes, underscores the key role of the innate immune system in the natural history of these disorders.

Advances in the past several years have significantly increased our understanding of these disorders, with the identification of four genes underlying six clinically distinct recurrent fever syndromes. The precise mechanism by which mutations in each of these genes causes recurrent fever and inflammation is still under investigation. However, data from both in vitro and in vivo models suggest that the dysregulation of innate immunity leads to overproduction of interleukin (IL)-1β, and the inflammatory phenotype. There is an emerging body of data indicating that both pyrin, the protein implicated in familial Mediterranean fever, and cryopyrin, the protein mutated in familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and neonatal-onset multisystem inflammatory disorder, are regulators of IL-1β production, NF-κB activation, and leukocyte cell death, all critical components of innate immunity. Similarly, while mutations in the extracellular domain of the p55 TNF receptor, as observed in TNF receptor-associated periodic syndrome, lead to increased TNF signaling, there also appears to be dysregulated IL-1β production. Although mutations in mevalonate kinase, a key enzyme in cholesterol biosynthesis, were quite unexpected in hyperimmunoglobulinemia D with periodic fever syndrome, new data suggest a nexus between the mevalonate pathway and IL-1β regulation. These findings have significantly enhanced our understanding of the molecular pathways involved in innate immunity and led to substantial successes in the treatment of autoinflammatory disorders.

THE CRYOPYRINOPATHIES

The cryopyrinopathies––familial cold autoinflammatory syndrome (FCAS, MIM 120100), Muckle-Wells syndrome (MWS, MIM 191100), and neonatal-onset multisystem inflammatory disease (NOMID, MIM 607115, also called chronic infantile neurologic cutaneous and articular [CINCA] syndrome)––are a group of autosomal dominant autoinflammatory conditions consisting of episodic or fluctuating inflammation with associated cutaneous and synovial symptoms. A large family with what is now called FCAS was described first (Kile et al., 1940), and Muckle and Wells published a family with their eponymous syndrome in 1962 (Muckle et al., 1962). NOMID/CINCA was first recognized as a clinical entity in the early 1980s (Hassink et al., 1983; Prieur et al., 1981), although it was not initially apparent that this condition is a genetic disorder due to decreased reproductive fitness in patients carrying the diagnosis.

Between 1999 and 2000, genetic markers associated with FCAS, MWS, and a clinical overlap syndrome sharing features of both conditions were independently mapped to the distal

Table 33.1 CHARACTERISTICS OF THE PERIODIC FEVER SYNDROMES

	FCAS	MWS	NOMID/CINCA	FMF	TRAPS	HIDS	PFAPA
GENE	*CI*AS1	CIAS1	CIAS1	MEFV	TNFRSF1A	MVK	UNKNOWN
Inheritance	Dominant	Dominant	De novo, dominant	Recessive	Dominant	Recessive	Unknown
Ethnicity	Mostly European	Mostly European	Any ethnicity	Turkish, Armenian, Arab, Jewish, Italian, Greek, other	Any ethnicity	Dutch, French, other European	Any ethnicity
Duration of attacks	12–24 hours	2–3 days	Continuous	12–72 hours	>7 days	3–7 days	3–5 days, regular periodicity
Cutaneous	Urticaria-like rash induced by cold temperatures	Urticaria-like rash	Urticaria-like rash	Erysipeloid erythematous rash on lower leg, ankle, foot	Migratory rash, often associated with underlying myalgia	Maculopapular rash on trunk and limbs, urticaria	Not common
Abdominal	Nausea	Abdominal pain	Not common	Sterile peritonitis, constipation	Peritonitis, diarrhea or constipation	Severe pain, vomiting, diarrhea, rarely peritonitis	Abdominal pain, nausea
Pleural	Not seen	Rare	Rare	Common	Common	Rare	Not seen
Arthropathy	Polyarthralgia	Polyarthralgia, oligoarthritis	Epiphyseal overgrowth, contractures, intermittent or chronic arthritis	Monoarthritis, occasionally protracted arthritis in knee or hip	Arthritis in large joints, arthralgia	Arthralgia, symmetrical polyarthritis	Arthralgia
Ocular	Conjunctivitis	Conjunctivitis, episcleritis	Uveitis, conjunctivitis, progressive vision loss	Rare	Conjunctivitis, periorbital edema	Uncommon	Not seen
Neurological	Headache	Headache, sensorineural deafness	Sensorineural deafness, chronic aseptic meningitis, mental retardation, headache	Rare	Rare	Headache	Not seen
Lymph nodes/ spleen	Not seen	Rare	Hepatosplenomegaly, adenopathy	Splenomegaly more common than lymphadenopathy	Splenomegaly more common than adenopathy	Cervical adenopathy more common than splenomegaly	Cervical adenopathy
Vasculitis	Not seen	Not seen	Occasional	Henoch-Schönlein purpura, polyarteritis nodosa	Henoch-Schönlein purpura, lymphocytic vasculitis	Cutaneous vasculitis common, rarely Henoch-Schönlein purpura	Not seen
Amyloidosis	Rare	Occurs in ~25%	May develop in a portion of patients reaching adulthood	Risk depends on *MEFV* and *SAA* genotypes, therapy, other factors	Occurs in ~10%	Case reports	Not seen

[1]Treatment of autoinflammatory disorders is evolving. Asterisks (*) denote approved therapies, although not in all countries. Other treatments, although they may be considered standard of care, have yet to be approved by regulatory agencies.

FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; HIDS, hyperimmunoglobulinemia D with periodic fever syndrome; MWS, Muckle-Wells syndrome; NOMID, neonatal-onset multisystem inflammatory disorder; NSAIDs, nonsteroidal anti-inflammatory drugs; TRAPS, TNF receptor-associated periodic syndrome.

region of the long arm of chromosome 1 (Cuisset et al., 1999; Hoffman et al., 2000; McDermott et al., 2000), suggesting that all three disorders were linked to the same gene. In 2001, several missense mutations associated with FCAS and MWS were identified in an exon of a newly discovered gene denoted *CIAS1* (cold-induced auto-inflammatory syndrome-1) (Hoffman et al., 2001a). This gene, which was also called *PYPAF1* (Manji et al., 2002), *NALP3* (Aganna et al., 2002a), and *CATERPILLER1.1* (O'Connor et al., 2003), is now referred to as *NLRP3* (Ting et al., 2008). Similarities between clinical features of NOMID/CINCA and MWS led to the discovery, in 2002, of de novo missense mutations in *CIAS1* in many patients with NOMID/CINCA (Aksentijevich et al., 2002; Feldmann et al., 2002). Currently, over 85 mutations linked to cryopyrinopathies have been found in *NLRP3.* An updated list of mutations is available at the Infevers website (http://fmf.igh.cnrs.fr/infevers/) (Milhavet et al., 2008). Several mutations are shared by more than one condition, and many patients evince symptoms that fall between the established diagnostic boundaries, creating a phenotypic spectrum (Aksentijevich et al., 2007; Neven et al., 2004). Variability in phenotype among patients with the same mutation suggests that other genetic or environmental factors may influence disease severity.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF THE CRYOPYRINOPATHIES

Familial Cold Autoinflammatory Syndrome (FCAS)

FCAS, also called familial cold urticaria, familial polymorphous cold eruption, and cold hypersensitivity, is considered the mildest of the cryopyrinopathies. Symptoms include episodes of fever, urticaria-like rash, and arthralgia, and, less commonly, drowsiness, fatigue, headache, nausea, and extreme thirst (Hoffman et al., 2001b; Johnstone et al., 2003; Wanderer et al., 2004). Febrile attacks are often brought on by generalized exposure to cold temperatures. In many patients, less than an hour of mild cold exposure is needed to precipitate symptoms (Hoffman et al., 2001b). Approximately 2 hours later, patients experience symptoms that last on average about 12 hours. Longer and more extreme exposure to cold correlates with more severe symptoms. In some individuals, attacks occur nearly daily, often worse in the evening and resolving by morning. Most patients have their first symptoms by 6 months of age, and more than half develop the characteristic rash within the first few days of life.

The rash associated with FCAS (Plate 33.I) can present as petechiae, erythematous patches, or confluent plaques, usually beginning on the face or extremities and spreading (Johnstone et al., 2003). Although the rash appears hive-like, skin biopsies reveal infiltrates of predominantly neutrophils but also eosinophils and lymphocytes that are often perivascular or perieccrine with little evidence of mast cell degranulation, indicating that the rash is not typical urticaria, but a neutrophilic urticarial dermatosis (Hoffman et al., 2001b; Kolivras et al., 2011).

Polyarthralgia and swelling involving the hands, knees, and ankles, and occasionally the feet, wrists, and elbows, usually accompany flares. Occasionally, some patients develop a nonerosive arthropathy with deformities of the metacarpophalangeal and proximal interphalangeal joints (Commerford et al., 1977). Some patients also complain of ocular symptoms, including pain, redness, watering, and blurred vision (Hoffman et al., 2001b). While FCAS is the mildest of the phenotypes, the disease has considerable effect on quality of life (Stych et al., 2008) and is rarely associated with amyloidosis.

Muckle Wells Syndrome (MWS)

The first published description of MWS was a 1962 report on a Derbyshire kindred (Muckle et al., 1962). Affected individuals suffered from "aguey bouts" of inflammation consisting of fever, malaise, an urticaria-like rash, and stabbing pains in the large joints. In addition, many affected members of the family developed bilateral sensorineural hearing loss and renal amyloidosis. Attacks were not usually linked to cold temperatures and tended to be longer and more severe than those associated with FCAS.

Age of onset in MWS ranges from infancy to adulthood, but most patients experience their first attack by adolescence. MWS-associated episodes typically last from 24 to 48 hours, but many patients have daily symptoms with a similar circadian pattern of worsening in the evening (Cuisset et al., 1999; Muckle, 1979; Muckle et al., 1962). In addition to the symptoms noted above, patients may also have headache, abdominal pain, conjunctivitis, and episcleritis (Cuisset et al., 1999; Watts et al., 1994). Skin manifestations similar to those associated with FCAS usually accompany episodes (Plate 33.I). Although arthralgia is much more common than arthritis, oligoarticular synovitis and sterile pyogenic arthritis occur occasionally (Schwarz et al., 1989; Watts et al., 1994). Approximately three fourths of patients develop sensorineural hearing loss, usually beginning in childhood with high-frequency hearing loss (Schwarz et al., 1989). Mucosal thickening and maxillary sinus hypoplasia is also commonly observed on magnetic resonance imaging (MRI; Ahmadi et al., 2011).

Systemic amyloidosis develops in approximately one third of adult patients due to the deposition of a fragment of serum amyloid A (SAA) in target organs, namely the kidneys. SAA is an acute phase reactant produced by the liver and found at high levels in the serum during inflammatory attacks. Patients with amyloid deposition in the kidneys progress from albuminuria to the nephrotic syndrome and ultimately to renal failure. Other target organs include the thyroid, adrenals, spleen, and testes (Schwarz et al., 1989). Hearing loss does not appear to be due to amyloid deposition in the inner ear or auditory nerve, and the current hypotheses focus on inflammation of the inner ear.

Neonatal onset multisystem inflammatory disease/ chronic infantile neurologic cutaneous and articular syndrome (NOMID/CINCA)

NOMID/CINCA is the most severe of the cryopyrinopathies. In addition to the rash, fever, arthralgia, headache, hearing loss, and amyloidosis seen in MWS, NOMID/CINCA

patients may have a distinct, deforming arthropathy (Hashkes et al., 1997; Hassink et al., 1983; Prieur, 2001; Prieur et al., 1981), as well as chronic aseptic meningitis, intellectual impairment, and significant eye involvement. Approximately 20 percent of patients die before age 20 years (Hashkes et al., 1997; Prieur et al., 1987).

The rash associated with NOMID/CINCA is similar to that associated with FCAS and MWS and is nearly always present to some degree (Prieur, 2001). Articular symptoms are variable (Hashkes et al., 1997; Prieur, 2001; Prieur et al., 1987), with some patients exhibiting mild swelling and pain but no radiographic changes, while others have severe deformities involving symmetrical overgrowth of the epiphyses and growth cartilage of the long bones, especially prominent in the knees, ankles, elbows, and hands. The latter changes may occur within the first year of life and contractures may severely restrict movement (Hashkes et al., 1997; Prieur, 2001; Prieur et al., 1987). Joint radiographs from severe cases may show enlarged, irregular ossification of the epiphyses of the femur and tibia and enlargement of the patella, often with a "breadcrumb" appearance. There may be early growth-plate closure and shortening of the long bones, suggesting abnormal endochondral bone growth (Hashkes et al., 1997; Kaufman et al., 1986). Skull radiographs may show frontal bosselation, delayed closure of the anterior fontanelle, and increased cranial volume. Synovial biopsy usually shows only modest inflammation.

The neurosensory manifestations of NOMID/CINCA are potentially of great concern. Many patients develop chronic aseptic meningitis, with increased cerebrospinal fluid (CSF) pressure, an elevation in CSF protein concentration, and a pleocytosis consisting mostly of polymorphonuclear leukocytes (Torbiak et al., 1989). Brain imaging studies may reveal ventricular dilatation, cerebral atrophy, and prominent sulci (Prieur, 2001). Although some patients perform well at school, other children with NOMID/CINCA have developmental delays and learning deficits and still others exhibit mental retardation (Dollfus et al., 2000; Torbiak et al., 1989). As in MWS, sensorineural hearing loss is frequent and is associated with cochlear enhancement on MRI (Ahmadi et al., 2011). Ocular involvement may range from conjunctivitis to anterior or posterior uveitis, sometimes leading to blindness (Dollfus et al., 2000). Episcleritis and corneal infiltrates have also been observed. Funduscopic examination frequently reveals optic disc edema, papilledema, or optic atrophy (Terrada et al., 2011).

Other findings include hepatosplenomegaly and lymphadenopathy, as well as vasculitis, thrombosis, and the aforementioned amyloidosis (Hashkes et al., 1997; Prieur, 2001; Prieur et al., 1987; Torbiak et al., 1989). Profound growth delay and reduced reproductive potential are also common.

LABORATORY FINDINGS IN THE CRYOPYRINOPATHIES

Laboratory features of the cryopyrinopathies include an accelerated erythrocyte sedimentation rate (ESR), thrombocytosis, and anemia of chronic disease at baseline and polymorphonuclear leukocytosis that increases during episodes (Hoffman et al., 2004). Elevated acute phase reactants, such as the C-reactive protein (CRP) and SAA, are also observed chronically without therapy. Elevated S100A12 levels have also been described (Kuemmerle-Deschner et al., 2011; Wittkowski et al., 2008). High-titer autoantibodies are not observed, although some patients do have modest titers of anti-cardiolipin antibodies.

MOLECULAR BASIS OF THE CRYOPYRINOPATHIES: THE NLRP3 GENE

NLRP3 consists of nine exons, encoding a 3105 bp potential open reading frame based on a second start site. An open reading frame of 3111 bp based on the first start site 6 bp upstream has resulted in some confusion when naming specific mutations due to the two additional amino acids. There is extensive alternative splicing of exons 4–9, resulting in multiple alternative splice forms of unclear significance (Hoffman et al., 2001a). Expression analyses detect the cryopyrin message primarily in leukocytes and chondrocytes (Feldmann et al., 2002; Hoffman et al., 2001a), although recent data suggest that is it is expressed at lower levels in several tissue and cell types with potential functional significance (Kummer et al., 2007; McCall et al., 2008; Shigeoka et al., 2010).

The protein product of *NLRP3* was named cryopyrin to emphasize the existence of an N-terminal PYRIN domain, initially described in the pyrin protein (see the section on familial Mediterranean fever), as well as the association with cold-induced symptoms in FCAS (Hoffman et al., 2001a). The PYRIN domain (Bertin et al., 2000), also known as PYD (Martinon et al., 2001), PAAD (Pawlowski et al., 2001), or DAPIN (Staub et al., 2001), has now been recognized in a total of over 20 human proteins involved in the regulation of inflammation and apoptosis (Harton et al., 2002; Tschopp et al., 2003). Computational modeling and subsequent nuclear magnetic resonance (NMR) spectroscopy have demonstrated that the PYRIN domain is the fourth member of the death domain-fold superfamily (Eliezer, 2003; Fairbrother et al., 2001; Hiller et al., 2003; Liepinsh et al., 2003; Liu et al., 2003; Richards et al., 2001), which also includes death domains, death effector domains, and caspase-recruitment domains (CARDs). All four assume a six alpha-helix three-dimensional structure that facilitates homotypic interactions through electrostatic charge interactions. Thus, the PYRIN domain of cryopyrin is a docking motif that facilitates cognate interactions with other PYRIN domain proteins.

Besides the PYRIN domain (amino acids [a.a.] 13–83), cryopyrin contains a central NACHT domain (a.a. 217–533) (Koonin et al., 2000), named for its presence in neuronal apoptosis inhibitor protein (*NA*IP), the major histocompatibility complex (MHC) class II transactivator (*C*IITA), the incompatibility locus protein from *Podospora anserina* (*H*ET-E), and mammalian telomerase-associated proteins (*T*P1). At the C-terminus of cryopyrin are seven leucine-rich repeats (LRRs) (a.a. 697–920). This arrangement of PYRIN-NACHT-LRRs is found in at least 14 proteins referred to as NLRPs, or NALPs in the human genome (Tschopp et al., 2003), and the

C-terminal domains, NACHT-LRR, are found in many other proteins in the NLR protein family (Ting et al., 2008).

FUNCTION OF CRYOPYRIN, THE NLRP3 GENE PRODUCT

The PYRIN domain of cryopyrin has been shown to interact specifically with ASC (apoptosis-associated speck-like protein with a CARD), a bipartite adaptor consisting solely of an N-terminal PYRIN domain and a C-terminal CARD in tandem (Dowds et al., 2003; Gumucio et al., 2002; Manji et al., 2002). Through its CARD, ASC binds caspase 1 (also known as IL-1β converting enzyme [ICE]) and other adaptor proteins. This macromolecular complex of cryopyrin, ASC, and caspase 1, and possibly a fourth protein called Cardinal, has been denoted the inflammasome (Agostini et al., 2004; Martinon et al., 2004b). Activation of the inflammasome leads to the cleavage of caspase 1 into enzymatically active p20 and p10 subunits (Agostini et al., 2004; Chae et al., 2003; Martinon et al., 2002, 2004b; Srinivasula et al., 2002; Stehlik et al., 2003; Wang et al., 2002). Activated caspase 1, in turn, cleaves IL-1β from its 31 kDa precursor form to its 17 kDa biologically active fragment, which is a potent mediator of fever and inflammation (Fig. 33.1). Studies in various transfection systems indicate that cryopyrin potentiates inflammation through its interaction with ASC. Cryopyrin has been shown to regulate IL-1β secretion (Stehlik et al., 2003; Wang et al., 2002), NF-κB activation (Dowds et al., 2003; Gumucio et al., 2002; Manji et al., 2002; O'Connor et al., 2003; Stehlik et al., 2002), and cell death (Dowds et al., 2003; Duncan et al., 2009; Fujisawa et al., 2007; Willingham et al., 2009; Willingham et al., 2007).

The NACHT domain contains seven conserved motifs, including an ATPase-specific P-loop and a Mg^{++} binding site, and is involved in protein oligomerization (Koonin et al., 2000). This domain has been found to have ATPase activity that is important to its function (Duncan et al., 2007). Disease-associated mutations are found almost exclusively in the NACHT domain, suggesting an important role for this motif in the function of cryopyrin.

LRRs are common components of the extracellular domains of Toll-like receptors (TLRs), as well as several cytoplasmic proteins known as NLRs. The LRRs of TLRs appear to recognize pathogen-associated molecular patterns (PAMPs), common molecules in bacterial cell walls, such as peptidoglycan and lipopolysaccharide (Chamaillard et al., 2003; Girardin et al., 2003; Inohara et al., 2002). Upon contact with a PAMP, TLRs transduce signals into the cell to upregulate proinflammatory mediators such as co-stimulatory molecules, cytokines, and inducible nitric oxide synthase (iNOS). LRRs on cytoplasmic proteins such as cryopyrin may serve a similar purpose in detecting intracellular bacteria or bacterial products. Several PAMPs have been shown to activate formation of the cryopyrin inflammasome (Lamkanfi et al., 2009; Martinon et al., 2004a). However, most of the activators of the cryopyrin inflammasome, such as various microorganisms, particles, and danger signals, are not thought to interact directly with cryopyrin. Instead, mechanisms involving potassium efflux, generation of reactive oxygen species, and membrane disruption have been proposed to mediate inflammasome activation (Hoffman et al., 2011).

Under normal conditions, cryopyrin is kept from activating caspase 1 in at least two possible ways. First, pyrin may compete with cryopyrin for binding to ASC (Dowds et al., 2003),

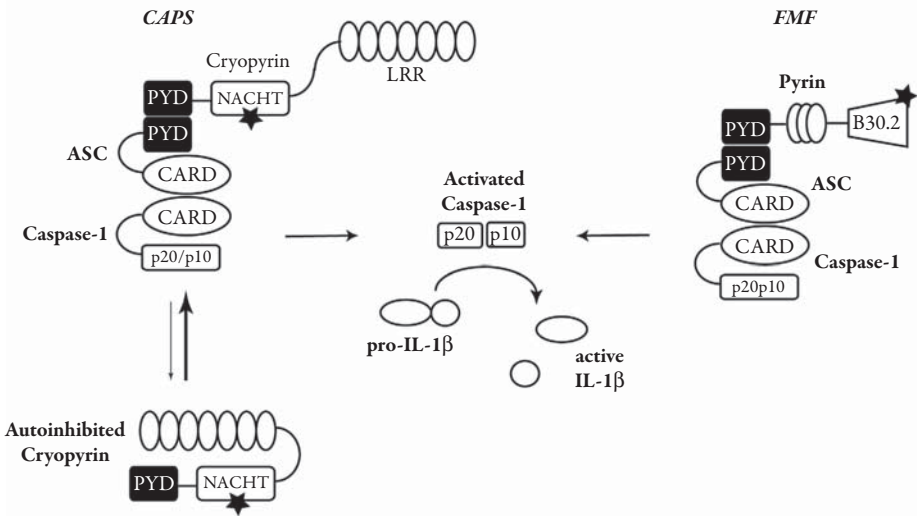

Figure 33.1 Enhanced production of IL-1β in cryopyrin-associated periodic disorders (CAPS) and familial Mediterranean fever (FMF). (*Left*) Formation of the cryopyrin (NLRP3) inflammasome. At baseline, interaction of the leucine-rich repeats (LRR) with the NACHT domain of cryopyrin prevents assembly of the complex. Mutations in the NACHT domain associated with familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID) may alter the LRR–NACHT interaction in such a way that the threshold of activation is diminished. Assembly of the inflammasome leads to the interaction of the catalytic domains (p20/p10) of caspase 1 molecules, leading to autocatalysis, release of p20 and p10, and subsequent IL-1β activation. (*Right*) PYRIN domain of pyrin interacts with ASC and caspase 1, leading to the cleavage of caspase 1 into its enzymatically active subunits, again resulting in IL-1β cleavage and activation. Stars denote the presence of mutations.

preventing formation of the cryopyrin inflammasome. Second, studies of LRR deletion mutants of both cryopyrin and NLRP1 (Agostini et al., 2004; Martinon et al., 2002), a related protein, suggest that the LRRs have an autoinhibitory function, maintaining the protein in an inactive state, although there are conflicting data in mice (Hoffman et al., 2010). Upon activation, the LRRs may release the rest of the protein from inhibition, allowing formation of the cryopyrin inflammasome.

MUTATION ANALYSIS IN THE CRYOPYRINOPATHIES

Nearly all of the known mutations occur in exon 3, encoding the NACHT domain. Although the crystal structure of cryopyrin has not been solved, computational modeling suggests that many of the disease-causing mutations are located along the nucleotide binding cleft or near a region that senses when a nucleotide is bound (Neven et al., 2004) or on a predicted surface of the protein domain, suggesting an effect on protein–protein interactions (Aksentijevich et al., 2007).

Mutation-associated changes in cryopyrin appear to increase its proinflammatory properties, perhaps by increasing the binding affinity of cryopyrin for ASC or rendering the protein more labile, so that minor stimuli (such as cold temperatures and low-dose lipopolysaccharide [LPS]) trigger inflammasome activation and IL-1β release, as observed in FCAS monocytes (Rosengren et al., 2007; Stack et al., 2005). In addition, there is no requirement for ATP as a second stimulus of IL-1β release from cultured monocytes of all mutation-positive cryopyrinopathy patients (Brydges et al., 2009; Gattorno et al., 2007). Disease-associated mutations have also been associated with NF-κB activation (Dowds et al., 2003; Manji et al., 2002), increased cathepsin B-mediated cell death known as pyronecrosis (Fujisawa et al., 2007; Saito et al., 2008; Willingham et al., 2007), an altered redox state that is proinflammatory (Tassi et al., 2010), and increased protein kinase activity postulated to be involved in the bone phenotype (Almeida et al., 2011). Disease-associated mutations may be considered gain-of-function genetic changes, consistent with the dominant inheritance patterns observed in the cryopyrinopathies.

There is some degree of genotype–phenotype correlation with specific mutations commonly associated with mild or severe disease, but there can be extensive phenotypic overlap with specific mutations or with variants within close proximity based on predicted primary, secondary, or tertiary structure (Aksentijevich et al., 2007). Almost all of the disease-associated *NLRP3* variants described are missense mutations. Many patients with a classic phenotype do not have easily identifiable mutations, suggesting the involvement of additional genes, and there is now considerable evidence for somatic mosaicism of *NLRP3* mutants in many patients previously thought to be mutation negative (Saito et al., 2008; Tanaka et al., 2011).

STRATEGIES FOR THE DIAGNOSIS OF THE CRYOPYRINOPATHIES

The diagnosis of these disorders is often a combination of clinical observations and genetic testing. Common features suggestive of the cryopyrinopathies include fever, urticaria-like rash, arthralgia, headache, childhood onset, and chronically increased CRP. For FCAS, a clinical diagnosis may be established by the presence of fever and rash induced by generalized cold exposure and at least four of the following: short (<24 hour) episodes, autosomal dominant inheritance, age of onset less than 6 months, conjunctivitis during attacks, and absence of deafness, periorbital edema, lymphadenopathy, and serositis. The absence of a positive ice cube test differentiates FCAS from typical cold urticaria (Johnstone et al., 2003). Longer episodes, hearing loss, lack of association with cold temperatures, and amyloidosis are more suggestive of MWS (Muckle, 1979), whereas aseptic meningitis, uveitis, and the characteristic arthropathy support the diagnosis of NOMID/CINCA (Hashkes et al., 1997; Neven et al., 2004; Prieur, 2001).

Disease severity may vary extensively, even among individuals harboring the same mutations, indicating that other factors influence phenotype. Some patients blur the boundaries between diagnoses, with some features of FCAS, such as cold sensitivity, and other findings consistent with MWS, such as amyloid nephropathy (Aganna et al., 2002a; Dode et al., 2002c; Hoffman et al., 2001a; Neven et al., 2004). Other patients may represent an overlap between MWS and NOMID/CINCA at the more severe end of the phenotypic continuum (Aksentijevich et al., 2002, 2007; Dode et al., 2002c; Feldmann et al., 2002; Granel et al., 2003; Lieberman et al., 1998; Neven et al., 2004; Rosen-Wolff et al., 2003; Saito et al., 2008; Tanaka et al., 2011).

Genetic testing is not necessary but can provide an unequivocal diagnosis, if positive. However, the sensitivity is not 100 percent, and only about half of patients meeting clinical criteria for NOMID/CINCA have demonstrable mutations in *NLRP3* (Aksentijevich et al., 2002; Neven et al., 2004). While some of these patients have been found to have somatic mutations, it is likely that other mutation-negative patients have defects in related genes. There are some mutations with reduced penetrance or atypical phenotypes, including V198M and R488K, and some variants with unknown significance such as Q703K (Aksentijevich et al., 2007; Arostegui et al., 2004; Ting et al., 2007; Verma et al., 2008).

Recently, patients with some phenotypic overlap with the cryopyrinopathies (cold-induced fever and arthralgia, but not urticaria-like rash) have been found to have mutations in the structurally related gene *NLRP12*. However, the pathogenic mechanisms appear to be different from that of NLRP3-associated diseases (Borghini et al., 2011; Jeru et al., 2008, 2011).

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

NLRP3 mutations are inherited in an autosomal dominant fashion, a pattern recognized early in families with FCAS and MWS (Johnstone et al., 2003; Kile et al., 1940; Muckle et al., 1962). Most NOMID/CINCA cases are sporadic, resulting from de novo mutations in the children of otherwise healthy individuals, although a small number of familial cases have been documented (Feldmann et al., 2002).

Thus far, most mutations in *CIAS1* show a high degree of penetrance, such that carriers nearly always show some clinical manifestations, although there are exceptions as described above. Again, it should be noted that family members with the same mutations may not exhibit all the same signs and symptoms with equal severity. Prenatal diagnosis of the cryopyrinopathies is certainly feasible but requires careful genetic counseling and consideration of the effectiveness of recent therapies.

TREATMENT AND PROGNOSIS

Patients with the cryopyrinopathies generally do not respond well to colchicine (Hoffman et al., 2001b). Corticosteroids are helpful in some cases (Tanaka et al., 2011), but they carry a high risk of side effects and often have minimal effect on the arthropathy or central nervous system manifestations of NOMID/CINCA (Hashkes et al., 1997; Prieur, 2001). NSAIDs offer some relief for arthralgia and constitutional symptoms but do little to control overall inflammation. TNF-α and IL-6 inhibitors have also been used in cryopyrinopathy patients with an incomplete response (Matsubara et al., 2006).

The most widely used and successful therapies for the cryopyrinopathies are IL-1–targeted therapies. Initial reports with IL-1 receptor antagonist in FCAS and MWS patients demonstrated essentially complete remission of all disease symptoms and normalization of systemic inflammatory markers (Hawkins et al., 2003, 2004; Hoffman et al., 2004). Larger open-label studies with daily anakinra (100 mg SQ) in cryopyrinopathy patients (Kuemmerle-Deschner et al., 2011; Leslie et al., 2006; Ross et al., 2008) have replicated the initial case reports, and longer studies have demonstrated sustained response and significantly improved quality of life (Lepore et al., 2010), sometimes even with lower or every-other-day dosing. However, the most impressive and life-altering response to anakinra has been observed in patients with NOMID/CINCA. Uveitis, rash, headache, and fever resolved, and pathologically elevated cerebrospinal pressure dropped significantly. Growth, development, hearing, and leptomeningeal lesions also improved in many patients with anakinra (1–2 mg/kg/day; Goldbach-Mansky et al., 2006). Other long-term studies have demonstrated similar impressive and sustained responses, although higher doses (up to 10 mg/kg/day) may be required in infants (Neven et al., 2010). It will be important to continue to follow children with NOMID/CINCA on anakinra to observe long-term academic performance and physical growth, as well as to determine whether very early treatment can avert joint deformities.

Two additional IL-1–targeted therapies have been applied to cryopyrinopathy patients with similar efficacy. Rilonacept, a fusion protein also known as IL-1 TRAP, demonstrated remarkable efficacy with weekly subcutaneous dosing in a placebo-controlled trial with more than 40 adult and adolescent FCAS and MWS patients (Goldbach-Mansky et al., 2008; Hoffman et al., 2008), while canakinumab, a monoclonal antibody to IL-1β, was effective when given every 2 months in more than 40 adults and children (Kuemmerle-Deschner et al., 2011; Lachmann et al., 2009). Both are now approved for use in cryopyrin-associated periodic syndromes.

Untreated, FCAS appears not to be associated with long-term sequelae, save for a few reports of renal amyloidosis occurring late in life in a few families (Hoffman et al., 2001b). Prognosis in MWS patients is highly dependent on the development of amyloidosis, which occurs in approximately one third of individuals. Many MWS patients develop significant bilateral sensorineural deafness. NOMID/CINCA patients often have a reduced life expectancy. Currently, about 20 percent die before the age of 20 of infection or amyloidosis (Hashkes et al., 1997; Prieur et al., 1987). Morbidities include intellectual impairment, vision loss, sensorineural hearing loss, and physical disability due to contractures.

Early and continued treatment with IL-1–targeted therapy decreases the risk of developing amyloidosis in cryopyrinopathy patients, possibly averting or delaying renal failure and the attendant complications. The role of IL-1 inhibition in reversing preexisting deficits depends on the circumstances. Aggressive treatment soon after the discovery of proteinuria has been shown to reverse the progression to renal failure (Thornton et al., 2007), and some patients have had improvement in their hearing after starting therapy (Rynne et al., 2006). Primary side effects from these drugs are injection-site reactions and increased risk of standard viral and bacterial infections, particularly *Streptococcus*.

ANIMAL MODELS

Studies using NRLP3 knockout mice established a role for the cryopyrin inflammasome in many disease models. However, the cryopyrinopathies are autosomal dominant gain-of-function mutations. Knock-in mice were developed that have proven to be fairly accurate models of human disease, with neutrophilic inflammation in the skin and other tissues and similar ex vivo responses (Brydges et al., 2009; Meng et al., 2009). Brydges et al. showed that murine disease is inflammasome dependent, partially IL-1 dependent, and independent of adaptive immunity. Meng et al. suggested a role for T_H17 cells and IL-17 in the cutaneous pathology, which is supported by recent human data (Lasiglie et al., 2011). Additional studies with these mice are under way to delineate further pathogenic mechanisms.

FAMILIAL MEDITERRANEAN FEVER

Although molecular genetic data suggest that founder mutations causing familial Mediterranean fever (FMF, MIM 249100) arose many centuries ago (International FMF Consortium, 1997), the first recognizable report of a case of FMF was published in 1908 (Janeway et al., 1908), and the first series of 10 cases of "benign paroxysmal peritonitis" was published in 1945 (Siegal, 1945). The predominance of case descriptions in North African and Iraqi Jewish populations led to the widely accepted "familial Mediterranean fever" nomenclature (Heller et al., 1958; Sohar et al., 1967), although it should be noted that other names, such as recurrent polyserositis,

recurrent hereditary polyserositis, and periodic disease, are sometimes used.

The high carrier frequencies in these populations gave rise to pseudodominance; however, careful segregation analysis indicated that FMF is recessively inherited, with incomplete penetrance (Sohar et al., 1962, 1967). Subsequent studies described in detail the serosal, synovial, and cutaneous manifestations of FMF and elucidated the connection between FMF and systemic AA amyloidosis (Sohar et al., 1967). Further epidemiological and family-based studies among non-Ashkenazi Jews and Armenians demonstrated extremely high frequencies of FMF (Rogers et al., 1989; Yuval et al., 1995), suggesting a possible heterozygote advantage, and identified ethnic differences in the susceptibility to amyloidosis (Meyerhoff, 1980; Pras et al., 1982).

Mapping of the FMF locus, *MEFV,* in 1992 (Pras et al., 1992) identification of the disease gene in 1997 (French FMF Consortium, 1997; International FMF Consortium, 1997) and the availability of genetic testing has broadened the clinical and ethnic/geographical spectrum of FMF, while studies of the *MEFV* gene product, pyrin, have shed new light on the regulation of cytokine production, NF-κB activation, and apoptosis, and have defined a functional domain present in over 20 human proteins involved in the regulation of inflammation.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF FMF

FMF is characterized by relatively discrete, usually 1- to 3-day episodes of fever with serositis, synovitis, or skin rash. In some patients attacks begin in infancy or very early childhood, and 80 to 90 percent of patients experience their first episode by age 20. Young children, especially less than 2 years of age, may present with fever alone (Padeh et al., 2010). The frequency of FMF attacks is highly variable, both among patients and for any given patient, with the interval between attacks ranging from days to years. Moreover, the type of attack (abdominal, pleural, arthritic) may vary over time. Some patients relate attacks to physical or emotional stress, although in many cases there is no obvious provocative event. There is a slight predominance of males in most series, possibly the result of underreporting in women or underrecognition because of confounding gynecological diagnoses. In some women, attacks may occur at a specific point in the menstrual cycle (Ben-Chetrit et al., 2001b) and sometimes remit during pregnancy (Schwabe et al., 1974; Sohar et al., 1967).

Attacks comprising fever and abdominal pain occur at some time in nearly all FMF patients and range from a dull aching pain to full-blown peritonitis, with boardlike rigidity, absent bowel sounds, and rebound tenderness. Constipation is common during the attacks, sometimes with a diarrhea occurring at the very end of the episode. Plain films may demonstrate air–fluid levels, and computed tomography (CT) may show thickened mesenteric folds, lymphadenopathy, splenomegaly, or a small amount of ascites (Zissin et al., 2003). On laparoscopy there may be a neutrophil-rich exudate. Repeated episodes may lead to peritoneal adhesions.

Pleurisy may occur alone with fever, or concurrently with abdominal pain. Pleuritic episodes are usually unilateral, with sharp, stabbing chest pain and, in some cases, diaphragmatic pain referred to the ipsilateral shoulder. Radiographic findings may include atelectasis (Brauman et al., 1987) due to splinting and, in a minority of cases, pleural effusion. Thoracentesis, when performed, yields a neutrophil-laden exudate. Pleural thickening sometimes develops after multiple attacks (Livneh et al., 1999).

Other forms of serosal inflammation may also be seen in FMF. Nonuremic pericarditis is much less common than peritoneal or pleural involvement (Kees et al., 1997; Turkish FMF Study Group, 2005; Tutar et al., 2003). Although small subclinical effusions are more frequent than symptomatic pericarditis, there have been rare reports of tamponade (Zimand et al., 1994). Unilateral acute scrotum occurs in about 5 percent of prepubertal boys with FMF (Livneh et al., 1994a; Majeed et al., 2000b), resulting from inflammation of the tunica vaginalis, an embryological remnant of the peritoneal membrane.

Joint involvement in FMF is particularly common among North African Jews (Brik et al., 2001; Pras et al., 1998) and has been related to the M694V homozygous genotype (Brik et al., 1999; Cazeneuve et al., 1999; Gershoni-Baruch et al., 2002), which is very frequent in this population. Acute monoarticular arthritis is most characteristic in FMF (Heller et al., 1966), often affecting the knee, ankle, or hip, and attacks tend to last longer than serosal episodes (often about 1 week), sometimes with large effusions, extreme pain, and inability to bear weight. Synovial fluid contains as many as 100,000 polymorphonuclear leukocytes/mm^3, but cultures are sterile. Soft tissue swelling may be apparent on X-rays taken during attacks, but erosive changes do not develop. A number of other less common oligo- or polyarticular patterns of arthritis may occur, especially in children (Ince et al., 2002; Majeed et al., 1997). Arthralgia is also very common. In the pre-colchicine era, about 5 percent of patients with acute monoarticular arthritis went on to develop protracted arthritis, usually affecting the hip (Sneh et al., 1977). In such cases, symptoms could last for several months, sometimes leading to secondary osteoarthritic radiographic changes and/or osteonecrosis, and requiring total hip replacement surgery. Chronic sacroiliitis may also occur in FMF, regardless of the HLA-B27 status or colchicine therapy (Brodey et al., 1975; Langevitz et al., 1997; Lehman et al., 1978).

Children with FMF frequently develop myalgia of the legs related to vigorous exertion (Majeed et al., 2000a). Much less commonly, FMF patients may experience attacks of febrile myalgia, with excruciating muscle pain unrelated to exertion, that can last from a few days to several weeks (Langevitz et al., 1994; Sidi et al., 2000). During these episodes the creatine kinase is normal, the ESR is prolonged, and the electromyogram shows nonspecific myopathic changes. Histologic data suggest that febrile myalgia is a form of vasculitis. Other forms of vasculitis, including Henoch-Schönlein purpura and polyarteritis nodosum, are also seen at increased frequency in FMF (Gedalia et al., 1992; Ozdogan et al., 1997; Ozen, 1999; Ozen et al., 2001; Rawashdeh et al., 1996; Tekin et al., 1999; Tinaztepe et al., 1997).

The most characteristic cutaneous lesion of FMF is erysipeloid erythema (Plate 33.II), a sharply demarcated, erythematous, warm, tender, swollen area 10 to 15 cm in diameter occurring unilaterally or bilaterally, usually on the dorsum of the foot, ankle, or lower leg (Azizi et al., 1976; Barzilai et al., 2000). On skin biopsy, there is a mixed perivascular infiltrate of polymorphonuclear leukocytes, histiocytes, and lymphocytes. As is the case for arthritis, the frequency of erysipeloid erythema may be increased among M694V homozygotes (Kone Paut et al., 2000).

Long-term complications of FMF necessitating preventive measures and prompt intervention include renal disease, which presents as glomerulonephritis or as a secondary manifestation of systemic amyloidosis (discussed below). FMF has been associated with crescentic rapidly progressive glomerulonephritis, mesangial IgA nephropathy, IgM nephropathy, and diffuse proliferative and exudative glomerulonephritis, with non-amyloid renal disease affecting up to 22 percent of patients (Akpolat et al., 2004; Cagdas et al., 2005). In these cases, glomerular injury is proposed to be secondary to chronic increased inflammation and may be diagnosed by persistent hematuria or proteinuria, with confirmation by renal biopsy.

As in the cryopyrinopathies, FMF attacks demonstrate elevated serum SAA levels, which lead to systemic amyloidosis in a subset of FMF patients. Deposition in the kidneys, adrenals, intestine, spleen, lung, and testes (Sohar et al., 1967) leads to organ dysfunction and failure. Patients with amyloid deposition in the kidneys may progress from albuminuria to complete renal failure, usually over the course of 3 to 5 years. Amyloid deposits in other organs may lead to malabsorption (Mor et al., 2003) and/or azoospermia and infertility (Ben-Chetrit et al., 1998a). Cardiac involvement, neuropathy, and arthropathy are very uncommon with the amyloidosis of FMF. The diagnosis is usually established by renal or rectal biopsy.

The amyloidosis of FMF usually occurs after the onset of inflammatory attacks (phenotype I) but rarely can occur as the first manifestation of FMF (phenotype II) (Sohar et al., 1967; Turkish FMF Study Group, 2005), perhaps due to subclinical elevations in the SAA. The overall risk of amyloidosis in FMF is the product of a complex interaction of factors, including the M694V/M694V genotype, which in most studies is associated with an increased risk of amyloidosis (Brik et al., 1999; Cazeneuve et al., 1999; Gershoni-Baruch et al., 2002, 2003; Majeed et al., 2002; Mansour et al., 2001). Other risk factors for amyloidosis include male gender, the SAA1 α/α genotype, a positive family history for amyloidosis, and colchicine noncompliance (Akar et al., 2003; Cazeneuve et al., 2000; Gershoni-Baruch et al., 2003; Turkish FMF Study Group, 2005). There are also geographical and secular effects on amyloid susceptibility (Akpolat et al., 2004; Cagdas et al., 2005; Touitou et al., 2007b), perhaps reflecting improvements in general medical care that may modify the SAA load from intercurrent illness.

Despite the underlying systemic inflammation, certain complications of chronic endothelial damage are rarely seen in FMF, including increased thrombotic events, and atherosclerosis, at least among patients receiving colchicine (Bilginer et al., 2008; Sari et al., 2007). Doppler imaging studies, however, have suggested that FMF patients have impaired left ventricular diastolic function and impaired coronary microvasculature (Caliskan et al., 2007; Grimaldi et al., 2006; Tavil et al., 2008), Whether these differences reflect the antiatherogenic effects of colchicine therapy (Yuksel et al., 2010), the populations studied, which trend toward younger patients (Ozcakar et al., 2011), or genotype–phenotype differences remains to be determined.

LABORATORY FINDINGS IN FMF

During the acute attacks of FMF, there is a leukocytosis, often with a left shift, an accelerated ESR, and increases in several serum acute phase proteins, including SAA, CRP, fibrinogen, haptoglobin, and the C3 and C4 complement components. The neutrophil-derived biomarker S100A12 is also significantly elevated (Kallinich et al., 2010). Urinalysis may demonstrate albuminuria and microscopic hematuria during attacks.

During the intercritical period, the white count and acute phase reactants may normalize, but in some patients there is biochemical evidence of persistent subclinical inflammation, including abnormalities of the ESR, SAA, CRP, S100A12, and fibrinogen (Duzova et al., 2003; Kallinich et al., 2010; Korkmaz et al., 2002; Tunca et al., 1999). Markers of hypercoagulability and fibrinolysis, including D-dimer, tissue plasminogen activator, and plasminogen activator inhibitor 1, may also be present (Demirel et al., 2008; Tayer-Shifman et al., 2011). Patients may also have a mild anemia of chronic disease and modest elevations in the serum immunoglobulins between attacks (Eliakim et al., 1981). A minority of patients have an increased serum IgD, although usually not to the level seen in hyperimmunoglobulinemia D with periodic fever syndrome (Medlej-Hashim et al., 2001).

Laboratory abnormalities are associated with the amyloidosis of FMF. The earliest finding is isolated albuminuria, without hematuria, with a normal or only slightly depressed serum albumin and normal renal function. As proteinuria increases, the serum albumin begins to fall, and renal function deteriorates over approximately 3 to 5 years to the point of renal failure necessitating replacement therapy. During this period hyperphosphatemia, acidosis, hyperkalemia, and anemia evolve, consistent with uremia.

MOLECULAR BASIS OF FMF: THE DISEASE GENE, MEFV

The gene mutated in FMF, *MEFV,* comprises 10 exons over an approximately 15 kb genomic interval on chromosome 16p13.3 (International FMF Consortium, 1997) and encodes a 781 a.a. open reading frame that is expressed in granulocytes, cytokine-activated monocytes, and synovial and peritoneal fibroblasts (Centola et al., 2000; Diaz et al., 2004; Matzner et al., 2000; Papin et al., 2003). However, identification of transmission of FMF following allogeneic bone marrow transplant emphasizes the role of bone marrow-derived cells in disease pathogenesis (Petropoulou et al., 2010; Touitou et al., 2007a). Initial computational analysis of the conceptual protein identified a cassette comprising a

B-box zinc finger (residues 375–407), an α-helical coiled-coil domain (residues 408–594), and a B30.2 domain (residues 598–774), all of which have been implicated in protein–protein interactions.

At the time of this writing, more than 90 FMF-associated *MEFV* mutations have been identified, with over 100 additional mutations and variants of unknown significance. An updated collection of these mutations is available on the Infevers website (http://fmf.igh.cnrs.fr/ISSAID/infevers/; Milhavet et al., 2008).The majority of the mutations are in exon 10, encoding the B30.2 domain, with several "hot spots" (M680, M694, K695, F743) that have more than one known mutation. The second major cluster of mutations is in exon 2, with a mutational "hot spot" at E148.

FUNCTION OF PYRIN, THE MEFV GENE PRODUCT

Work on the function of pyrin, the *MEFV* gene product, has focused on interactions mediated by the N-terminal pyrin domain. Similar to cryopyrin, the PYRIN domain of pyrin interacts specifically with the homologous domain of ASC, forming a pyrin inflammasome (Chae et al., 2003; Dowds et al., 2003; Masumoto et al., 1999, 2003; Richards et al., 2001). These proteins co-localize to polymerizing, actin-rich regions of the cell (Waite et al., 2009). As in the cryopyrinopathies, ASC binding of caspase 1 leads to the cleavage of caspase 1 into its enzymatically active subunits (Agostini et al., 2004; Chae et al., 2003; Martinon et al., 2002, 2004b; Srinivasula et al., 2002; Stehlik et al., 2003; Wang et al., 2002), which results in IL-1β cleavage and activation (Fig. 33.1). The critical role of mutations in pyrin leading to persistent inflammation has been confirmed in a murine knock-in model and further implicates the role of IL-1β in disease pathogenesis in an ASC-dependent manner (Chae et al., 2011).

Although less completely understood, the interaction of pyrin with ASC also appears to regulate leukocyte apoptosis. Peritoneal macrophages from pyrin-deficient mice exhibit a defect in apoptosis through a caspase 8-dependent, IL-1β–independent pathway, suggesting a role for wild-type pyrin in limiting the duration of the innate immune response through cell death (Chae et al., 2003). Nevertheless, underscoring the complexity of the process, in certain transfection systems wild-type pyrin exerts an antiapoptotic effect (Dowds et al., 2003; Masumoto et al., 2003; Richards et al., 2001).

Finally, pyrin may modulate NF-κB activation, another important component of the innate immune response, via two mechanisms: its interaction with ASC and as a direct substrate for caspase 1. ASC has been shown to bind to components of the IκB kinase complex, which regulates NF-κB through the phosphorylation of IκB (Stehlik et al., 2002). Depending on the cellular context, co-transfection of wild-type pyrin with ASC may potentiate or suppress NF-κB activation (Dowds et al., 2003; Masumoto et al., 2003; Stehlik et al., 2002). In a second pathway leading to NF-κB translocation, caspase 1 may cleave pyrin itself, and these cleavage events are notably greater in leukocytes from FMF patients than those from healthy controls (Chae et al., 2008). These data may account for the gain-of-function and autoinflammatory phenotype observed even in single-FMF-mutation carriers.

While the interaction of the N-terminal domain of pyrin with ASC sheds new light on the regulation of inflammation, it does not yet explain the molecular mechanism by which missense mutations in pyrin, many of which are at the C-terminal end of the protein, lead to autoinflammatory disease. Possibly, these mutations indirectly influence the effect of pyrin on IL-1β processing, apoptosis, and/or NF-κB activation, perhaps conferring a selective advantage by pushing the balance, under some circumstances, toward heightened innate immunity.

MUTATION ANALYSIS IN FMF

Prior to the identification of *MEFV,* FMF was thought to be primarily a disease of non-Ashkenazi Jews, Armenians, Arabs, and Turks. Availability of genetic testing has identified numerous cases among several additional populations with Mediterranean roots, including Ashkenazi Jews (Aksentijevich et al., 1999; Gershoni-Baruch et al., 2001; Kogan et al., 2001; Samuels et al., 1998; Stoffman et al., 2000), Italians (Aksentijevich et al., 1999; La Regina et al., 2003; Samuels et al., 1998), Greeks (Konstantopoulos et al., 2003), Spaniards (Touitou, 2001), and Cypriots (Deltas et al., 2002), and in a broad range of other ethnicities (Dode et al., 2000; Touitou, 2001). In some of these newly recognized patients, the clinical phenotype is milder than that of the classically affected ethnic groups, perhaps owing to documented differences in the population distribution of specific *MEFV* mutations.

Direct screening for mutations has confirmed previous estimates of extraordinarily high carrier frequencies in several ethnic groups. Carrier frequencies of at least 20 percent have now been established among North African, Iraqi, and Ashkenazi Jews, Arabs, Turks, and Armenians (Gershoni-Baruch et al., 2001; Kogan et al., 2001; Stoffman et al., 2000; Yilmaz et al., 2001). Since these figures overestimate the disease frequencies (Ozen et al., 1998; Yuval et al., 1995), it is likely that there are substantial numbers of individuals with two *MEFV* mutations but minimal symptoms. Recent family studies support this assertion (Tunca et al., 2002). The high frequencies combined with availability of genetic testing has led to a third subset of patients, phenotype III, described as subclinical or preclinical FMF, in which patients have two *MEFV* mutations but are asymptomatic.

As noted above, over half of the known mutations in *MEFV* are located in exon 10, a figure that is enhanced when the frequencies of the various mutations among patients are taken into account (Touitou, 2001). Among certain populations, such as Ashkenazi Jews, E148Q (exon 2) and P369S (exon 3) are also observed at relatively high frequency (Aksentijevich et al., 1999). For this reason, some commercial and academic laboratories screen for FMF by sequencing exon 10 and performing mutation-specific tests, such as restriction endonuclease assays, for E148Q and P369S.

Identification of specific mutations may have important implications for prognosis, and increased genetic testing has identified a spectrum of disease. E148Q may be the only

identifiable mutation in *trans* with an exon 10 mutation in patients with moderate to severe disease, yet asymptomatic individuals with the same genotype have been found within the same kindreds (Akar et al., 2001; Aksentijevich et al., 1999; Ben-Chetrit et al., 2001a; Booth et al., 2000; Samuels et al., 1998). At the other end of the genotype–phenotype spectrum is M694V. Studies of Jewish, Arab, and Armenian patients indicate that M694V homozygotes are at increased risk of amyloidosis, possibly through reduced responsiveness to colchicine (Brik et al., 1999; Cazeneuve et al., 1999; Gershoni-Baruch et al., 2002; Gershoni-Baruch et al., 2003; Majeed et al., 2002; Mansour et al., 2001), although data in the Turkish population are conflicting (Soylemezoglu et al., 2010; Turkish FMF Study Group, 2005). M694V homozygotes may also be at increased risk for arthritis and erysipeloid erythema, as well as for an early age of onset and frequent attacks (Brik et al., 1999; Cazeneuve et al., 1999; Dewalle et al., 1998; Gershoni-Baruch et al., 2002; Kone Paut et al., 2000). Although the data are less extensive, the M694I mutation may also confer increased risk of amyloidosis (Ben-Chetrit et al., 2001a; Mansour et al., 2001).

Mutational analysis has identified a substantial fraction (up to 30 percent) of patients with typical clinical findings of FMF, including a therapeutic response to colchicine, who have only one demonstrable *MEFV* mutation (Akar et al., 2000; Aksentijevich et al., 1999; Cazeneuve et al., 1999; Mansour et al., 2001; Medlej-Hashim et al., 2000; Padeh et al., 2003), even when the entire coding region is screened (Cazeneuve et al., 2003). It is possible that, at least on certain genetic backgrounds, a single *MEFV* mutation is sufficient to manifest symptoms. Consistent with this view, it is now well established that FMF carriers often exhibit biochemical evidence of intermittent inflammation, and there are at least two rare *MEFV* mutations (ΔM694 and the M694I-E148Q complex allele) that transmit clinically typical FMF in a dominant fashion (Booth et al., 2000). Finally, on the basis of Turkish FMF families unlinked to chromosome 16 (Akarsu et al., 1997) and FMF patients from Palma de Mallorca with no demonstrable *MEFV* mutations (Domingo et al., 2000), some have posited the existence of at least one additional FMF gene besides *MEFV,* perhaps accounting for the "mutation deficit" in symptomatic heterozygotes.

STRATEGIES FOR THE DIAGNOSIS OF FMF

In many instances, the possibility of FMF is first considered in a child with recurrent, unexplained episodes of fever, with or without the localized inflammatory manifestations described above. In Western countries, patients often experience multiple episodes over a period of several months before the diagnosis is entertained, and it is not unusual for such patients to have already undergone extensive evaluations for infection, malignancy, and, in some cases, inflammatory bowel disease. It is important to recall that there are occasional FMF patients without known Mediterranean heritage, and, owing to the recessive mode of inheritance of FMF and the small family size and increased mobility of Western society, about half of the patients in most series have no known family history of periodic fever.

A number of sets of clinical criteria were proposed prior to the identification of *MEFV,* the most widely quoted of which was developed at a large center in Tel-Hashomer, Israel (Livneh et al., 1997b). The various sets of criteria agree that the cardinal features of FMF are short (12 hour to 3 day), recurrent (three or more) episodes of fever (rectal temperature >38°C) with painful manifestations in the abdomen, chest, joints, or skin, in the absence of any other demonstrable causative factors. The Tel-Hashomer criteria enumerate milder attacks, exertional leg pain, and a favorable response to colchicine as minor criteria, and a positive family history, age of onset less than 20 years, appropriate ethnicity, parental consanguinity, an acute phase response during attacks, episodic proteinuria/hematuria, and an unproductive laparotomy as supportive criteria. The diagnosis is then established with appropriate combinations of major, minor, and supportive criteria.

Although the Tel-Hashomer criteria perform extremely well in high-risk populations, they probably do not work as well in Western nations, where the disease is milder (due to a different spectrum of mutations), physicians have had much less clinical experience with FMF, and the frequency of other hereditary periodic fevers may be higher than the frequency of FMF. Clinical features that may help differentiate FMF from the other hereditary periodic fevers include ethnicity, duration of attacks, type of skin rash, and responsiveness to colchicine (Table 33.1).

Genetic testing has assumed a major adjunctive role in the diagnosis of FMF and has extended both the clinical and the ethnic spectrum of FMF. Nevertheless, the aforementioned issues of sensitivity (the "mutation deficit") and penetrance underscore the need to consider clinical information in the interpretation of *MEFV* genetic test results (Booty et al., 2009).

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

Standard teaching is that FMF is inherited as an autosomal recessive disorder with reduced penetrance in females (M:F ratios approximately 1.5 to 1). Since the measured carrier frequencies for Jewish, Arab, Armenian, and Turkish populations are often more than 20 percent, in many cases this translates into a risk of 10 percent or more. However, we now know that some mutations, such as M694V, have greater penetrance than others, such as E148Q; that a few *MEFV* mutations truly show a dominant mode of inheritance; that there is a biochemical inflammatory phenotype associated with the FMF carrier state; and that a substantial number of patients (often with relatively mild symptoms) have only one demonstrable mutation. Although such information complicates genetic counseling, it has been widely enough recognized to deserve inclusion in the information provided to patients and their families.

Given the rare occurrence of FMF phenotype II, in which patients present with amyloidosis as the first manifestation of the disease, the question may be raised whether asymptomatic relatives of FMF patients should be screened for *MEFV* mutations, perhaps with the intention of initiating prophylactic

colchicine in those individuals who test positive for two mutations. In Western nations in which phenotype II is exceedingly rare, where the M694V frequency is low and amyloidosis is uncommon even in patients with FMF, screening of asymptomatic family members is generally not performed, since the discovery of "genetic FMF" may adversely affect the insurability of individuals who may never develop symptoms. There is still no consensus on presymptomatic screening in families with a strong history of amyloidosis, and some would advocate careful follow-up rather than colchicine prophylaxis in asymptomatic family members with two mutations.

Prenatal diagnosis of FMF is feasible but requires careful genetic counseling to appropriately explain decreased penetrance and interpretation of heterozygous genotypes. In addition, given the relative effectiveness of colchicine therapy, prenatal diagnosis raises significant moral and ethical issues regarding the possible termination of pregnancy for what many regard to be a treatable disease.

TREATMENT AND PROGNOSIS

Daily oral colchicine therapy has been established as effective in preventing both the acute attacks of FMF and systemic amyloidosis. Nearly three fourths of adult FMF patients taking 1.2 to 1.8 mg of colchicine per day experience a near-complete remission of their attacks, and over 90 percent demonstrate a marked improvement. Colchicine may cause diarrhea or gastrointestinal upset, but this side effect can be minimized by starting at a low dose and gradually titrating upward, and by dividing the daily dose. In some patients the gastrointestinal effects of colchicine are aggravated by lactose intolerance (Fradkin et al., 1995), and a lactose-free diet may be helpful. Colchicine is safe in children and has been shown to have beneficial effects on height and weight parameters (Zung et al., 2006), but it must be carefully titrated to efficacy and toxicity (Ozkaya et al., 2003; Zemer et al., 1991).

Oral colchicine may also prevent amyloid progression in FMF patients who already have proteinuria due to amyloidosis (Akse-Onal et al., 2010; Livneh et al., 1994b; Oner et al., 2003; Sevoyan et al., 2009; Simsek et al., 2000). The prognosis is best if the serum creatinine is less than 1.5 mg/dL and is adversely affected by tubulointerstitial disease at diagnosis and by noncompliance. Doses of 1.5 mg per day or more are most effective in these patients, as well as in patients who have already undergone renal transplantation (Livneh et al., 1992). Posttransplant colchicine may be even more important in preventing renal allograft interstitial fibrosis, as well as amyloid recurrence, and could account for better graft survival rates (Ozdemir et al., 2006). The combination of colchicine and cyclosporine should be avoided when possible in transplant patients, since cyclosporine inhibits the MDR1 transport system required for hepatic and renal colchicine excretion (Gruberg et al., 1999; Minetti et al., 2003; Simkin et al., 2000; Speeg et al., 1992).

Agents that inhibit or compete for the hepatic cytochrome P450 system component CYP 3A4, such as cimetidine, erythromycin, lovastatin, and grapefruit juice, may increase colchicine blood levels (Ben-Chetrit et al., 1998b). Colchicine toxicity other than diarrhea is rare in patients taking standard doses but can occur in the presence of inhibitors of clearance, in elderly patients with renal insufficiency (Altiparmak et al., 2002; Kuncl et al., 1987), or if colchicine is given intravenously to abort an attack in patients already receiving oral colchicine (Bonnel et al., 2002; Putterman et al., 1991; Wallace et al., 1988).

Most experts advise continuing colchicine in female FMF patients during conception and pregnancy. Previously, performing an amniocentesis during the second trimester was proposed to screen for the slightly increased risk of trisomy 21 (Ben-Chetrit et al., 2003). However, retrospective studies (Ben-Chetrit et al., 2010) and a recent prospective observational comparative cohort study examining 238 colchicine-exposed pregnancies demonstrated no increased risk of cytogenetic anomalies (Diav-Citrin et al., 2010), but the issue remains open for further study. Although small concentrations are present in the breast milk of women taking colchicine, breast-feeding is considered safe (Ben-Chetrit et al., 1996).

Colchicine may prevent the attacks of FMF by multiple mechanisms. Colchicine is concentrated in granulocytes, perhaps because these cells express only low levels of the *MDR1*-encoded P-glycoprotein pump (Ben-Chetrit et al., 1998c, 1998d). Through its interaction with microtubules or other less well-defined mechanisms, colchicine inhibits L-selectin expression on neutrophils (Cronstein et al., 1995), which inhibits neutrophil chemotaxis (Bar-Eli et al., 1981; Dinarello et al., 1976). Furthermore, colchicine inhibits the P2X7 pore formation, which is necessary for ATP-induced inflammasome activation and, consequently, IL-1β release from immune cells (Marques-da-Silva et al., 2011).

The management of patients with FMF who do not respond well to colchicine remains controversial, and several adjunctive approaches have been investigated, including subcutaneous interferon-α (Calguneri et al., 2004a, 2004b; Tunca et al., 1997, 2004; Tweezer-Zaks et al., 2008) and weekly low-dose intravenous colchicine (Lidar et al., 2003). More recently, biological therapies targeting TNF (Erten et al., 2011; Ozgocmen et al., 2011) or IL-1β have shown promising results. Specifically targeting IL-1β, given its underlying role in the pathogenesis of FMF, has demonstrated significant benefit in reducing the frequency and severity of attacks, lowering acute phase reactants, and leading to the resolution of proteinuria ε (Meinzer et al., 2011; Mitroulis et al., 2008, 2011; Ozen et al., 2011). Allogeneic bone marrow transplantation has also been proposed as a treatment for refractory FMF (Milledge et al., 2002), but many experts regard the risk–benefit ratio as unacceptable (Touitou et al., 2003).

In a large majority of patients with FMF, the prognosis on standard colchicine therapy is excellent, allowing for a full range of activities and a normal lifespan. Amyloidosis is the major life-limiting manifestation of FMF, but fortunately the incidence is much reduced with colchicine prophylaxis. Renal transplantation has proven to be effective in patients who take adequate doses of colchicine in the posttransplant period, with graft survival similar to non-amyloidotic controls (Celik et al., 2006). Patients who respond poorly to colchicine are

often very impaired functionally and are a major therapeutic priority.

ANIMAL MODELS

Chae et al. (2003) reported the development of a mouse line expressing a truncated, hypomorphic form of pyrin and an inflammatory phenotype. Consistent with the role of pyrin in IL-1β maturation, peritoneal macrophages from these mice exhibited increased caspase 1 activation and increased IL-1β processing and secretion. Peritoneal macrophages from these animals also exhibited a defect in apoptosis that was independent of IL-1β but associated with impaired caspase 8 cleavage. Low doses of bacterial LPS induced an accentuated body temperature response in homozygous mutant mice, and higher doses induced increased lethality in the homozygous mutants relative to wild type. Moreover, the induction of inflammatory peritoneal exudates by thioglycollate was increased in homozygous mutants relative to heterozygotes or wild-type mice.

To study the pathogenesis of specific mutations in pyrin that lead to FMF, the same group generated various gene insertion or "knock-in" murine models using the frequent mutations M680I, M694V, and V726A. Contrary to the truncated pyrin model described above, these mice display a profound inflammatory phenotype, comparable to that observed in FMF patients (Chae et al., 2011). This model confirms that bone marrow-derived cells, specifically granulocytes, are necessary for the disease phenotype, as observed in in vitro studies and transmission following allogeneic bone marrow transplant from a affected donor in human patients (Petropoulou et al., 2010; Touitou et al., 2007a). The role of IL-1β is further implicated, as crossing knock-in mice with IL-1-receptor-deficient mice led to attenuation of inflammatory disease. Additional crosses revealed that mutant PYRIN mediated the activation of ASC and caspase 1 independently of NLRP3, but the stimulus for activation of PYRIN itself remains unknown. As the increased availability of genetic testing has led to the recognition of patients heterozygous for MEFV mutations, with subclinical or mild phenotypes, this model has important implications for a gain-of-function role of PYRIN mutations (Chae et al., 2011).

TNF RECEPTOR-ASSOCIATED PERIODIC SYNDROME

The name "familial Hibernian fever" (FHF; MIM142680) was first proposed to describe a large family of Irish/Scottish ancestry afflicted with recurrent episodes of fever, abdominal pain, myalgia, and erythematous rash that responded to corticosteroid but not colchicine treatment (Williamson et al., 1982). Fifteen years later, a follow-up report confirmed a dominant mode of inheritance in this family and extended the clinical phenotype to include conjunctivitis, periorbital edema, and systemic AA amyloidosis (McDermott et al., 1997). Several other reports described families with similar dominantly inherited inflammatory symptoms from different ethnic backgrounds (Bergman et al., 1968; Gadallah et al., 1995; Gertz et al., 1987; Hawle et al., 1989; Karenko et al., 1992; Mache et al., 1996; Zaks et al., 1997; Zweers et al., 1993).

In 1998, two independent groups mapped the susceptibility loci for FHF and an Australian (Scottish) variant denoted "familial periodic fever syndrome" to chromosome 12p13 (McDermott et al., 1998; Mulley et al., 1998), suggesting that the same locus was responsible for both syndromes. Candidate gene analysis, the central role of TNF signaling in inflammation, and the observation of reduced levels of the soluble p55 receptor in the serum of several patients with FHF led to the identification of mutations in *TNFRSF1A,* which encodes the 55 kDa receptor for TNF (also known as TNFR1, TNFRSF1A, p55, p60, and CD120a; McDermott et al., 1999). The discovery of mutations in *TNFRSF1A* consolidated these clinical variants into a single nosological entity denoted the TNF receptor-associated periodic syndrome (TRAPS).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF TRAPS

In the largest single group of TRAPS patients reported to date (Hull et al., 2002b), the median age of onset of symptoms was 3 years, ranging from 2 weeks to 53 years of age. Males and females are affected equally. In contrast with FMF, the duration of TRAPS attacks is quite variable (Dode et al., 2002a), ranging from short episodes of 1 to 2 days to month-long flares; in rare cases, patients experience nearly continuous, fluctuating symptoms (McDermott et al., 1997). At the onset of an attack, inflammatory symptoms, such as muscle cramping, abdominal pain, or pleuritic chest pain, may be relatively subtle, gradually increasing over the course of 1 to 3 days. Pain often persists at its maximum intensity for several days before gradual resolution. The onset of attacks has been described with physical or emotional stress, menses, or local trauma, but in many cases there does not appear to be a definite provoking stimulus. In women, pregnancy is sometimes associated with remission (Kriegel et al., 2003; McDermott et al., 1997), with possible exacerbation during the postpartum period (Rosen-Wolff et al., 2001).

Nearly all patients develop fever in association with their attacks, although it may be absent during some attacks in adults. Temperature greater than 38°C (maximally 41°C) usually lasts for more than 3 days, often heralding the onset of other inflammatory symptoms.

Serosal involvement is a prominent feature of TRAPS (Hull et al., 2002b). Attacks consisting solely of fever and abdominal pain occur in over 90 percent of patients with TRAPS and can be the result of inflammation of the peritoneum, the abdominal musculature, or both. Serosal inflammation often produces the physical findings of an acute abdomen, and approximately half of the patients in one series had undergone at least one laparoscopy or exploratory laparotomy. Findings frequently include mononuclear infiltrates in the bowel wall or peritoneal adhesions, which eventually can cause bowel necrosis. Pleuritic attacks, with or without radiographic evidence of effusion, occur in about 50 percent of TRAPS patients. Less

common serosal manifestations include pericarditis and episodes of scrotal pain.

Localized myalgia is extremely common during TRAPS attacks. The myalgia of TRAPS manifests as cramplike discomfort, fluctuating in severity but disabling at its worst. Affected areas are warm, tender to palpation, and often associated with an erythematous patch. When found on an extremity, the myalgia and rash of TRAPS characteristically migrate centrifugally (as opposed to spreading) from proximal to distal limb over several days. As the region of inflammation passes over a joint (e.g., knee or elbow), there is often evidence of synovitis and effusion, with transient contracture. Although most commonly affecting the limbs and torso, the myalgia and rash of TRAPS can also occur on the face and neck. During the episodes of myalgia, serum creatine kinase and aldolase concentrations remain normal. MRI demonstrates focal areas of edema in the affected muscular compartments and intramuscular septa (Hull et al., 2002d), and this may persist between episodes (Quillinan et al., 2010). The limited number of biopsies reported in TRAPS patients with active myalgia have demonstrated monocytic fasciitis or lymphocytic vasculitis, but not myositis (Drewe et al., 2003a; Hull et al., 2002d).

TRAPS attacks frequently lead to arthralgia or arthritis, either as a part of the migratory myalgia picture or independently. Polyarticular arthralgia is by far the most common rheumatic manifestation of TRAPS. The arthritis of TRAPS tends to be nonerosive and either monoarticular or pauciarticular and asymmetrical, most commonly affecting the hips, knees, and ankles.

The most distinctive of the cutaneous manifestations of TRAPS is the aforementioned centrifugally migratory erythematous rash (Plate 33.III), sometimes overlying areas of myalgia (Toro et al., 2000). Such lesions are warm and tender, blanch on palpation, and may reach 30 cm in diameter. Histologically, there is a superficial and deep perivascular and interstitial mononuclear cell infiltrate, sometimes with a low-grade lymphocytic vasculitis (Toro et al., 2000). Other less unusual rashes include urticaria-like plaques and serpiginous erythematous patches and plaques (Toro et al., 2000). These variants often involve several different areas of the body simultaneously and are neither migratory nor associated with concurrent myalgia. Relapsing episodes of panniculitis have also been reported in TRAPS (Lamprecht et al., 2004).

Eye involvement occurs in over 75 percent of patients (Hull et al., 2002b). The most frequent ocular findings are conjunctivitis and periorbital edema. Uveitis is relatively rare but should be considered in patients experiencing blurred vision or eye pain.

As in other fever disorders, systemic amyloidosis is the most serious complication of TRAPS (Dode et al., 2002b; Jadoul et al., 2001; Simon et al., 2001b). The frequency of amyloidosis among reported cases is currently about 10 percent. Nephrotic syndrome and renal failure are the most common consequences; there is also one case of hepatic transplantation due to TRAPS amyloidosis reported in the literature (Hull et al., 2002b).

LABORATORY FINDINGS IN TRAPS

The attacks of TRAPS are nearly always associated with a vigorous acute phase response (Hull et al., 2002b), including an accelerated ESR and increased CRP, haptoglobin, fibrinogen, C3 and C4 complement, and ferritin. Although not widely available, the SAA level represents the most sensitive and rapid measure of the acute phase response and may be an important determinant to monitor in patients with systemic amyloidosis (Gillmore et al., 2001). During attacks patients may have prominent leukocytosis and neutrophilia, sometimes with white counts above 20,000/mm^3, and children often have thrombocytosis.

TRAPS patients frequently manifest biochemical evidence of ongoing inflammation even between their acute episodes, although the magnitude of laboratory abnormalities may be diminished. The anemia of chronic disease is common among patients with frequent attacks, and a moderate polyclonal gammopathy is often seen. Although usually normal, modest elevations in the serum IgD have been reported (Dode et al., 2002a; Simon et al., 2001c). Low-titer anticardiolipin antibodies and antinuclear antibodies are seen in a minority of patients.

Albuminuria, usually without significant hematuria, is the most common manifestation of systemic amyloidosis in TRAPS. Initially, renal function is normal, although TRAPS amyloidosis may progress to renal failure within 1 to 2 years. Hepatic involvement usually causes an elevated alkaline phosphatase with normal transaminases.

MOLECULAR BASIS OF TRAPS: THE DISEASE GENE, TNFRSF1A

TNFRSF1A is a 10-exon gene with a 455 codon open reading frame (Fuchs et al., 1992; Loetscher et al., 1990). The encoded protein has a 29 a.a. leader, a 182 a.a. extracellular domain, a 21 a.a. transmembrane domain, and a 223 residue intracellular domain. At the time of this writing, more than 65 mutations in *TNFRSF1A* have been reported in patients with recurrent episodes of fever and inflammation, and an updated database of mutations is available online at the Infevers website (http://fmf.igh.cnrs.fr/infevers/; Milhavet et al., 2008). There are several mutational "hot spots," including five at cysteine residues (C30, C33, C52, C70, and C88, numbered relative to the leucine immediately following the cleavage of the signal peptide) and four noncysteine residues (Y20, H22, T50, and R92). To date, no patients have been identified with mutations in the transmembrane or intracellular domains of the TNFRSF1A protein; null mutations; or mutations in the p75 TNF receptor (TNFRSF1B). Several reports have described families or individuals with TRAPS-like clinical findings but no demonstrable mutations in *TNFRSF1A*, raising the possibility of locus heterogeneity (Aganna et al., 2003; Aksentijevich et al., 2001; Dode et al., 2002a).

FUNCTION OF THE P55 TNF RECEPTOR, THE TNFRSF1A GENE PRODUCT

TNF is a proinflammatory cytokine with pleiotropic biological effects (Vassalli, 1992). At a cellular level, TNF stimulation

can lead either to activation of various signaling pathways (NF-κB or JNK) or apoptosis. As noted above, there are two cellular receptors for TNF, a 55 kDa protein encoded on chromosome 12p13 (TNFRSF1A) and a 75 kDa receptor encoded on chromosome 1p36 (TNFRSF1B) (Smith et al., 1990). Both are members of a family of cell-surface receptors with repeating cysteine-rich extracellular domains (CRDs) (Bazzoni et al., 1996). Both receptors have four extracellular CRDs with intrachain disulfide bonds stabilizing the structure of each CRD. The intracellular segment of the p55 receptor also includes an death domain that is involved in signal transduction (Hsu et al., 1995). The p55 receptor is expressed widely, while the p75 receptor is expressed predominantly on leukocytes and endothelial cells.

TNF forms homo-trimers that, in turn, aggregate homotrimers of either p55 or p75 receptors on the cell surface (Engelmann et al., 1990). All of the cysteine mutations as well as some other mutations (T50M) in the p55 receptor are predicted to have a major effect on its three-dimensional structure, since they would prevent the formation of highly conserved disulfide bonds important to maintaining proper folding of the molecule (Rebelo et al., 2006). Initially, evidence was presented that mutant p55 receptors are refractory to activation-induced cleavage of the ectodomain, a homeostatic process that normally limits repeated signaling at the cell surface and creates a pool of potentially antagonistic soluble receptors (Fig. 33.2). The so-called "shedding" hypothesis was supported by diminished levels of soluble p55 in the serum of several TRAPS patients and increased membrane p55 and reduced activation-induced clearance on peripheral blood leukocytes from patients with one mutation (C52F). Impaired receptor shedding has been observed by flow cytometry in leukocytes from patients with nine mutations (H22Y, C30S, C33G, P46L, T50M, T50K, C52F, F112I, and I170N) (Aganna et al., 2003; Aksentijevich et al., 2001; McDermott et al., 1999; Nevala et al., 2002). The mechanism by which specific disease-associated mutations impair cleavage most likely represents an indirect structural effect, since all but one of the known mutations are remote from the metalloprotease-induced cleavage site (Gullberg et al., 1992).

Current evidence suggests that impaired ectodomain cleavage is unlikely to be the primary explanation for the TRAPS phenotype, since shedding appears to be normal in many patients (Aganna et al., 2003; Aksentijevich et al., 2001; Huggins et al., 2004). Disease-associated mutations have been shown to affect receptor folding and trafficking, resulting in retention of the receptor in the endoplasmic reticulum, loss of normal TNF signaling function, inability to interact with normal TNF receptors, and reduced turnover of mutant TNF receptors (Lobito et al., 2006; Simon et al., 2010; Todd et al., 2004). Intracellular accumulation of the mutant receptor has been shown to activate various signaling pathways, resulting in cytokine-mediated inflammation (Simon et al., 2010). This is supported by the finding of upregulation of several cytokine pathways, altered NF-κB signaling, and defective apoptosis pathways in many patients (D'Osualdo et al., 2006; Nedjai et al., 2008, 2009, 2011; Rebelo et al., 2009; Siebert et al., 2005; Simon et al., 2010; Stjernberg-Salmela et al., 2010), but some of these changes may vary with the specific mutation (Rebelo et al., 2009). In addition, TRAPS patient cells are hyperresponsive to innate immune signals (Simon et al., 2010) and exhibit altered mitochondrial function with enhanced oxidative capacity due to mitochondrial reactive oxygen species generation (Bulua et al., 2011) (Fig. 33.2).

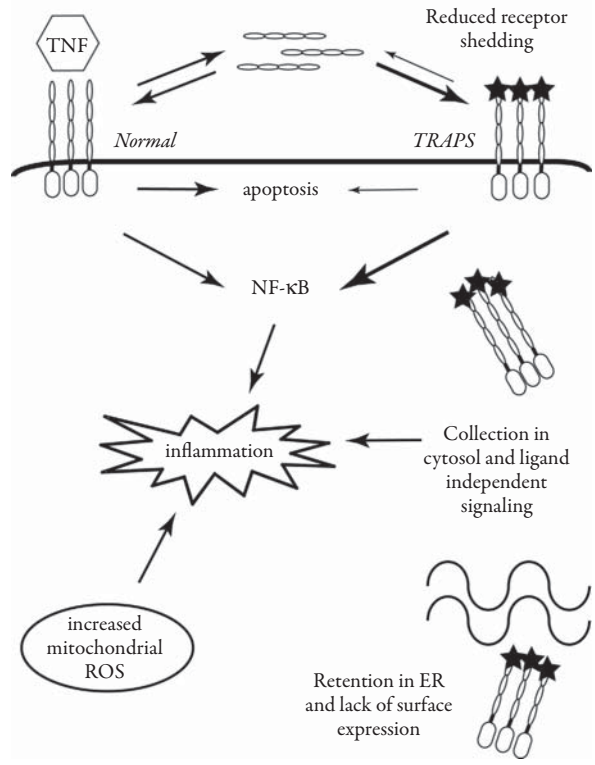

Figure 33.2 Summary of proposed mechanisms of pathogenesis in TNF receptor-associated periodic syndrome (TRAPS). Mutations in the p55 TNF receptor may have several effects on intracellular trafficking, receptor expression, and subsequent signaling following binding of TNF. Reduced metalloprotease cleavage may lead to impaired shedding of sTNFRSF1A and decreased TNF antagonist activity. Mutations affecting surface expression of the TNF receptor may result from structural misconformation with retention of receptor subunits in the endoplasmic reticulum (ER) or collection of p55 in the cytosol with signaling independent of TNF-binding, amplified by enhanced ROS production. Stars denote the presence of mutations.

MUTATION ANALYSIS IN TRAPS

Almost all of the mutations are in exons 2 to 4 of the 10 exon gene and are in the first two cysteine-rich domains (those furthest from the membrane) of the receptor protein. Therefore, traditional mutational screening has focused on these high-probability regions of the gene. The conventional system for numbering mutations in TRAPS found in this chapter and most published reports denotes the leucine that immediately follows the cleavage of the signal peptide as residue 1. Inclusion of the signal peptide would increase these numbers by 29.

There is some genotype–phenotype correlation in that cysteine mutations are often associated with more severe disease and a higher risk of amyloidosis, which may be due to different functional effects of mutations (Rebelo et al.,

2006). However, significant variation in severity has been observed within patients with the same mutation, even within the same family (Lehmann et al., 2010). Furthermore, two specific noncysteine *TNFRSF1A* mutations are sufficiently common to be considered polymorphisms in some populations (Aksentijevich et al., 2001; Ravet et al., 2006). R92Q, which is present in almost half of the independent TRAPS chromosomes identified in a large cohort followed at the U.S. National Institutes of Health, is also present in approximately 1 percent of Caucasian control chromosomes. Since the population frequency of TRAPS is far less than 1 percent, the penetrance of this variant must be low. However, data are accumulating that the TRAPS phenotype is but one end of a spectrum of inflammatory conditions associated with R92Q (Cantarini et al., 2009; Pelagatti et al., 2011). Similarly, the P46L variant is found in approximately 2 percent of African-American control chromosomes (Aksentijevich et al., 2001) and at an even higher frequency among some sub-Saharan African populations (Tchernitchko et al., 2004).

STRATEGIES FOR THE DIAGNOSIS OF TRAPS

Clinical suspicion is the cornerstone of the diagnosis of TRAPS. Among the clinical features of TRAPS that help distinguish it from the other periodic fever syndromes are the duration of attacks (episodes lasting >1 week suggest TRAPS, although shorter attacks can be seen), the migratory myalgia and overlying erythematous rash, the presence of periorbital edema during attacks, a dominant pattern of inheritance, and the differential response to corticosteroids over colchicine (Table 33.1). Systemic-onset juvenile idiopathic arthritis (SOJIA) and adult-onset Still's disease can be distinguished by the fever pattern (temperatures usually return to normal or below normal each day), the clinical course of the arthritis (progressive, erosive polyarticular arthritis), and the cutaneous manifestations (evanescent salmon-colored macular or maculopapular rash).

Once the clinical suspicion has been established, the diagnosis of TRAPS may be confirmed by *TNFRSF1A* sequence analysis. Most diagnostic laboratories routinely screen exons 2 to 5 of the gene, which would detect most of the currently known mutations. More complete sequencing may be entertained if the clinical suspicion is high, but the yield is relatively low. As in FMF and the cryopyrinopathies, there are numerous sporadic and some familial cases that clinically resemble TRAPS but do not have *TNFRSF1A* mutations, suggesting involvement of additional genes (Cantarini et al., 2012).

Serum levels of soluble p55 receptor, while of theoretical interest, have not proven to be an adequate substitute for genetic testing since they can be low, normal, or high among patients who are suspected of having TRAPS but are found to be mutation negative (Aganna et al., 2003). Moreover, although some mutation-positive TRAPS patients do have low levels of soluble p55, inflammatory attacks or renal insufficiency can spuriously normalize soluble p55 measurements.

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

Although TRAPS is inherited in an autosomal dominant fashion, penetrance is not 100 percent, even for substitutions at cysteine residues. Further complicating the issue, several cases of de novo *TNFRSF1A* mutations have been reported (Aganna et al., 2002b, 2003). Careful history taking can sometimes identify unsuspected cases among the allegedly unaffected relatives of TRAPS patients, and genetic testing is of benefit in establishing the correct diagnosis in these individuals. Genetic testing may also be warranted for asymptomatic relatives in families with a strong history of TRAPS-associated amyloidosis. However, in cases where the risk of amyloidosis is low, the possible benefits of identifying other mutation-positive asymptomatic relatives should be weighed against the potential impact of such information on insurability. Similarly, the use of molecular techniques for prenatal diagnosis should be approached with great caution, since there are still insufficient data to make reliable estimates of penetrance, and effective, targeted cytokine-inhibitory therapies are now available.

TREATMENT AND PROGNOSIS

In contrast with FMF, colchicine prevents neither the acute attacks nor the amyloidosis of TRAPS (Dode et al., 2002b; Hull et al., 2002b). The efficacy of nonsteroidal anti-inflammatory drugs is limited to mild attacks. Short courses of oral or parenteral corticosteroids may be effective in more severe episodes, but escalating doses are often required, with the attendant toxicities. Initial studies demonstrated that twice- or thrice-weekly administration of etanercept, the p75 TNFR:Fc fusion protein, was effective in reducing, although usually not eliminating, the clinical and laboratory manifestations of TRAPS and reducing corticosteroid use (Drewe et al., 2003b; Galon et al., 2000; Hull et al., 2002a, 2002b; Kastner et al., 1999; Lamprecht et al., 2004; Nigrovic et al., 2001; Simon et al., 2001c; Weyhreter et al., 2003). Etanercept may also have a role in preventing amyloid deposition, although monitoring of SAA levels is necessary to titrate the dosage (Drewe et al., 2000, 2004; Hull et al., 2002c). However, the response is highly variable and positive effects may not be sustained, as there are reports of patients with progressive amyloidosis while on etanercept therapy (Hull et al., 2002c; Simsek et al., 2010). Other anti-TNF antibody therapies, such as infliximab, have either been ineffective or have had a paradoxical response with worsening symptoms (Bodar et al., 2007a; Drewe et al., 2007; Jacobelli et al., 2007; Nedjai et al., 2009).

More recently, the use of other non-TNF biologics has shown promise in the treatment of TRAPS. A number of case reports and two small series have demonstrated the efficacy and safety of anakinra in patients with TRAPS who had persistent symptoms despite treatment with daily prednisone or with etanercept. Daily subcutaneous anakinra eliminated symptoms and led to normalization of CRP and SAA and to the resolution of proteinuria with stabilization of renal function (Gattorno et al., 2008; Obici et al., 2011; Sacre et al., 2008; Simon et al., 2004a). Additionally, a preliminary report

of one patient with TRAPS demonstrated that treatment with tocilizumab (IL-6 antibody) aborted an evolving attack and prevented further attacks of TRAPS during the therapeutic period and reduced acute phase reactants (Vaitla et al., 2011). These early studies suggest that biological modulation of other inflammatory cytokines may be effective treatment options for patients with refractory symptoms, and are consistent with the role of multiple cytokine pathways in the pathogenesis of TRAPS.

The prognosis of TRAPS is largely related to development of systemic amyloidosis, which is more frequent among patients with cysteine substitutions or a positive family history of amyloidosis (Aksentijevich et al., 2001; Kallinich et al., 2004). Infrequently, TRAPS patients develop life-threatening abdominal complications, such as bowel obstruction, abscesses, or necrosis.

ANIMAL MODELS

Kollias et al. reported knock-in mice that express a nonsheddable p55 TNF receptor with a mutation at the cleavage site (Xanthoulea et al., 2004). These mice exhibited a dominantly inherited autoinflammatory phenotype that supports the hypothesis that TNF receptor shedding is an important negative homeostatic mechanism. Mutant mice developed chronic active hepatitis, were more susceptible to the toxic effects of bacterial LPS and TNF, and exhibited increased susceptibility to experimental autoimmune encephalomyelitis and TNF-induced arthritis. Moreover, macrophages from these mice exhibited increased innate immune responses to Toll-like receptor stimulation.

Recently, knock-in mice with disease-associated missense mutations were reported that confirmed functional studies in humans supporting intracellular accumulation of mutant receptors and enhanced mitochondrial oxidative capacity. Heterozygous mutant mice were hypersensitive to LPS-induced shock while homozygous mice were resistant, similar to TNFR1 knockout mice, suggesting functional cooperation of WT and mutant receptors in TRAPS consistent with an autosomal dominant model. In addition, pharmacological blockade of mitochondrial reactive oxygen species (ROS) reduced the inherent hyperresponsiveness in these mice, emphasizing that multiple intracellular signaling pathways may contribute to the inflammatory attacks in TRAPS (Bulua et al., 2011; Simon et al., 2010).

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS, MIM 260920) was initially described as a unique disorder in 1984, in six Dutch patients with a clinical picture similar to FMF but distinguishing features of prominent lymphadenopathy and less severe abdominal symptoms than usually seen with FMF, as well as their Dutch ancestry (without relatives of the typical ethnicities for FMF) (van der Meer et al., 1984). Moreover, all six Dutch patients were found to have polyclonal elevations in their serum IgD levels, and all five of the Dutch patients who underwent bone marrow aspiration and biopsy had markedly increased numbers of δ^+ plasma cells in the marrow. The HIDS nomenclature was proposed to describe this apparently new periodic fever syndrome as a clinical entity (Drenth et al., 1994b).

Three of the initial patients had a positive family history, but it was only after additional patients and families were identified that a clear autosomal recessive mode of inheritance was apparent (Drenth et al., 1994c; Livneh et al., 1997a). In 1999, 15 years after its initial description, two groups from the Netherlands independently discovered HIDS-associated mutations in *MVK,* the gene encoding mevalonate kinase, an enzyme involved in cholesterol and nonsterol isoprene biosynthesis (Drenth et al., 1999; Houten et al., 1999). Although not well understood, *MVK* mutations still account for most cases of clinical HIDS (Simon et al., 2001a). Nevertheless, as is the case for both FMF and TRAPS, elucidation of the underlying gene has permitted recognition of additional complexity. Thus, it is now clear that some periodic fever patients have raised serum IgD levels without *MVK* mutations (Simon et al., 2001a), while others with *MVK* mutations have normal IgD levels (Frenkel et al., 2000; Houten et al., 1999; Saulsbury, 2003; Takada et al., 2003). As we gain further insight into the role of the mevalonate pathway in regulating inflammation, the study of HIDS promises dividends that will extend far beyond these patients.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF HIDS

HIDS was first recognized in the Netherlands, and even 20 years later the majority of reported cases are of Dutch or neighboring northern European ancestry (Drenth et al., 2001a; Simon et al., 2003). Typically, febrile attacks begin within the first year of life, often precipitated by childhood immunizations, and there is no gender bias (Drenth et al., 1994b). The duration of attacks, 3 to 7 days, is somewhat longer than the duration of FMF attacks but shorter than the episodes sometimes seen in TRAPS. In addition to immunizations, minor infections, trauma, surgery, and menses may trigger attacks. On average attacks occur about once or twice a month, but usually without true periodicity, in childhood and adolescence. Attacks may become less frequent or severe in adults, with the majority of patients reporting more attacks prior to the age of 20 years and fewer attacks after the age of 20 years (van der Hilst et al., 2008a).

The attacks of HIDS often begin with chills and headache. In children, diffuse tender lymphadenopathy, particularly in the cervical chains, is common and is much more frequent than in FMF or TRAPS. As in the latter two disorders, abdominal pain is often present during attacks. Although the incidence of peritoneal signs in HIDS is much lower than in FMF or TRAPS (Drenth et al., 1994b; Livneh et al., 1997a), some patients may still present with an acute abdomen, prompting suspicion for appendicitis or mimicking inflammatory bowel disease and resulting in exploratory surgery (Oretti et al.,

2006; van der Hilst et al., 2008a). Moreover, whereas the abdominal attacks of FMF and TRAPS are frequently associated with constipation, because of decreased peristalsis, the abdominal attacks of HIDS are often accompanied by diarrhea and vomiting. Nevertheless, nearly 10 percent of patients with HIDS do develop adhesions, probably due to recurrent, sterile, peritoneal inflammation (van der Hilst et al., 2008a). Scrotal pain (Saulsbury, 2003) and pericarditis (Breda et al., 2009) have been reported in HIDS, but pleurisy has not been observed.

HIDS can present with a number of different mucocutaneous findings, including diffuse, painful, erythematous macules, a diffuse, erythematous macular and papular rash (Plate 33.IV), erythematous papules and nodules, urticaria, and a morbilliform rash (Drenth et al., 1994a, 1994b). Unlike FMF, there is no predilection for the feet, ankles, or lower legs, and, unlike TRAPS, the rash of HIDS is not migratory. Histologically, cutaneous vasculitis, perivascular inflammatory cells, and deposits of IgD, IgM, or C3 may be present. Other forms of cutaneous vasculitis reported in HIDS include Henoch-Schönlein purpura (Haraldsson et al., 1992) and erythema elevatum diutinum (Miyagawa et al., 1993). Aphthous ulcers of the mouth and vagina may also be seen in HIDS, which, in combination with fever and cervical lymphadenopathy, may be confused with the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and adenopathy (see below) (Marshall et al., 1987, 1989; Thomas et al., 1999).

Joint manifestations are the third most common symptom of HIDS, after abdominal pain and lymphadenopathy, and are most frequently reported as polyarthralgia (Drenth et al., 1993, 1994b; Haraldsson et al., 1992; Loeliger et al., 1993). HIDS may also present with intermittent episodes of polyarticular arthritis of the large joints, usually but not always with fever, and sometimes coinciding with abdominal attacks. Arthritic attacks are more common in children and are usually nondestructive, although joint contractures have been reported in four patients with HIDS (van der Hilst et al., 2008a). As in FMF, the sterile synovial fluid is rich in granulocytes.

Ocular symptoms tend to be limited to the more severe cases of mevalonic aciduria, consisting of retinal dystrophy, optic atrophy, and cataracts. Until recently, no cases of ocular inflammation had been reported in HIDS.

Systemic amyloidosis is uncommon in HIDS but has been reported (D'Osualdo et al., 2004; Obici et al., 2004; Siewert et al., 2006; Tsimaratos et al., 1999) with an estimated frequency of less than 3 percent of patients (van der Hilst et al., 2008b). Despite elevated levels of SAA, both during and between attacks, there is no progression to amyloidosis in most patients with HIDS (van der Hilst et al., 2005). This was previously postulated to be secondary to the milder phenotype, or resolution of the inflammatory episodes in adulthood. However, in vitro human cell culture studies of the HMG-CoA reductase inhibitor lovastatin as a model for the deficiency of isoprenoid products as seen in MVK deficiency have demonstrated that the isoprenoid pathway may play a critical role in the development of amyloid deposits (van der Hilst et al., 2008b). This suggests that mutations in MVK may offer some level of protection against amyloid-induced end-organ disease and, perhaps more importantly, identifies statins as a potential therapeutic agent for patients with autoinflammatory disorders that are susceptible to amyloidogenesis (van der Hilst et al., 2008b).

LABORATORY FINDINGS IN HIDS

Prior to the identification of the underlying gene, HIDS was defined by the polyclonal elevation of the serum IgD (>100 IU/mL or >14.1 mg/dL) on two occasions at least 1 month apart (Drenth et al., 1994b). While the vast majority of *MVK* mutation-positive patients with recurrent fevers meet this criterion, a small percentage of these patients do not. Serum IgD levels do not correlate with the severity of HIDS, either when following an individual patient or when comparing patients, and do not predictably fluctuate with attacks (Drenth et al., 1994b; Hiemstra et al., 1989). Over 80 percent of HIDS patients also have persistent polyclonal increases in serum IgA levels, the significance of which remains unclear (Haraldsson et al., 1992; Hiemstra et al., 1989; Klasen et al., 2001). Although it has been postulated that mevalonate pathway products modulate the induction or survival of IgD-producing B cells (Chen et al., 2011), the true mechanism by which mevalonate kinase deficiency influences IgD levels remains unknown.

As in FMF and TRAPS, during their inflammatory attacks HIDS patients present with leukocytosis and a left shift, an accelerated ESR, elevated acute phase reactants (including CRP and SAA), and occasionally transient hematuria (Drenth et al., 1994b, 2001a; Frenkel et al., 2000). Serum levels of several proinflammatory cytokines may be increased during attacks, as is the urinary excretion of neopterin and leukotriene E_4 (Drenth et al., 1995; Frenkel et al., 2001b). Urinary levels of mevalonic acid are also markedly increased during attacks (Drenth et al., 1999; Frenkel et al., 2001a; Houten et al., 1999; Kelley et al., 2002).

MOLECULAR BASIS OF HIDS: THE DISEASE GENE, MVK

HIDS is caused by recessively inherited mutations in *MVK*, encoded on the long arm of human chromosome 12 (Drenth et al., 1999; Houten et al., 1999). HIDS-associated mutations lead to a marked reduction in mevalonate kinase enzymatic activity (discussed below), but fibroblasts from patients nevertheless typically demonstrate 1 to 3 percent of the activity seen in fibroblasts from healthy controls. *MVK* mutations leading to the complete loss of enzymatic activity cause mevalonic aciduria, an extremely rare condition that manifests not only the periodic fevers, lymphadenopathy, abdominal pain, rash, and arthralgia seen in HIDS, but also dysmorphic features, hypotonia, mental retardation, cataracts, and failure to thrive, which result in a compromised life expectancy (Hoffmann et al., 1986, 1993; Kelley, 2000).

MVK spans a genomic region of 22 kb and comprises 11 exons, the first of which encodes most of the 5′ untranslated region in the cDNA (Cuisset et al., 2001; Houten et al., 2001). The gene encodes a 396 a.a. protein (Schafer et al.,

1992). At the time of this writing, more than 100 HIDS-associated mutations have been identified, and an updated database of mutations is available at the Infevers website (http://fmf.igh.cnrs.fr/ISSAID/infevers/; Milhavet et al., 2008). HIDS-associated *MVK* mutations are distributed throughout the coding sequence predominantly affecting stability and folding of the mevalonate kinase protein (Mandey et al., 2006), while mutations causing mevalonic aciduria are concentrated around sequences encoding the active sites of the mevalonate kinase enzyme (Cuisset et al., 2001; Houten et al., 2001).

FUNCTION OF MEVALONATE KINASE, THE MVK GENE PRODUCT

Mevalonate kinase catalyzes the conversion of mevalonic acid to 5-phosphomevalonic acid in the synthesis of the sterols, which include cholesterol, vitamin D, bile acids, and steroid hormones (Brown et al., 1997; Goldstein et al., 1990; Valle, 1999). This pathway also leads to the production of nonsterol isoprenoids, which are involved in a host of cellular functions. It is unlikely that the autoinflammatory phenotype of HIDS is due to a deficiency in cholesterol, since HIDS patients usually have cholesterol levels in the low-normal range, and since the autoinflammatory phenotype is not seen in patients with other more profound disorders of the mevalonate pathway, such as Smith-Lemli-Opitz syndrome, in which cholesterol deficiency is more significant (Kelley, 2000).

There are several hypotheses on the pathogenesis of HIDS (Fig. 33.3). The first proposes that the inflammatory phenotype is due to the buildup of mevalonic acid, the substrate for the mevalonate kinase enzyme (Simon et al., 2004b). The second hypothesis holds that the disorder is due to deficiencies in isoprenoids normally synthesized through the mevalonate pathway (Frenkel et al., 2002). Although there are in vitro data demonstrating accentuated IL-1β secretion in HIDS leukocytes that can be reversed by the addition of farnesol and geranyl-geraniol (isoprenoid compounds), the issue has been controversial. More recently, the role of apoptosis in HIDS pathogenesis has been proposed in one study noting decreased apoptosis in stimulated lymphocytes from HIDS patients during a symptom-free interval.

The association of HIDS attacks with immunizations and infections may be accounted for by these hypotheses. The decreased apoptosis of stimulated lymphocytes suggests failure to curtail the immunological response, with subsequent systemic inflammation after a minor stimulus (Bodar et al., 2007b). Both the isoprenoid deficiency and mevalonate accumulation hypotheses predict a worsening of symptoms with decreased mevalonate kinase enzymatic activity. In vitro studies of cell lines harboring wild-type or HIDS-mutant *MVK* indicate that the mutant enzyme functions best at 30°C, with a diminution at 37°C and further decreases at 39°C (Houten et al., 2002). This temperature-specific response supports the association of HIDS attacks with immunizations and infections and may also account for the increased urinary mevalonic acid levels seen during HIDS attacks. The role of fever on the apoptotic pathway requires evaluation.

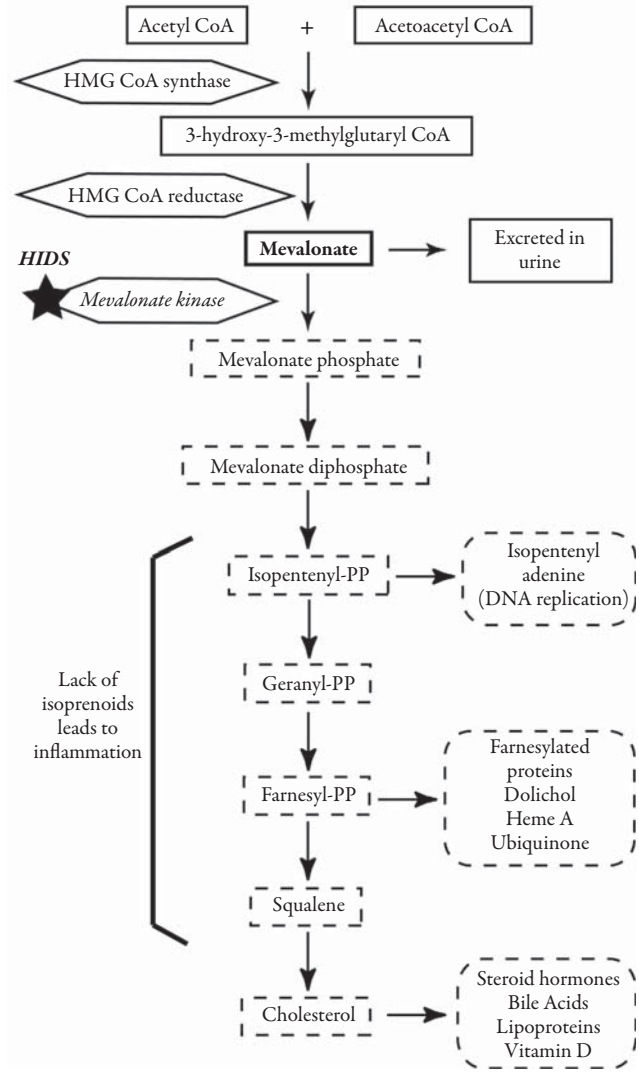

Figure 33.3 Interruption of the mevalonate pathway in the hyperimmunoglobulinemia D with periodic fever syndrome (HIDS). HIDS is caused by recessively inherited mutations in the mevalonate kinase enzyme. HIDS-associated mevalonate kinase mutations typically leave 1 to 3 percent residual enzymatic activity, but the buildup of the mevalonate kinase substrate, mevalonic acid, may be detected in the urine of HIDS patients during inflammatory episodes. Failure of the mevalonate pathway to progress results in decreased isoprenoid formation and subsequent inflammation. Stars denote the presence of mutations. PP, pyrophosphate.

MUTATION ANALYSIS IN HIDS

A very high percentage of HIDS patients harboring *MVK* mutations have at least one copy of the substitution of isoleucine for valine at residue 377 (V377I) (Cuisset et al., 2001; D'Osualdo et al., 2004; Houten et al., 2001). Population-based surveys of newborns in the Netherlands indicate a carrier frequency of 0.6 percent for the V377I mutation among the Dutch (Houten et al., 2003), with haplotype data supporting a founder effect (Houten et al., 2003). Analysis of *MVK* genotypes among HIDS patients indicate an underrepresentation of V377I homozygotes, suggesting a milder phenotype or reduced penetrance for V377I homozygotes (Houten et al., 2003).

Because many patients with HIDS are heterozygous for V377I, commercial and academic laboratories may perform an initial screen for the V377I mutation by restriction endonuclease analysis, and occasionally for the second most common mutation I268T. More extensive screening, usually by DNA sequencing, is reserved for patients who are heterozygous for either mutation (but not for compound heterozygotes, in whom the molecular diagnosis of HIDS would be already established).

STRATEGIES FOR THE DIAGNOSIS OF HIDS

There are currently three possible strategies for diagnosing HIDS: clinical, molecular, and biochemical. Consistent with practice before the identification of the underlying gene, the clinical diagnosis of HIDS is established by documenting elevations in serum IgD levels (>100 IU/mL, or >14.1 mg/dL) on two occasions at least a month apart, with a compatible clinical history. The molecular diagnosis is established by documenting two mutations in *MVK*, while the biochemical diagnosis is established by documenting elevations in urinary mevalonic acid during attacks, or decreased enzymatic activity in cells cultured from the patient. In many cases, all three strategies agree, in which case the patient is sometimes said to have "classic-type HIDS" (Simon et al., 2001a).

Although there is a strong concordance between molecular and biochemical diagnosis, clinical and molecular diagnoses sometimes diverge. About one quarter of patients satisfying clinical criteria for HIDS have no demonstrable *MVK* mutations (Simon et al., 2001a). These patients tend to have milder disease and lower IgD levels than patients with classic-type HIDS and in the past have been called "variant-type HIDS." There are also a few patients who meet genetic and biochemical criteria for HIDS, with a compatible clinical picture, except for persistently normal IgD levels (Frenkel et al., 2000; Houten et al., 1999; Saulsbury, 2003; Takada et al., 2003), although the sensitivity of a high IgD has been estimated at only 0.79 (Ammouri et al., 2007). This discrepancy is more frequent in young children, who may eventually exhibit increased serum IgD levels (Drenth et al., 2001a).

Further complicating the picture, a small percentage of patients with FMF and TRAPS may have modest elevations in their serum IgD, although not to the very high levels seen in some HIDS patients (Dode et al., 2002a; Livneh et al., 1997a; Medlej-Hashim et al., 2001; Simon et al., 2001c). The differential diagnosis of an elevated serum IgD level also includes IgD multiple myeloma, Hodgkin's disease, cigarette smoking, diabetes mellitus, pregnancy, hyperimmunoglobulinemia E syndrome, ataxia-telangiectasia, acquired immunodeficiency syndrome, and recurrent infections such as tuberculosis and aspergillosis (Boom et al., 1990; Drenth et al., 1994b; Hiemstra et al., 1989). Given these complexities, it is reasonable to take a combined approach in patients in whom there is a suitable index of suspicion for HIDS/mevalonate kinase deficiency, combining serum IgD measurement with genetic and/or biochemical analysis.

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

HIDS is inherited as an autosomal recessive trait. There are currently no data on the penetrance of individual HIDS genotypes, although population-genetic studies suggest that V377I homozygotes may not always manifest HIDS symptoms. In light of the likelihood of reduced penetrance, the generally favorable prognosis for HIDS, and the possibility of genetic discrimination, genetic testing is usually reserved for symptomatic individuals. Prenatal diagnosis of HIDS is possible but raises a number of ethical issues if undertaken with the possibility of terminating a pregnancy for what is usually a nonfatal disorder with a number of new treatment options.

TREATMENT AND PROGNOSIS

Despite the onset of symptoms in infancy, the average delay to diagnosis is 9.9 years, and a significant number of patients present with alternative diagnoses (van der Hilst et al., 2008a). The recurrent nature of the inflammatory episodes, especially for patients experiencing more than six attacks per year, may have an impact on social functioning and other quality-of-life measures (van der Hilst et al., 2008a). Thus, the therapeutic focus remains largely on prevention or suppression of inflammatory episodes.

Various approaches have been evaluated in an attempt to reduce inflammatory episodes and to modify the altered metabolic systems, but at the current time, there is no consensus on the treatment of HIDS. Most patients with HIDS do not respond to colchicine, although a few patients do show some improvement with daily treatment. Cyclosporine and intravenous immunoglobulin are not generally effective in HIDS. Corticosteroids at high doses at the onset of an attack may reduce its severity in a subset of patients (van der Hilst et al., 2008a).

More recently, therapeutic trials in HIDS have focused on the mevalonate pathway and on cytokine inhibition. The statin class of drugs inhibits HMG-CoA reductase, the enzyme immediately preceding mevalonate kinase in the mevalonate pathway. Although one member of this pharmacological family, lovastatin, caused exacerbations in the more severe mevalonic aciduria, simvastatin appears safe in HIDS, and preliminary data suggest a possible benefit (Attout et al., 2008; Simon et al., 2004b). Evaluation of the use of biological modulators in reducing the inflammation in HIDS is ongoing. A small trial of thalidomide, which, among other effects, inhibits TNF-α production, resulted in a nonsignificant decrease in acute phase reactants and no effect on the attack rate (Drenth et al., 2001b). In contrast, the more potent TNF inhibitor etanercept produced substantial improvement in three HIDS patients (Demirkaya et al., 2007; Takada et al., 2003), notably where treatment with corticosteroids and simvastatin had failed (Demirkaya et al., 2007). IL-1 inhibition may represent yet another possible therapeutic strategy. Use of anakinra in HIDS has led to the reduction or resolution of inflammatory attacks, decreased use of corticosteroids, and improvement in quality-of-life scores (Cailliez et al., 2006).

Furthermore, failure of efficacy of one biological agent does not eliminate the possible benefit from an alternate one (i.e. anakinra vs. etanercept; van der Hilst et al., 2008a).

Systemic amyloidosis remains a very rare complication of HIDS (D'Osualdo et al., 2004; Obici et al., 2004). Moreover, as noted above, symptoms usually ameliorate in adulthood, and the overwhelming majority of patients with HIDS have a normal life expectancy (Drenth et al., 1994b).

ANIMAL MODELS

Recently, two different murine models of HIDS have been reported. Hager et al. describe mice with loss of one allele of *Mvk* that demonstrate elevations of serum IgD, IgA, and TNF-α, consistent with reports of HIDS patients (Hager et al., 2007). Whereas complete knockout of the *Mvk* gene is embryonic lethal, the 50 percent reduction in mevalonate kinase activity is associated with accumulation of mevalonate in tissues, specifically the spleen, kidney, and heart. The associated splenomegaly and mild elevation in temperature suggest that this model is a reasonable phenocopy of human HIDS (Hager et al., 2007). Subsequent studies have demonstrated that these mice have altered expression of co-stimulatory molecules on T cells, B cells, and macrophages, as well as gender differences in the ability of splenocytes to proliferate in response to activation stimuli (Hager et al., 2012). These findings may lead to new information on the role of mevalonate kinase in inflammation.

In an alternate approach, postulating that the inflammatory mechanism in HIDS stems from the lack of isoprenoids rather than the accumulation of mevalonate, Marcuzzi et al. (2008) have evaluated mice with an MKD-like disorder induced by aminobisphosphonate, a mevalonate pathway inhibitor, and muramyldipeptide, a bacterial compound provided to mimic vaccine-induced episodes of inflammation. These mice demonstrate elevated SAA and peritoneal exudate cells, which resolved with administration of exogenous isoprenoids (Marcuzzi et al., 2008). Further studies using a similar approach in a murine monocyte cell line demonstrated that the combination of mevalonate pathway inhibition and bacterial stimulus led to programmed cell death and IL-1β secretion (Marcuzzi et al., 2011). More importantly, the cell death appears to be a combination of apoptosis and pyroptosis and could be rescued by treatment with anakinra (Marcuzzi et al., 2011). These findings may account for the resolution of symptoms observed in some HIDS patients following treatment with anakinra and provide in vitro support for the use of IL-1 receptor antagonists in patients with HIDS.

PERIODIC FEVER, APHTHOUS STOMATITIS, PHARYNGITIS, AND ADENITIS

In 1987, Marshall et al. described a series of 12 children with fevers that occurred with regular periodicity. In contrast to the hereditary recurrent fever disorders, these children displayed symptoms on a cyclical basis, with a period of 4.5 weeks on average, beginning prior to the age of 5 years and continuing through adolescence. Initially designated Marshall syndrome (Marshall et al., 1987) and subsequently FAPA, to include the associated symptoms of aphthous stomatitis, pharyngitis, and tender cervical adenopathy (Feder et al., 1989), the syndrome is now recognized as periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) to emphasize the characteristic periodicity of the febrile episodes.

Unlike the early descriptions of FMF and HIDS, which identified significant ethnic predilections, the original cohort comprised children from diverse ethnic ancestry, with mixtures of Northern European and Native American heritage. Additionally, none of the 12 children had a family history of recurrent fever disorders.

The molecular genetic etiology of PFAPA remains unknown. Children with PFAPA are noted to be not particularly susceptible to infection, clarifying that this unique syndrome is not an immunodeficiency but rather a dysregulation of the immune system, similar to the hereditary fever syndromes. Serum studies during febrile episodes in PFAPA patients have demonstrated elevated inflammatory cytokines, including IFN-γ and IL-18, which normalize during the asymptomatic period, consistent with the characteristic periodicity. Cytokines such as IL-1β, IL-6, and TNF-α remain elevated in the serum (Stojanov et al., 2006, 2011) compared to healthy controls, suggesting an underlying dysregulation of the innate immune system.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS OF PFAPA

PFAPA is classically recognized by its unique periodicity, in which patients have discrete episodes of high fevers, lasting 3 to 5 days per cycle, with a frequency of 10 to 11.5 febrile episodes per year (Thomas et al., 1999). Episodes begin prior to the age of 5 years, and most studies have demonstrated a slight male predominance (Thomas et al., 1999). As the name describes, in addition to fever, patients experience aphthous stomatitis, pharyngitis, and tender cervical adenopathy, although all may not be present in a given episode (Table 33.1). Nonspecific symptoms such as chills, headache, arthralgia, lethargy, and decreased appetite have also been described (Tasher et al., 2006; Thomas et al., 1999). Abdominal pain, nausea, and vomiting are more frequently observed with temperatures near 41°C but, unlike FMF, there is no serosal involvement (Marshall et al., 1987). The episodes are notable for the lack of upper respiratory symptoms. Rash and conjunctivitis (Kolokotronis et al., 2007) are rarely reported. The associated symptoms end abruptly with the fever, and patients are completely asymptomatic between episodes, with normal growth and development (Marshall et al., 1987). There is no identifiable trigger for the inflammatory episodes of PFAPA. Additionally, children with PFAPA are often noted to be less susceptible to infection (Marshall et al., 1987).

Although PFAPA is classically considered to be a syndrome of childhood, there are several reports of adults presenting with recurrent symptoms of fever, malaise, cervical

adenopathy, and exudative pharyngitis, similar to PFAPA (Colotto et al., 2011; Padeh et al., 2008). Compared to onset before the age of 5 years, adults with PFAPA less commonly experience aphthous stomatitis during their febrile episodes (Padeh et al., 2008). Of note, the delay in diagnosis tends to be longer in these patients (Padeh et al., 2008), possibly due to the increased age at onset. Additionally, one study reported that two thirds of adult patients with PFAPA experienced multiple, 2- to 6-month intervals that were symptom-free, thereby interrupting the characteristic periodicity of PFAPA syndrome (Padeh et al., 2008). It is possible that adult-onset PFAPA represents a unique subset on the spectrum of recurrent fever disorders, but evaluation of additional cases is necessary.

LABORATORY FINDINGS IN PFAPA

Similar to the other periodic fever syndromes, febrile episodes are marked by significant elevations in acute phase reactants, including ESR and CRP, which tend to be higher on days 2 to 4 of the fever cycle (Forsvoll et al., 2007). Normal to mildly elevated leukocyte counts with predominant neutrophilia have also been described (Thomas et al., 1999) but are not necessary for diagnosis (Forsvoll et al., 2007). These laboratory findings normalize completely between episodes, and there are no indications of subclinical inflammation. Quantitative immunoglobulins are within normal limits, although IgD may be elevated in a subset of PFAPA patients (Kovacs et al., 2010; Padeh et al., 1999). Similar to the hereditary fever disorders, autoantibodies are largely absent and complement studies are normal (Marshall et al., 1987). Cultures, such as pharyngeal swabs for *Streptococcus*, and serologies for *Toxoplasma*, *Mycoplasma,* Epstein-Barr virus, and cytomegalovirus are negative.

Recognition of the periodicity of fever episodes is of utmost importance in identifying PFAPA syndrome. Due to the frequency of the episodes, which occur once per month, and the early age at which symptoms develop, it is not uncommon for patients to be treated for viral illnesses, or empirically for streptococcal pharyngitis, otitis media, and sinusitis, with at least five courses of antibiotics (Forsvoll et al., 2007). The recurrent nature, high temperatures, and lack of identifiable source of the fevers may also prompt multiple subspecialty referrals. A child with PFAPA may have had evaluations by Infectious Diseases, Hematology, Oncology, Otolaryngology, Allergy/Immunology, and Rheumatology, as well as multiple visits to the primary pediatrician, over several years, before the diagnosis is reached.

MOLECULAR BASIS OF PFAPA

The etiology of PFAPA remains unknown. Whole-blood gene expression analysis and subsequent quantitative PCR has demonstrated upregulation of complement pathway genes, IL-1 and inflammasome-associated genes, and IFN-induced genes. In contrast, transcripts for receptors such as CXCR3, expressed on T lymphocytes, were downregulated compared to asymptomatic intervals (Stojanov et al., 2011). These findings indicate that at the level of gene expression, asymptomatic PFAPA patients are indistinguishable from healthy controls, and support the characteristic periodicity of this syndrome.

During febrile episodes, IFN-γ, IL-6, IL-18, G-CSF, IFN-inducible protein of 10 kDa (IP-10/CXCL10), monokine induced by IFN-γ (MIG/CXCL9), and macrophage inflammatory protein 1β (MIP-1β/CCL4) are significantly elevated in the serum (Brown et al., 2010; Stojanov et al., 2006, 2011). Further evaluation of cytokine profiles has demonstrated that patients with PFAPA have elevated IL-1β, IL-6, TNF-α, G-CSF, MIG/CXCL9, MIP-1β, and IL-12p70 between attacks compared to healthy controls (Stojanov et al., 2006, 2011). One of these genes, IP-10/CXCL10 (a chemoattractant for activated T cells and chemokines and chemokine receptors expressed by monocytes), was found to be a particularly good biomarker of disease.

At the cellular level, immunophenotyping has demonstrated that in addition to neutrophilia, numbers of monocytes, eosinophils, and activated $CD4^+$ lymphocytes are significantly altered during PFAPA flares, specifically a monocytosis with reduced numbers of eosinophils and $CD4^+HLA\text{-}DR^+$ and $CD4^+CD25^+$ T cells (Brown et al., 2010; Stojanov et al., 2011). There is no reported difference in activated CD8+ T cells during febrile episodes (Stojanov et al., 2011). These early studies demonstrate that inflammatory flares in PFAPA involve both innate and adaptive immune responses and confirm the hypothesis that immunodysregulation may be the basis of the PFAPA syndrome.

MUTATION ANALYSIS IN PFAPA

At the present time, a Mendelian inheritance pattern has not been clearly defined and no specific genetic mutation has been identified as the cause of PFAPA. The presence of the known periodic fever genes, specifically *MEFV*, *TNFRSFA1*, *CIAS1*, and the Crohn's disease-associated gene *CARD15/NOD2* in PFAPA patients has been examined. In one study, the frequency of the observed mutations in *MEFV* was not higher than the expected carrier frequency in their ethnic populations (Dagan et al., 2010). In another population, the presence of a single MEFV mutation, especially M694V, was associated with milder PFAPA episodes (Berkun et al., 2011). One patient did possess the R92Q mutation in *TNFRSFA1*; however, given the frequency of this mutation and the lack of other symptoms in the patient, it was considered more consistent with a genetic variant leading to mild or asymptomatic TRAPS (Dagan et al., 2010). Similarly, mutations in *CARD15/NOD2* have been shown to be similar in carrier frequency and less often associated with PFAPA than with Crohn's disease (Dagan et al., 2010; Maschio et al., 2006). These studies have been limited to evaluations of the predominant mutations rather than full gene sequencing. Whether the presence of these mutations, in the context of other genetic or environmental influences, leads to PFAPA remains to be determined.

STRATEGIES FOR THE DIAGNOSIS OF PFAPA

The diagnosis of PFAPA is made clinically, usually by exclusion of the hereditary periodic fever disorders previously described, lack of infections and lack of malignancy or a hematological process. The defining symptom of PFAPA is truly the characteristic periodicity of the fever cycles, which is not observed in the previously described fever syndromes. Criteria proposed by Thomas et al. (1999) have been traditionally used for diagnosis, specifically regularly recurring fevers with onset at less than 5 years of age and constitutional symptoms in the absence of upper respiratory infection with at least one of the following clinical signs: aphthous stomatitis, cervical adenitis, or pharyngitis. The patients must be completely asymptomatic during the interval between episodes and display normal growth and development. Exclusion of cyclic neutropenia is also recommended (Thomas et al., 1999).

The differential diagnosis of PFAPA includes viral infections, such as adenovirus and recurrent bacterial pharyngitis, both of which may present with fever, pharyngitis, and elevated CRP. However, even in cases of repeat infection, the lack of regular periodicity would distinguish between these illnesses and PFAPA. Behçet syndrome may also present with aphthous stomatitis, although these patients are less often febrile. Additionally, genital ulcers and iritis, which complete the classic Behçet's triad, would not typically be observed in PFAPA. Cyclic neutropenia may be the most similar to PFAPA in terms of regular febrile episodes. Cyclic neutropenia is a rare, autosomal dominant disorder that may be associated with mutations in the neutrophil elastase gene, *ELA-2*. It presents as episodes of fever, painful oral ulcers, and bacterial infections such as cellulitis, bronchitis, otitis, and sinusitis, secondary to severe neutropenia occurring every 3 weeks (Dale et al., 2011). Cyclic neutropenia may be complicated by chronic gingivitis, tooth loss, bacteremia, and septic shock, none of which is reported in PFAPA. Treatment is with subcutaneous granulocyte colony-stimulating factor.

A small case series has also associated PFAPA with Kawasaki syndrome in either the patient or a first-degree relative. Whether these specific cases point to variability in penetrance of a gene yet to be identified or the influence of environmental factors remains to be determined (Broderick et al., 2011). These cases also illustrate the difficulty in diagnosing children with recurrent fever disorders, given the necessity of episode recurrence for the clinical diagnosis.

PFAPA now appears to be more common than initially appreciated, with patients dispersed across subspecialties due to the chronic, persistent nature of the recurrent fever episodes. Evaluation of increasing numbers of patients with recurrent fevers has led to the recognition of a substantial number of patients with fevers of regular periodicity, similar to PFAPA, but without the associated symptoms of aphthous stomatitis, pharyngitis, or adenopathy. Parents of these children similarly report normal growth and development, negative microbial cultures, and a lack of response to antibiotics. We support the proposal by K. Barron to identify this subset of patients with the diagnosis of syndrome of undifferentiated recurrent fevers (SURF). It is too early to determine if these patients represent a milder form of PFAPA or if they will progressively display additional symptoms and merely represent an earlier stage of the PFAPA syndrome. Furthermore, the role of corticosteroids and/or tonsillectomy in these patients remains to be seen.

MODE OF INHERITANCE, CARRIER DETECTION, AND PRENATAL DIAGNOSIS

There are limited case reports describing PFAPA in siblings (Anton-Martin et al., 2011; Sampaio et al., 2009; Valenzuela et al., 2009), including one set of monozygotic twins and their mother (Adachi et al., 2011). Furthermore, it is not uncommon for parents of children with PFAPA to recall episodes of recurrent pharyngitis and fevers in their own childhoods (Cochard et al., 2010). Given the recent description of PFAPA only a few decades ago, no studies exist in which patients with PFAPA have been prospectively followed to determine whether *their* children would develop the syndrome. Moreover, for the vast majority of patients, a clear autosomal dominant pattern is not observed.

At the time of publication, no specific gene mutation has been identified for PFAPA, and carrier detection and prenatal diagnosis are not feasible. Despite the lack of specific genetic testing, parents should be reminded of the good prognosis for patients with PFAPA and the lack of known long-term morbidity or mortality.

TREATMENT AND PROGNOSIS

The prognosis for PFAPA is favorable. Despite the impact on quality of life due to monthly high fevers, there is no known mortality associated with PFAPA, and children have normal growth and development. Spontaneous resolution of inflammatory episodes occurred in over 40 percent of patients after a mean of 4.5 years in one cohort (Thomas et al., 1999). Longer courses of the syndrome are typically marked by increased intervals between fevers and less severe symptoms.

Medical treatment of febrile episodes in PFAPA is primarily supportive and targeted at reducing the high fevers. In terms of antipyretics, ibuprofen has demonstrated superiority over acetaminophen (Thomas et al., 1999). Antibiotic therapy has no utility in PFAPA episodes, and management should include avoiding unnecessary antibiotics. Numerous case reports have described alternative medical therapies aimed at remedying the syndrome, but the majority have been met with limited success. Colchicine therapy has been proposed as prophylactic therapy and in one series led to a significant increase in the asymptomatic interval in the majority of patients over a 2-year period (Tasher et al., 2008). A second small series demonstrated that twice-daily treatment with the H2-antagonist cimetidine may induce remission in a subset of patients (Feder, 1992; Thomas et al., 1999). Cessation of cimetidine therapy after 6 months, however, led to recurrence of symptoms in a few patients (Thomas et al., 1999). Prednisone has been used with considerable success in eliminating inflammatory episodes in PFAPA if given at the onset of fever. A single dose, typically 1 mg/kg, is effective in eliminating the fever within the first 24 hours of administration (Berlucchi et al., 2003). Associated symptoms, such as aphthous stomatitis, may take longer to resolve. This

remarkable response to corticosteroids may be considered an additional criterion aiding in the diagnosis of PFAPA. Unfortunately, the use of prednisone has also been associated with reducing the periodicity and shortening the interval between fever cycles in up to 50 percent of patients (Tasher et al., 2006; Thomas et al., 1999). The mechanism by which prednisone quells the fever episode, as well as by which corticosteroid therapy influences the cycle frequency, remains under evaluation. More recently, treatment of five PFAPA patients with subcutaneous anakinra, the recombinant IL-1R antagonist, on the second day of fever led to resolution of the fever and associated symptoms within hours of administration in three of the children (Stojanov et al., 2011). While this observation supports innate immune dysregulation as the mechanism behind the recurrent inflammatory episodes, further studies of the role of biological therapy is necessary.

Surgical intervention has been evaluated as an alternate therapy, and a potentially curative one, for PFAPA. In numerous case reports (Berlucchi et al., 2003; Licameli et al., 2008; Padeh et al., 1999; Peridis et al., 2010a, 2010b; Pignataro et al., 2009; Tasher et al., 2006; Thomas et al., 1999; Wong et al., 2008) and two small clinical trials (Garavello et al., 2009; Renko et al., 2007), tonsillectomy with or without adenoidectomy was shown to be effective in leading to clinical resolution. Adenoidectomy alone is not effective (Thomas et al., 1999), but it is unclear whether the combination of adenoidectomy with tonsillectomy is of additional benefit (Burton et al., 2010).

The mechanism behind the efficacy of tonsillectomy is unknown. Some have speculated that the palatine tonsils are responsible for immune dysregulation in PFAPA, and the removal of this active lymphatic tissue leads to clinical resolution. Follow-up in the current studies is variable, ranging from 3 to 41 months, and in some cohorts relapse occurred after a period of remission (Colotto et al., 2011; Tasher et al., 2006). Recurrence was proposed to be secondary to compensation by other oral lymphatic tissue (Colotto et al., 2011). In contrast, a smaller literature does not advocate tonsillectomy as a curative therapy for PFAPA. A single study of two patients reports diagnosis of PFAPA retrospectively following adenotonsillectomy (Parikh et al., 2003), and others have questioned the utility of surgical intervention for a syndrome that will likely resolve without long-term consequences (Leong et al., 2006). However, a recent meta-analysis comparing corticosteroid therapy and tonsillectomy did not demonstrate any statistically significant differences between the two approaches and confirmed the effectiveness of both in the treatment of PFAPA (Peridis et al., 2010b). Ultimately, the parents and clinical team must consider the risks and benefits of surgery against the alternative of recurrent episodes, which are likely to spontaneously resolve after a finite, but unknown, period of time.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The recurrent fever disorders represent a unique group of primary immune diseases characterized not by immunodeficiency and infection but by dysregulation of the innate immune system, resulting in inappropriate systemic and tissue inflammation. These conditions, now classified as autoinflammatory disorders, encompass several previously defined Mendelian fever disorders as well as other clinically related diseases with no known genetic basis. Recent advances in our understanding of the molecular basis of the hereditary fever disorders have helped to elucidate the complexity of the innate immune regulatory mechanisms, improved our diagnostic abilities, and led directly to effective targeted therapy of patients. In the future, identification of additional disease genes will help to elucidate the pathogenesis of the majority of recurrent fever patients who currently have no known defect.

For the practicing clinician, recognition of the shared and unique clinical characteristics of the recurrent fever syndromes is the initial step in diagnosis and management of patients with these disorders. Genetic testing can be used to confirm the diagnosis, define the prognosis, and aid in the selection of appropriate therapeutics from the many available targeted therapies to an individual patient.

INTRODUCTION TO INNATE IMMUNITY AND SYNDROMIC PRIMARY IMMUNODEFICIENCY DISORDERS

Jean-Laurent Casanova

Inborn errors of immunity, often referred to as primary immunodeficiencies (PIDs) in Europe and primary immunodeficiency diseases (PIDD) in the Americas, may be classified according to various criteria, including mode of inheritance (Mendelian vs. more complex traits), affected cell type (e.g., complement vs. B-cell deficiency), clinical phenotype (infectious vs. autoimmune), or age at onset (pediatric vs. adult-onset conditions). All these classifications are somewhat arbitrary and imperfect. Furthermore, they are not mutually exclusive, and this has paradoxically resulted in some confusion, even leading to the lack of an accurate, formal, and universal definition of PID/PIDD themselves. "PID" was historically used in a narrow, immunological, exclusive, and conservative sense (Fischer, 2007), whereas this term is now increasingly used in a broader, clinical, more inclusive, and liberal sense (Casanova and Abel, 2007). Despite this absence of a universal classification and definition of PIDs the field is rapidly evolving in at least two opposite directions, with the traditional search for new genetic etiologies for known PID phenotypes and the more recent discovery of new phenotypes resulting from inborn errors of immunity (Notarangelo and Casanova, 2009).

In this context, perhaps the most consensual but least rigorous classification, combining some but not all of these criteria in a somewhat inconsistent manner, is that adopted by the International Union of Immunological Societies (IUIS) expert committee for PIDs. This classification assigns PIDs to eight broad categories: "combined T- and B-cell deficiencies," syndrome PIDs (often T-cell defects), "antibody deficiencies," "diseases of immune dysregulation," "defects of phagocytes," "defects of innate immunity," "autoinflammatory disorders," and "complement deficiencies"(Al-Herz et al., 2011). The classification of PIDs adopted in this textbook was inspired by this IUIS classification. This brief introduction precedes two sections dealing with "syndromic PIDs" and "PIDs of innate immunity," corresponding approximately to Tables II and VI of the IUIS classification. "Syndromic PIDs" is the term used to describe PIDs with clinical features extending well beyond the immunological boundaries of PIDs. Several important "syndromic PIDs" are described in other sections (e.g., ataxia-telangiectasia), and the immunological features of these "syndromic PIDs" differ considerably between conditions (ranging from T-cell to phagocyte defects). It is therefore very difficult to define this group of PIDs, which encompasses diseases as diverse as cartilage-hair hypoplasia (CHH), hyper-IgE syndromes (HIES), hepatic veno-occlusive disease with immune deficiency (VODI), WHIM syndrome, pulmonary alveolar proteinosis, epidermodysplasia verruciformis, and Wiskott-Aldrich syndrome (WAS), but not anhidrotic ectodermal dysplasia with immune deficiency, Schimke disease, Fanconi anemia, or ataxia-telangiectasia.

The "PIDs of innate immunity" selected in this section are even more difficult to define, especially given that the only two chapters assigned to this section concern "disorders of the IL-12-IFN-γ circuit" and "defects of the NF-κB pathway." In the immunological lexicon, adaptive immunity refers to the antigen-specific, lymphoid immunity mediated by T and B cells. By contrast, innate immunity refers to NK lymphocytes and to myeloid cells, comprising polymorphonuclear phagocytes, including neutrophil, eosinophil, and basophil granulocytes, and mononuclear phagocytes, including various types of monocytes, macrophages, and dendritic cells. Continuing a longstanding immunological tradition, this dichotomy omits key players in host defense, such as the nonhematopoietic cells present in mucocutaneous barriers and internal organs. This arm of nonhematopoietic immunity is sometimes referred to as "intrinsic immunity," although this term is ambiguous to some extent, as antiviral intrinsic immunity mechanisms also

occur in leukocytes themselves (Bieniasz, 2004). In any event, there is no obvious reason why "disorders of phagocytes" or "disorders of complement" should be distinguished from those of "innate immunity," particularly when the only two PIDs from the innate immunity group dealt with here have a major effect on adaptive immunity. This effect is probably even stronger than those on innate and intrinsic immunity, as IL-12 is a key activator of T cells and IFN-γ is a key T-cell cytokine, with NF-κB being used as a transcription factor by multiple T- and B-cell receptors.

These difficulties are inevitable and reflect the fact that this classification of PID is based largely on a cellular classification of immunity, corresponding to nonhematopoietic (intrinsic), myeloid (innate), and lymphoid (adaptive) cells. Adaptive immune responses are clonal, antigen-specific, diverse, and endowed with memory. Innate immunity is considered to differ from adaptive immunity on each of these points. Indeed, this historical view of immunology revolves around the antigen, which defines antigen-specific (adaptive) immune responses as the quintessential basis of immunity, with little consideration of the contribution of nonspecific (innate) immune responses, and the banishment of other (intrinsic) layers of host defense to obscurity. However, these three arms of the immune system are closely connected and a defect in any one of these arms may affect the other two. For example, defects of antigen-specific cells may affect pathogen-digesting effector cells, and defects of antigen-presenting cells may affect antigen-specific lymphocyte responses. Would this justify a classification based on the distinction between intrinsic, innate, and adaptive inborn errors of immunity? In fact, the terms "intrinsic," "innate," and "adaptive" are appropriate when we are referring to the cells involved in host defense, but they are not entirely appropriate for use with genes, and thus for inborn errors of immunity and PIDs.

Indeed, only a very small number of genes can be viewed as truly and purely "adaptive": those encoding RAG, TCR, BCR, HLA-I, and HLA-II molecules and perhaps a few associated molecules. These "adaptive" molecules define about 20 to 30 genes, 50 at most if we also include genes that are almost exclusively functional in T and B cells. Does this imply that the remaining 20,950 human genes (from a total of about 21,000 genes, without even considering the noncoding DNA segments) are innate or intrinsic? Most of these genes are expressed in both innate and adaptive cells, not to mention nonhematopoietic cells. As a result, only a handful of known PIDs, such as HLA-I, HLA-II, CD3, and RAG defects, are purely adaptive. Most other PIDs affect both innate and adaptive immunity or, more rarely, innate immunity alone. Some recently described PIDs even affect intrinsic immunity, alone or in combination with hemopoietic immunity. Conversely, very few PIDs are purely innate or intrinsic, because the morbid genes are also expressed in B and T cells. As a result, the chapters covered in this section of the textbook cover disorders typically affecting all three types of immunity (e.g., NF-κB disorders, errors of IL12-IFN-γ, CHH, HIES, and WAS). Complicating matters even further, these disorders have also been somewhat arbitrarily selected, with some being exceedingly rare (VODI) and others more common (HIES); some being genetically homogeneous (CHH) and others extremely heterogeneous (IL-12-IFN-γ deficiencies); and some being defined in terms of a remotely shared cellular phenotype (NF-κB) and others in terms of their clinical phenotype (WAS).

So, readers should probably avoid trying to decipher the rationale underlying the classification of PIDs throughout this book, including their assignment to two groups. The truth is that there is no clear-cut rationale for PID classification, and a random selection of chapters and sections, and a random distribution of chapters within sections, would undoubtedly have generated as coherent a table of contents as that presented here. For example, the terms "syndromic PIDs" and "PIDs of innate immunity" cannot adequately convey the content of these two sections. Is this incoherence a problem? We don't think so. Indeed, it elegantly illustrates the current lack of a consistent paradigm in the field of PIDs, and the current drifting of this field, with no rigorous definition and no appropriate classification. We know from the history of science that such crises generally precede a profound shift of paradigm (Kuhn, 1962). The extraordinarily rapid expansion of knowledge about PIDs over the past 20 years has thrown up increasing numbers of exceptions to the paradigm first defined in the 1950s (reviewed by Casanova and Abel, 2007). The discovery of new genotypes and phenotypes has called previous definitions and classifications of PIDs into question. This crisis is undoubtedly the harbinger of a revolution. There is currently no better definition and classification available than that presented here—no new paradigm to make sense of these data. In this context, the next two sections will provide the reader with an overview of the current crisis in the field of PIDs, perhaps more so than the other sections, which have been less disturbed by recent findings.

INHERITED DISORDERS OF THE INTERLEUKIN-12–INTERLEUKIN-23/ INTERFERON-γ CIRCUIT

Steven M. Holland and Jean-Laurent Casanova

The recognition of severe disseminated infections with weakly virulent mycobacteria in individuals without recognized predisposing immunodeficiency as well as high rates of affected siblings and parental consanguinity suggested the existence of a novel set of primary immunodeficiency syndromes, subsequently subsumed under the name *Mendelian susceptibility to mycobacterial disease* (MSMD, MIM 209950). Mycobacteria involved include many species of environmental nontuberculous mycobacteria (NTM) and several *Mycobacterium bovis* Bacille Calmette-Guérin (BCG) vaccine substrains. Patients with MSMD are also prone to develop tuberculosis. Molecular investigation of these families has so far identified mutations in seven genes in the interleukin (IL)-12-dependent interferon-gamma (IFN-γ) circuit, one of the genes in the respiratory burst pathway, and one gene in the early hematopoietic pathway, highlighting the importance of these pathways in human immunity to mycobacteria and select other intramacrophagic pathogens. However, there remain patients for whom genetic etiologies are likely in whom mutations have not yet been identified, indicating that other morbid genes are yet to be found.

Sporadic cases of disseminated NTM infection in the absence of recognized immunodeficiency have been well described over many decades (Buhler and Pollack, 1953; van der Hoeven et al., 1958). Familial-disseminated NTM infection was first reported in 1964—three members of the same Danish family had fatal disseminated *Mycobacterium avium* complex (MAC) (Engbaek, 1964). Uchiyama et al. (1981) identified two siblings with *M. avium* infection. Holland et al. reported three male members of one family with disseminated NTM infection (Frucht and Holland, 1996; Frucht et al., 1999; Holland et al., 1994).

Idiopathic disseminated BCG infection following vaccination was first reported in 1951 (Mimouni, 1951). A sporadic case born to consanguineous parents was described in 1973 (Ulgenalp et al., 1973), and families with more than one affected member were first reported at around the same time (Fedak, 1974; Sicevic, 1972). Patients with inherited susceptibility to mycobacterial infections may also be at increased risk of *Salmonella* infection, as first highlighted by Heyne (1976), who described a brother and sister from Germany with generalized infection after neonatal BCG vaccination. The boy later developed *Salmonella* enteritis and osteomyelitis. In Prague, a 3-year-old boy who had been vaccinated with BCG at 3 days of age developed disseminated *Salmonella* and BCG infection, resulting in his death 3 years later (Doleckova et al., 1977). A first cousin of this child also had disseminated BCG infection (Dvoracek et al., 1959).

The first family in which the molecular basis of susceptibility to NTM was elucidated was described in 1995 (Levin et al., 1995). Four children from the same village in Malta all developed disseminated NTM infection. Two were brothers related to a third child as fourth cousins, while the fourth child was not knowingly related to the others. Each child was infected with a different mycobacterial species (*M. chelonae*, *M. fortuitum*, and two different strains of MAC). Extensive immunological investigation failed to identify any known defect predisposing to such infections. However, the patients had defective monocyte responses to IFN-γ when added to endotoxin (Levin et al., 1995) and defective antigen presentation (D'Souza et al., 1996). The high degree of consanguinity within the Maltese family suggested that the children were homozygous for a rare recessive mutation inherited from a common ancestor. A whole-genome search in three of the affected children mapped a homozygous region of chromosome 6q containing the gene encoding the IFN-γ receptor ligand binding chain (IFN-γR1) of the IFN-γ receptor complex (Newport et al., 1996), and sequence analysis identified a mutation in the extracellular domain of *IFNGR1* resulting in complete absence of IFN-γR1 expression on the cell surface.

Casanova et al. (1995) surveyed 108 cases of disseminated BCG infection following vaccination reported since 1951, finding that fully 50 percent were not accounted for by previously recognized molecular defects. A retrospective study of all cases of disseminated BCG infection following vaccination in France between 1974 and 1994 confirmed that of 32 children identified, 16 had no recognized predisposing immunodeficiency (Casanova et al., 1996). Further, among 60 children worldwide with idiopathic disseminated BCG infection for whom information was available, four pairs of siblings and one pair of first cousins were identified, and parental consanguinity was noted in 24 families. Clinical and histopathological features in a Tunisian child with disseminated BCG infection, born to consanguineous parents, were remarkably similar to those of the Maltese children with NTM infections. A series of candidate genes involved in antimycobacterial immunity in the mouse model of BCG infection were tested by homozygosity mapping. The segregation of markers within *IFNGR1* suggested linkage, and a frameshift mutation resulting in the absence of IFN-γR1 was identified (Jouanguy et al., 1996).

Although mutations in *IFNGR1* were subsequently identified in other cases of MSMD, there were a number of patients in whom mutations within *IFNGR1* were not detected. Investigation of other candidate genes involved in IFN-γ–mediated immunity led to the identification of mutations in seven genes (Table 35.1) involved in IL-12–dependent, IFN-γ–mediated immunity, one involved in NADPH oxidase activity (*CYBB*), and one involved in early hematopoiesis (*GATA2*) (Al-Muhsen and Casanova, 2008; Bigley et al., 2011; Bustamante et al., 2011a; Casanova and Abel, 2002, 2004; Dickinson et al., 2011; Dorman and Holland, 2000; Filipe-Santos et al., 2006a; Fortin et al., 2007; Hsu et al., 2011; Rosenzweig and Holland, 2005; Vinh et al., 2010).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

The central feature of MSMD is infection with NTM or BCG, weakly pathogenic mycobacteria to which exposure is common and disease rare. There is a clinical spectrum of MSMD that closely follows the extent of residual function of the affected gene: at one end of the spectrum are complete loss-of-function mutations in *IFNGR1* or *IFNGR2*, which result in no functional protein at the cell surface (complete receptor deficiency). These complete defects lead to the development of disseminated infection in early childhood and usually progressively fatal disease (Dorman and Holland, 1998; Dorman et al., 2004; Jouanguy et al., 1996; Newport et al., 1996). At the other end of the spectrum, *IFNGR1* and *IFNGR2* mutations that permit the expression of abnormal but somewhat functional protein cause partial receptor deficiency and are associated with milder phenotypes that retain some response to IFN-γ (Doffinger et al., 2000; Dorman et al., 2004; Jouanguy et al., 1997, 1999b). There is a correlation between the cellular phenotype (response to IFNγ) and the clinical phenotype (severity of mycobacterial disease) (Dupuis et al. 2000). Recessive mutations in the genes encoding the IL-12p40 subunit (*IL12B*) or the IL-12 receptor β1 subunit (*IL12RB1*) resulting in complete deficiency of either protein generally result in a less severe phenotype and good response to antibiotics and IFN-γ treatment. Likewise, dominant negative mutations in signal transducer and activator of transcription 1 (*STAT1*) or IRF8 (Hambleton et al., 2011) cause a partial cellular defect and relatively mild clinical phenotypes (Dupuis et al., 2000). For mutations with some residual function, screening of asymptomatic family members has identified individuals who carry mutations but have not developed infection with either mycobacteria or *Salmonella*, indicating that the clinical penetrance is incomplete, unlike in families with complete defects in *IFNGR1*, *IFNGR2*, or *STAT1* (Altare et al., 2001; Caragol et al., 2003; Dupuis et al., 2001; Jouanguy et al., 1999b; Picard et al., 2002).

One of the most striking features of MSMD is the relatively narrow susceptibility to poorly pathogenic mycobacterial species, including slow-growing species (e.g., *M. kansasii*, *M. avium*, *M. scrofulaceum*, and *M. szulgai*) and rapid-growing species (e.g., *M. smegmatis*, *M. abscessus*, *M. chelonei*, *M. fortuitum*, *M. peregrinum*) (Koscielniak et al., 2003; Marazzi et al., 2010; Pierre-Audigier et al., 1997). The more virulent *M. tuberculosis* has been implicated in or isolated from individuals

Table 35.1 **GENES INVOLVED IN DEFECTIVE MACROPHAGE ACTIVATION**

GENE	GENE PRODUCT	CHROMOSOMAL LOCATION	MIM NO. (PHENOTYPE MIM NO.)
IFNGR1	Interferon-γ receptor ligand binding chain	6q23.3	107470 (209950)
IFNGR2	Interferon-γ receptor signal transducing chain	21q22.1–2.2	147569 (209950)
IL12RB1	Interleukin-12 receptor β-1 subunit	19p13.11	601604 (209950)
IL12B	Interleukin-12p40 subunit	5q33.3	161561
STAT1	Signal transducer and activator of transcription 1	2q32.2	600555 (209950)
CYBB	Cytochrome b; NADPH oxidase 2 (NOX2), $gp91^{phox}$	Xp11.4	300645
IKBKG	NFκB essential modulator (NEMO), IKK-G	Xq28	300248 (300636)
IRF8	Interferon regulatory factor 8	16q24.1	601565
GATA2	GATA binding protein 2	3q21.3	137295 (614172)

with IFN-γR1, IL-12p40, and IL-12Rβ1 deficiencies and patients with unique mutations in gp91^{phox} (Altare et al., 2001; Boisson-Dupuis et al., 2011; Bustamente et al., 2011a; Caragol et al., 2003; Jouanguy et al., 1997; Özbek et al., 2005; Picard et al., 2002). Haploinsufficient mutations in the *GATA2* gene predispose to infections with both rapid- and slow-growing mycobacteria (Bigley et al., 2011; Vinh et al., 2010). The mycobacterial species isolated seem to track with the underlying genetic defect to some extent: rapid-growing mycobacteria are mostly recovered from children with complete IFN-γR1 or IFN-γR2 deficiencies, whereas they are quite uncommon in children or adults with partial defects, suggesting that even a small amount of residual IFN-γR activity is enough to keep rapid-growing mycobacteria at bay (Table 35.2).

Despite the predominance of NTM in MSMD, they are not the only opportunistic infections encountered. *Salmonella* infections ranging from protracted gastroenteritis to septicemia and disseminated infection occurred in about a quarter of cases, more commonly in association with IL-12p40 and IL-12Rβ1 deficiency than IFN-γR defects (MacLennan et al., 2004). Other pathogens isolated from MSMD cases include *Listeria monocytogenes* (Roesler et al., 1999), *Histoplasma capsulatum* (Jouanguy et al., 1999b; Zerbe and Holland, 2005), *Coccidioides immitis* (Vinh et al. 2009, 2011), *Nocardia asteroides* complex (Picard et al., 2002), *Nocardia* spp. (Luangwedchakarn et al., 2009), *Klebsiella pneumoniae* (Pedraza et al., 2010), *Kingella kingae* (Staretz-Haham et al., 2003), and *Leishmania* spp. (Sanal et al., 2007). Filamentous fungi and bacterial pathogens such as staphylococci have not caused infection in MSMD, despite the presence of indwelling intravenous catheters in many patients. However, a substantial fraction of patients with IL-12p40 and IL-12Rβ1 deficiency (deBeaucoudry et al., 2008, 2010), but not other forms of MSMD, have some forms of chronic mucocutaneous candidiasis, probably related to impairment of their IL-23/IL-17 circuit (Puel et al. 2010, 2011).

Increased susceptibility to viral infections, particularly herpes viruses, has been noted in some patients with IFN-γR1 deficiency (Cunningham et al., 2000; Dorman et al., 1999; Novelli and Casanova, 2004; Roesler et al., 2011; Uzel et al., 2000). One 11-year-child with complete IFN-γR1 deficiency who had developed mycobacterial disease at the age of 5 months was diagnosed with human herpesvirus-8 (HHV-8)-associated Kaposi sarcoma (Camcioglu et al., 2004). However, most other MSMD patients have had classical childhood viral infections without problems. Partial functional mutations in *STAT1* have not resulted in increased susceptibility to viral infection despite the role of *STAT1* in both IFN-γ– and IFN-α–mediated immunity (see the section "Molecular Basis of Disease," below).

Patients with MSMD due to complete IFN-γR1 deficiency often present in childhood with a characteristic syndrome of chronic fever, weight loss, lymphadenopathy, and hepatosplenomegaly due to disseminated infection. The clinical presentation varies according to the gene defect and its severity. For example, dominant partial IFN-γR1 deficiency is almost always associated with NTM osteomyelitis (Dorman et al., 2004; Jouanguy et al., 1999b; Sasaki et al., 2002; Villela et al., 2001; Vinh et al., 2009; Zerbe and Holland, 2005), whereas lymphadenopathy is a very common feature of IL-12p40 or IL-12Rβ1 deficiency (Aksu et al., 2001; Altare et al., 1998a, 1998c, 2001; de Jong et al., 1998; Picard et al., 2002; Sakai et al., 2001). The distinct clinical features of each genetic defect will be more fully described as more patients with MSMD are identified. The age of onset varies according to the gene involved, the type of mutation, and whether the affected individual received BCG vaccination at birth or acquired NTM infection via natural routes (Dorman et al., 2004). A correlation between clinical phenotype and histopathology has been observed (Emile et al., 1997). Two distinct histological types have been documented that appear to be associated with distinct clinical phenotypes (Color Plate 35.I).

Approximately half the patients with disseminated BCG infections had tuberculoid (type I) granulomata with well-defined epithelioid giant cells surrounded by lymphocytes and fibrosis containing only occasional acid-fast bacilli. The remaining patients had lepromatous-like (type II) lesions with poorly formed granulomata containing large numbers of acid-fast bacilli. Patients with type I granulomata had a good prognosis, but virtually all the children with poor granuloma formation (type II) died. NTM granulomata tend to be poorly formed irrespective of the clinical outcome and underlying genetic defect.

LABORATORY FINDINGS

Chronic infection leads to normochromic, normocytic anemia and raised inflammatory markers. Immune function in patients with MSMD has been extensively investigated in an attempt to identify a known immunodeficiency and is in general remarkably normal. $CD4^+$ T cells are often normal but may be low, probably due to chronic infection. Levels of serum immunoglobulins, including IgG subclasses, are normal or elevated, and antigen-specific antibody titers are normal. T-cell proliferation in vitro to various mitogens and recall antigens is also normal. Polymorphonuclear neutrophils are normal in terms of morphology, CD18 expression, chemotaxis, and respiratory burst, even in the case of the CYBB mutations associated with MSMD. Delayed-type hypersensitivity (DTH) testing in vivo and blastogenesis in vitro to purified protein derivative (PPD) are normal, even in patients with complete IFN-γR1 and IL-12Rβ1 deficiency, indicating that IL-12 and IFN-γ are not required for DTH or blastogenesis to mycobacterial antigens.

MOLECULAR BASIS OF THE DISEASE

Mutations in seven genes of the IL-12/IFN-γ axis, and one each in the NADPH oxidase and in the primitive hematopoietic pathway causing increased susceptibility to mycobacteria, have been identified to date (summarized in Fig. 35.1). In humans, these pathways are central to the immune response to intramacrophagic pathogens such as mycobacteria, *Salmonella*, and certain dimorphic yeasts.

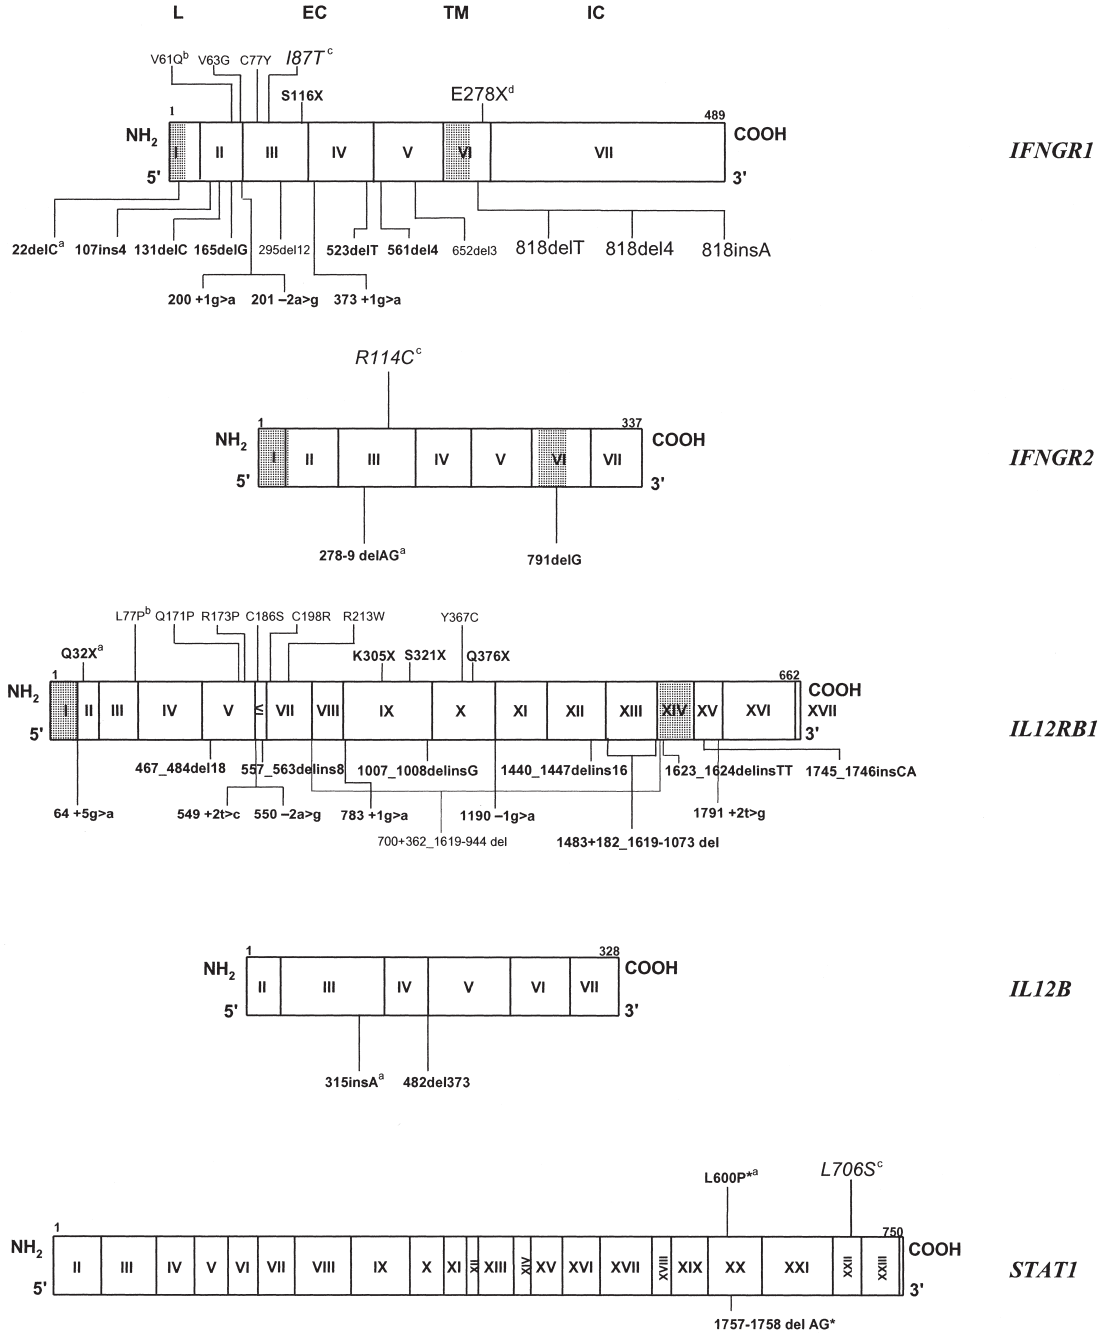

Figure 35.1 Mutations identified to date in five of the nine known MSMD genes. The gene-coding regions are indicated with vertical bars separating the exons, designated by Roman numerals. [a]Nonsense, splice-site mutations, and frameshift insertions and deletions (recessive) causing complete deficiency with no detectable protein expression at the cell surface (small font in bold); [b]missense mutations and in-frame deletions (recessive) causing complete deficiency with detectable surface protein expression (small font); [c,d]mutations that are recessive (large font, italic)[c] or dominant (large font),[d] causing partial deficiency; *indicates two patients with homozygous STAT1 mutation who were susceptible to not only mycobacterial but also severe or eventually lethal viral infections.

FUNCTIONAL ASPECTS OF THE PROTEINS

The receptor for IFN-γ consists of two subunits: IFN-γR1, the ligand-binding chain (previously known as the α chain), and IFN-γR2, the signal-transducing chain (previously known as the β chain or accessory factor 1) (Bach et al., 1997). When the ligand-binding chains interact with IFN-γ homodimers they dimerize and become associated with two signal transduction chains. This leads to the activation of specific members of two protein families—the Janus kinases (JAK) and the signal transducers and activators of transcription (STAT). JAK1 and JAK2 phosphorylate key tyrosine residues on the intracellular domains of the ligand-binding chains. This leads to the recruitment, phosphorylation, and dimerization of STAT1, which translocates to the nucleus as a phosphorylated homodimer (also known as gamma activating factor [GAF]) to activate a wide range of IFN-γ-responsive genes. Subsequently, the phosphorylated STAT1 dimers are dephosphorylated and released from the DNA. After signaling, the receptor complex is internalized and dissociates. The IFN-γR1 chain is recycled to the cell surface, while the IFN-γR2 is more selectively expressed. IFN-γR1 is expressed constitutively at moderate levels on the surface of all nucleated cells. IFN-γR2 is also constitutively expressed at low levels but expression is regulated by external stimuli, including IFN-γ itself (Bach et al., 1995).

Interleukin-12 is a heterodimeric cytokine composed of two subunits, p40 and p35, which together form the biologically active p70 molecule. The IL-12p40 subunit is shared by IL-23 (Fieschi and Casanova, 2003). IL-12 and IL-23 are produced by activated antigen-presenting cells such as dendritic cells and macrophages in response to a number of microorganisms and microbial products, including lipopolysaccharide, lipoarabinomannan, and bacterial superantigens (Trinchieri, 1998). It can also be secreted upon stimulation by T cells in a CD154(CD40L)-CD40–dependent and IFN-γ–dependent manner. The stimulation of whole blood by live BCG was shown to trigger the IL-12/IFN-γ axis by an IRAK-4– and NEMO-dependent, noncognate interaction among monocytes and natural killer (NK) cells and T lymphocytes (Feinberg et al., 2004). It promotes cell-mediated immunity to intracellular pathogens by inducing the production of IFN-γ by both T and NK cells. The IL-12 receptor complex, expressed on activated T and NK cells, consists of two subunits known as the β1 and β2 subunits. Binding of IL-12 to the heterodimeric IL-12 receptor complex induces the phosphorylation of tyrosine kinase 2 (Tyk2) and JAK2 and subsequent activation of STAT4, which dimerizes and translocates to the nucleus to activate IL-12–inducible genes. The IL-12Rβ1 subunit is also part of the IL-23 receptor. Figure 35.2 shows the cytokine interactions between the macrophage and T or NK cell in the context of mycobacterial infection, illustrating the interaction between IL-12 and IFN-γ. IRF8 is an IFN-γ inducible transcription factor required for the induction of various target genes, including IL-12. Gp91^{phox} is the critical transmembrane X-linked component of the phagocyte NADPH oxidase. GATA2 is a critical transcription factor that drives early hematopoiesis as well as mature macrophage function.

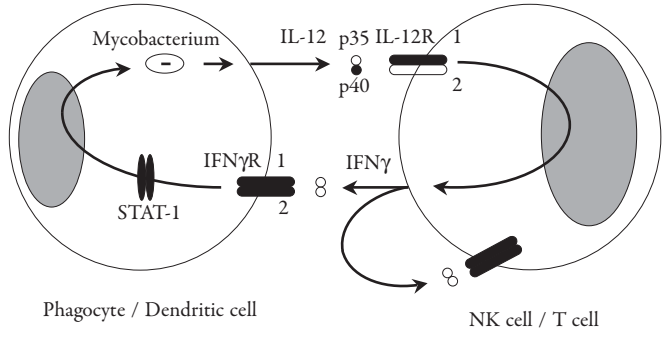

Figure 35.2 Cytokine interactions between the macrophage or dendritic cell and T or NK cell in the context of mycobacterial infection, illustrating the interaction between IL-12 and IFN-γ. Upon infection, primary host response cells such as macrophages release a range of cytokines, including IL-12, which stimulate T and NK cells to secrete IFN-γ, activate m-acrophages to kill intracellular pathogens, and enhance the differentiation of IFN-γ–producing T helper cells.

IFNGR1

Mutations in this gene were the first to be identified as the cause of MSMD (Jouanguy et al., 1996; Newport et al., 1996). Subsequent investigation of patients with increased susceptibility to poorly pathogenic mycobacteria has led to the identification of numerous null-recessive mutations in this gene (Fig. 35.1) (Allende et al., 2001; Altare et al., 1998b; Cunningham et al., 2000; Dorman et al., 2004; Holland et al., 1998; Jouanguy et al., 2000; Koscielniak et al., 2003; Noordzij et al., 2007; Pierre-Audigier et al., 1997; Roesler et al., 1999; Rosenzweig et al., 2002; Vesterhus et al., 1998). In one patient complete IFN-γR1 deficiency was caused by paternal uniparental disomy of chromosome 6 (Prando et al., 2010). The identification of families in which mycobacterial infections occurred in more than one generation suggested that dominant mutations might also exist (Jouanguy et al., 1999b; Han et al., 2004). Investigation of 18 individuals from 12 kindreds led to the identification of a small deletion hot spot within *IFNGR1*. A 4 base pair (bp) deletion at nucleotide position 818 (818del4) was identified in 11 of the unrelated kindreds, and the 12th family had a single nucleotide deletion (T) in this position (818delT) (Glosli et al., 2008). The 818del4 (818delT) mutation leads to a premature stop codon at position 827–829 within the intracellular domain of the receptor. The receptor is expressed on the cell surface, but the mutant receptor lacks the three motifs required for intracellular signaling (the JAK1 and STAT1 binding sites, and the tyrosine phosphorylation site). It also lacks a recycling motif, so the truncated receptor accumulates on the cell surface and interferes with signaling by the normal receptor encoded by the normal copy of *IFNGR1*. Thus, the mutant allele has a dominant negative effect (in comparison to the recessive form of IFN-γR1 deficiency, in which parents are healthy carriers of the mutations). Subsequently, other *IFNGR1* mutations resulting in a dominantly inherited phenotype were identified (Dorman et al., 1999; Sasaki et al., 2002; Villella et al., 2001). A second small deletion hot spot was recently identified in *IFNGR1*, in this case with a recessive phenotype (Hoshina et al., 2011; Rosenzweig et al., 2002).

In summary, a range of mutations, including frameshift, insertion, deletion, nonsense, missense, and splice mutations, have been identified in *IFNGR1* (Fig. 35.1). All recessive mutations identified to date occur in the part of the gene encoding the extracellular domain of the receptor chain, the majority of which result in complete lack of receptor expression. Two of the recessive mutations allow expression of a poorly functioning protein, leading to partial deficiency (Jouanguy et al., 1997; Kong et al., 2010a ; Sologuren et al., 2011). Partial recessive receptor deficiency is more common than previously thought. Partial defects may also result from dominant mutations that cause the receptor to be deprived of its intracytoplasmic segment and therefore neither able to signal properly nor leave the plasma membrane, leading to overaccumulation of a mutant inhibitory protein.

IFNGR2

Complete deficiency of IFN-γR2 was found in a child with disseminated *M. fortuitum* and MAC infections in whom cell-surface expression of IFN-γR1 and *IFNGR1* sequence were normal (Dorman and Holland, 1998). Sequence analysis of *IFNGR2* led to the identification of a homozygous 2 bp deletion (277–278delAG), which in turn led to a premature stop codon (Fig. 35.1). The truncated protein lacked both the transmembrane and intracellular (signaling) domains and was not expressed at the cell surface. Both parents, though unrelated, carried this mutation without cellular phenotype. Another recessive complete 2-base deletion (949delTG) with severe recurrent mycobacterial disease and adolescence-onset diffuse squamous cell cancer has also been reported (Toyoda et al., 2010), confirming the importance of the IFNγ/IL-12 pathway in cancer surveillance. A case of partial IFN-γR2 deficiency has also been described (Doffinger et al., 2000) due to an amino acid substitution at position 114 (arginine → cysteine) within the extracellular domain (Fig. 35.1). The mutant IFN-γR2 is expressed normally on the cell surface, but presumably the affinity between IFN-γR1 and IFN-γR2 is impaired. Dominant negative mutations have also been identified in *IFNGR2*, somewhat similar to those in *IFNGR1* (Rosenzweig et al., 2004). Vogt et al. (2005) identified a gain of glycosylation site in IFNGR2 leading to impaired signaling. They went on to identify numerous other genetic disorders characterized by aberrant gains of glycosylation, indicating novel pathways of therapy. New forms of partial and complete recessive IFN-γR2 deficiency were subsequently identified (De Paus et al., 2011; Vogt et al. 2008).

IL12B

IL-12B (IL-12p40) combines with IL-12A (IL-12p35) to form the biologically active molecule IL-12p70. IL-12p40 can also function as a homodimer, but in this context it has much less stimulatory activity and may inhibit IL-12 signaling. IL-12B can also combine with p19 to form the biologically active compound IL-23. Complete IL-12B (IL-12p40) subunit deficiency was first described in a child born to consanguineous Pakistani parents who was immunized with BCG at birth (Altare et al., 1998c). Sequencing of *IL12B* revealed a large deletion involving two coding exons resulting in a frameshift deletion of 374 nucleotides between positions 482 and 854 (Fig. 35.1). The parents and a healthy sibling were carriers of this mutation; the affected child was homozygous. Eleven additional patients from five other families have been identified to date (Fieschi and Casanova, 2003; Picard et al., 2002). One child had only salmonellosis. All other patients had mycobacterial disease, BCG-osis in 10 children. Four children with BCG-osis also had salmonellosis, one had tuberculosis, one had *M. chelonae*, and one had nocardiosis. Five children died, but all survivors are well and no longer on treatment. Interestingly, one kindred from India had the same large deletion previously reported in the Pakistani kindred. A founder effect was documented and dated to approximately 29 generations ago (95 percent confidence interval [CI] 9–115) and 700 years ago (95 percent CI 216–2760) by means of a novel mutation-dating method (Genin et al., 2004). The other four kindreds originated from the Arabic peninsula and were all found to carry the same *IL12B* frameshift insertion (315insA) (Picard et al., 2002). A founder effect was again documented and dated to 47 generations ago (95 percent CI 22–110) and 1,100 years ago (95 percent CI 528–2640). The fact that all patients with IL-12B deficiency identified to date have *IL12B* mutations resulting from a founder effect, one in the Indian subcontinent and another in the Arabic peninsula, is consistent with the rarity of IL-12p40 deficiency among patients with MSMD. It was the first example of a founder effect among Mendelian mycobacterial susceptibility genes. Because IL-12p40 is also a component of IL-23, IL-12p40 deficiency results in IL-23 deficiency. IL-12B polymorphisms are clearly associated with a variety of infectious and inflammatory diseases, including psoriasis (Nair et al., 2008), hepatitis C (Houldsworth et al., 2005), cytomegalovirus infection following kidney transplant (Hoffmann et al., 2009), and tuberculosis (Morris et al., 2011).

IL12RB1

IL-12Rβ1 serves as one of the receptor chains for IL-12p70 when it partners with IL-12Rβ2. When it partners with IL-23R, it serves as the receptor for the dimer IL-12p40 and p19, otherwise known as IL-23. Mutations in *IL12RB1* (which encodes the β1 subunit of the IL-12 receptor) have been identified in 141 patients from over 100 families from around the world (Altare et al., 1998a, 2001; Asku et al., 2001; de Beaucoudrey et al., 2010; de Jong et al., 1998; Fieschi et al., 2003; Gruenberg et al., 2010; Sakai et al., 2001; Staretz-Haham et al., 2003; Verhagen et al., 2000; Yancoski et al., 2009). Most patients had BCG or NTM disease, often with salmonellosis, but several were found to suffer from salmonellosis only and some from tuberculosis only (de Beaucoudrey et al., 2010; Fieschi et al., 2003; Fieschi and Casanova, 2003; Sanal et al., 2006; Staretz-Haham et al., 2003). One case of visceral leishmaniasis has been reported as well (Sanal et al., 2007). *Klebsiella* infection has also been reported in IL-12Rβ1 deficiency (Pedraza et al., 2010), as has esophageal cancer and mucocutaneous candidiasis (Cardenes

et al., 2010). A significant fraction of patients were asymptomatic. A total of 34 unique mutations have been identified, including nonsense, splice, and frameshift mutations, which lead to premature termination of translation in the extracellular domain (Fig. 35.1), abrogating cell surface expression of IL-12Rβ1 resulting in complete deficiency. Missense mutations resulting in a lack of receptor expression at the cell surface have been validated as well (Altare et al., 2001; Sakai et al., 2001). Complete IL-12/IL-23 receptor β1 deficiency due to cell-surface–expressed nonfunctional receptors also occurs (Fieschi et al., 2004). Only recessive, loss-of-function mutations have been identified in *IL12RB1* to date. *IL12RB1* mutations also impair IL-23 activation, as shown by the impaired induction of IL-17–producing cells by IL-12Rb1–deficient lymphocytes (de Beaucoudrey et al., 2008).

STAT1

The identification of two unrelated families presenting with MSMD in the absence of mutation in any of the genes discussed above led to the discovery of the fifth MSMD gene. A 33-year-old French woman with a history of disseminated BCG infection following childhood vaccination and a 10-year-old North American girl with disseminated *M. avium* infection were found to carry de novo mutations (the parents of both patients had two wild-type copies of *STAT1*) in the coding region of *STAT1* (Dupuis et al., 2001). Both were heterozygous for c.2116T>C resulting in L706S in the COOH-terminal region (Fig. 35.1). The abnormal protein exerts a dominant negative effect on the normal protein in response to IFN-γ, which leads to STAT-1 dimer formation (GAF), but not in response to IFN-α, which leads to formation of STAT-1/STAT-2/p48 trimers (also known as interferon-stimulated gamma factor 3 [ISGF3]). The *STAT1* mutation is remarkable because it is dominant for IFN-γ signaling (it impairs phosphorylation of tyrosine 701 leading to impaired GAF activation) but recessive for ISGF3 activation. To our knowledge it is the first reported mutation in a human gene to be dominant and recessive for two cellular phenotypes. Vulnerability to mycobacteria and resistance to viruses indicate that GAF mediates antimycobacterial IFN-γ activity, whereas the antiviral effects of IFNs are either STAT-1 independent or ISGF3 dependent. This novel disorder proves that IL-12–induced, IFN-γ–mediated immunity against mycobacteria is both STAT-1 and GAF dependent.

In contrast to the effect of the heterozygous *STAT1* mutation L706S, homozygous loss-of-function mutations lead to loss of IFN-α/β and IFN-γ ability to activate STAT1-containing transcription factors. Two unrelated infants found to be homozygous for two unique mutations of *STAT1* in exon 20 (Fig. 35.1) suffered from mycobacterial disease, but in the complete absence of STAT1 activity both died of viral disease (Dupuis et al., 2003). Furthermore, viral multiplication in vitro was not inhibited by adding recombinant IFN-α/β to cell lines from the two individuals. Thus, complete impairment of STAT1-dependent responses to human IFN-α/β results in increased susceptibility to both mycobacterial and viral diseases (Chapgier et al., 2006a; Dupuis et al., 2003). Subsequently, several more mutations in STAT1 have been identified, some working as autosomal recessive partial defects of IFN-α/β and IFN-γ signaling (Chapgier et al., 2009; Kong et al., 2010b; Kristensen et al., 2010) and others working as autosomal dominant inhibitors of GAF formation (Averbuch et al., 2011; Chapgier et al., 2006b). More recently, gain-of-function mutations in STAT1 have been associated with chronic mucocutaneous candidiasis, autoimmunity, epithelial cancers, and aneurysms (Liu et al., 2011; van de Veerdonk et al., 2011). Another cohort of patients with the same mutations predominantly in the coiled-coil domain have localized nodal mycobacterial disease along with disseminated coccidioidomycosis and histoplasmosis (Sampaio et al., 2013).

NEMO

The identification of boys with osteopetrosis, lymphedema, ectodermal dysplasia, and severe immune deficiency who were born to mothers with incontinentia pigmenti led to the identification of the syndrome now known as NEMO deficiency (Doffinger et al., 2001; Jain et al., 2001) (see Chapter 36). NEMO, the NFκB essential modulator, is critical to the signal transduction from numerous cell-surface Toll-like receptors and TNF family receptors (Shih et al., 2011). NEMO (also known as IKKγ) is required for the integrity of the kinase complex that phosphorylates IκB, the inhibitor that keeps NFκB tethered in the cytoplasm and unable to transactivate target genes. Activation of the IκB kinase (IκK, composed of α, β, and γ subunits) leads to ubiquitination and phosphorylation of IκB, liberating NFκB (Gautheron and Curtois, 2010). NEMO is central to several signal transduction pathways, including most TLR receptors, IL-1 receptor, TNF-α receptor, and dysplasin, a receptor associated with isolated ectodermal dysplasia, explaining the complex syndrome that is NEMO deficiency. Filipe-Santos et al. (2006b) showed in several families that NEMO accounted for one form of X-linked susceptibility to mycobacterial disease. Hanson et al. (2008) performed an exhaustive survey of reported mutations and suggested broad possible genotype–phenotype associations. However, it is clear that the syndrome is quite variable and that the somatic and immunological features can be easily segregated in a given case. Therefore, there is no requirement that any particular patient with NEMO immunodeficiency has ectodermal dysplasia (Hoshina et al., 2011).

CYBB

gp91^{phox} encoded by *CYBB* is a major component of the NADPH oxidase (NOX2) complex that traverses the cytoplasm or phagosome membrane in complex with its partner, p22^{phox}. With phagocyte activation, cytoplasmic proteins complex to the gp91^{phox}/p22^{phox} heterodimer and facilitate the oxidation of NADPH with the coincident generation of superoxide. Mutations in any of the five genes involved in the NADPH oxidase lead to the condition known as chronic granulomatous disease (CGD) (Segal et al., 2000) (see Chapter 52). Typically, patients with CGD have a host of

infections and inflammatory problems, usually beginning in infancy or childhood. Mutations in *CYBB* leading to impaired superoxide production are typically manifest in neutrophils, monocytes, macrophages, and B cells and detected by assays of cellular superoxide generation in response to stimulation. Mycobacterial infections, especially those due to BCG and tuberculosis, are part of the spectrum of CGD infections (Bustamente et al., 2007a; Winkelstein et al., 2000). In infancy severe BCG infections are well recognized to be increased in CGD and often precede other infections. Bustamente et al. (2007b) recognized a syndrome that appeared X-linked based on inheritance and manifest with only extrapulmonary BCG and tuberculosis. Subsequently, they showed that this X-linked gene is *CYBB* (Bustamante et al., 2011a, 2011b). This was quite surprising since these patients have normal neutrophil and monocyte gp91^{phox} protein expression and superoxide production. However, differentiated macrophages and Epstein-Barr virus (EBV)-transformed B cells display a much more profound defect of gp91^{phox} expression, resulting in impaired gp91^{phox}/p22^{phox} heterodimer assembly and impaired superoxide production (Bustamente et al., 2011a, 2011b). The mutations causing this condition are novel and are located in the transmembrane domain and extracellular loop, indicating that regulation of gp91^{phox} expression is tightly regulated at the differentiated cell level and that not all mutations in *CYBB* are detectable in neutrophils and monocytes.

IRF8

Two types of lRF8 deficiency have been recently reported (Hambleton et al. 2011). In a child born to consanguineous parents, disseminated BCG disease led to the discovery of a lack of circulating monocytes and dendritic cells in infancy. The severity of disease, mimicking severe combined immunodeficiency, required hematopoietic stem cell transplantation. Following a candidate gene approach, the child was found to have complete IRF8 deficiency due to a homozygous missense change (K108E). IRF8 is expressed at high levels in myeloid cells and mediates interferon and TLR responses, indicating that the IL-12/IFNγ circuit would be profoundly disrupted by an IRF8 defect. In two additional, unrelated patients with a history of recurrent BCG infection, an identical heterozygous IRF8 (T80A) mutation was found, defining an autosomal dominant partial form of IRF8 deficiency. The mutation is severely hypomorphic and dominant negative. Interestingly, the IL-12-IFNγ circuit does not appear to be disrupted. Nevertheless, the population of circulating CDlc^{+} CD11c^{+} myeloid dendritic cells is lacking in the two patients with autosomal dominant lRF8 deficiency. This cell population produces high amounts of IL-17 in normal individuals, indicating that it is possible that their absence may contribute to these patients' MSMD phenotype.

GATA2

The syndrome of monocytopenia, B and NK lymphocytopenia, and mycobacterial infections has been recognized for several decades, in some cases associated with myeloid cancers such as acute myelogenous leukemia (AML) or chronic myelomonocytic leukemia (CMML) as well as myelodysplasia (MDS) (Holland et al., 1994; reviewed in Vinh et al., 2010). This syndrome has been called MonoMAC for its concurrent monocytopenia and mycobacterial infection (Vinh et al., 2010) or DCML for its dendritic cell, monocyte, and B and NK lymphoid deficiency (Bigley et al., 2011). Hahn et al. (2011) identified GATA2 as the gene responsible for familial AML and MDS, leading to its investigation in MonoMAC/DCML. Hsu et al. (2011) sequenced GATA2 in their cohort of MonoMAC patients and found 12 distinct heterozygous missense and insertion/deletion changes in 20 patients, demonstrating that GATA2 haploinsufficiency was the cause of the syndrome. Dickinson et al. (2011) used whole-exome sequencing to find missense changes in the second zinc finger of GATA2 in four patients with the same disease. Subsequently, GATA2 was show to be the etiologic gene for the syndrome of lymphedema and MDS/AML, known as Emberger syndrome (Ostergaard et al., 2011). GATA2 has extensive effects on the early development of lymphatics and their valves that explain its role in Emberger syndrome (Kazenwadel et al., 2012). GATA2 is a transcription factor expressed in early hematopoiesis but also expressed in many terminally differentiated hematologic and somatic cells. The clinical presentation of GATA2 deficiency is remarkable for relatively late onset (late childhood to midlife) with disseminated NTM, histoplasmosis, and warts. There have been no cases of BCG infection so far, which may reflect lack of exposure but is more likely due to relatively intact hematopoiesis early in life that slowly fails over time. The precise mechanism by which GATA2 deficiency leads to NTM susceptibility is unknown, but the lack of monocytes and NK cells removes important responders to and producers of IFNγ.

ISG15

Two unrelated patients, a 15 year old girl and a 12 year old boy with unexplained MSMD, both born to consanguineous parents, were investigated by combined whole-exome sequencing and genome-wide linkage analysis. Two disease-causing homozygous mutations, one a nonsense and one a frame shift mutation in the *ISG15* gene were identified, resulting in undetectable protein in both patients (Bogunovic et al., 2012). ISG15 is an intracellular IFN-α/β-inducible protein that conjugates to proteins in an ubiquitin-like fashion (Sauk et al., 2010) and is known to be a potent IFN-γ-inducing cytokine playing an essential role in anti-mycobacterial immunity. The clinical and immunological phenotypes of these two ISG15-deficient patients resemble those of patients with IL-12p40 or IL-12Rβ1 deficiency, with impaired but not abolished IFN-γ immunity and relatively mild MSMD.

MUTATION ANALYSIS

Mutations in *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB1* (Fig. 35.1), *IRF8*, *NEMO*, *CYBB*, and *GATA2* can be detected by direct sequencing. Primers to amplify and sequence all

exons and flanking intron regions have been published and are available upon request.

STRATEGIES FOR DIAGNOSIS

CLINICAL DIAGNOSIS

Inherited defects of the IL-12/IFN-γ axis (and those of IRF8, NEMO, CYBB, and GATA2) should be considered in the differential diagnosis of all patients presenting with severe infection (including disseminated and recurrent diseases) with intracellular microorganisms, particularly when the organism is considered to be nonpathogenic in the "immunocompetent" individual. However, these defects should be sought especially aggressively in patients with severe nontuberculous mycobacterial or *Salmonella* infections. Furthermore, a high index of suspicion is warranted in patients presenting with chronic fever, wasting, hepatosplenomegaly, lymphadenopathy, and anemia in whom a pathogen is not isolated, as cultures may be persistently negative (Levin et al., 1995; Pierre-Audigier et al., 1997). Diagnosis may also be confounded by the lack of usually diagnostic granulomata, in which microbes may or may not be visible. An initial diagnosis of histiocytosis X has occasionally been made, so MSMD should be considered in chemotherapy-resistant children with a tentative diagnosis of histiocytosis without formal histological criteria (Edgar et al., 2001). In many individuals, MSMD becomes apparent following BCG vaccination, so vaccination history is essential. Because of the high incidence of parental consanguinity and affected relatives, family history is important. Specific attention must be directed at possible parental consanguinity. Defects in the IL-12/IFN-γ axis should not only be sought in patients with disseminated or recurrent BCG/NTM disease but also considered in patients with acute local BCG/NTM, severe tuberculosis, severe histoplasmosis, listeriosis, paracoccidioidomycosis, coccidioidomycosis, and severe viral infections. Despite the progress outlined in this chapter, our understanding of the molecular basis of MSMD is still in its relative infancy; it is likely that there are many aspects of the disease that are yet to be unraveled. It is therefore prudent to consider the disorder in those diagnostic conundrums in which infectious, malignant, or inflammatory diagnoses are entertained.

LABORATORY DIAGNOSIS

In vitro testing is based on (1) circulating IFN-γ levels, (2) protein expression (FACS, ELISA), (3) functional studies, and (4) DNA analysis.

Levels of circulating IFN-γ in either plasma or serum are frequently abnormal in actively infected patients with complete IFN-γR deficiency (Fieschi et al., 2001). These children have high levels of plasma IFN-γ, whereas IFN-γ is low or undetectable in plasma taken from healthy controls. Patients with partial IFNγR1 deficiency typically have lower levels of circulating IFN-γ (Soluguren et al., 2011). High IFN-γ levels have been thought to be due to sustained production of IFN-γ in the setting of active disease, along with the requirement for an intact IFN-γR for ligation and removal of IFN-γ from the circulation. Although this observation provides a simple assay for individuals with severe BCG/NTM disease who are suspected to have defects in the IFN-γR, it should be kept in mind that elevated plasma or local (e.g., pleural tuberculosis) IFN-γ levels are seen in normal hosts with active disease. Further, when patients with complete IFN-γR deficiency are not actively infected, their circulating IFN-γ levels are normal. Similar data have been clearly shown in mouse models (Rottman et al., 2008). In addition, normal ranges for circulating IFN-γ levels in the setting of other diseases (bacterial osteomyelitis, leukemia) are not available, making interpretation of this test complex at best. Therefore, while an elevated IFN-γ level may be useful in suggesting a complete IFN-γR defect, it is not shown to be helpful in excluding or including other defects in the IFN-γ/IL-12 circuit.

The IFN-γR is expressed ubiquitously on all nucleated cells, whereas the IL-12 receptor is found only on NK and T cells. Analysis of EBV-induced B lymphoblasts, SV-40 fibroblasts, or peripheral blood mononuclear cells (PBMCs) for IFN-γR cell-surface expression by fluorescence-activated cell sorting (FACS) is a simple means to assess the presence or absence of these receptors, as demonstrated for the first reported cases of complete IFN-γR1 deficiency (Jouanguy et al., 1996; Newport et al., 1996). Mutations causing the dominant form of IFN-γR1 deficiency abrogate the receptor recycling motif, leading to high levels of cell-surface IFN-γR1 expression (up to 10-fold), which is easily detectable by FACS staining (Dorman et al., 2004; Jouanguy et al., 1999b; Sasaki et al., 2002; Villela et al., 2001). Normal expression of IFNγ-R1, as detected by FACS, even using blocking antibodies, does not exclude partial or even complete IFNγ-R1 deficiency from mutations that result in the surface expression of an abnormal protein (Jouanguy et al., 1997, 2000). Antibodies that recognize low levels of IFN-γR2 present on resting cells are not yet adapted to routine laboratory use. Antibodies that recognize IL-12Rβ1 work well on phytohemagglutinin (PHA) blasts and allow a diagnosis of IL-12Rβ1 deficiency. To date, most *IL12RB1* mutations identified cause a loss of expression of the encoded chain. There is one mutation with residual expression of IL-12Rβ1 (de Beaucoudrey et al., 2010; Fieschi et al., 2004). Staining of *Herpesvirus saimiri*-transformed T-cell lines and EBV-transformed B lymphoblasts also works well. Secreted IL-12p40 and p70 can be detected by ELISA in the supernatant of whole blood or PBMCs stimulated by BCG or IFN-γ as well as in the supernatant of EBV-transformed B lymphoblasts stimulated with phorbol 12,13-dibutyrate (PDBu) (Feinberg et al., 2004; Picard et al., 2002). To date, all *IL12B* mutations identified have been associated with a lack of detectable IL-12p40 and IL-12p70. However, prolonged stimulation of IL-12Rβ1–deficient T-cell lines has been reported in one instance to rescue some degree of IL-12 responsiveness (Verhagen et al., 2000).

Expression of IFN-γR or IL-12R does not necessarily confer function, and therefore other in vitro assays are required to identify which component(s) of the IL-12/IFN-γ pathway are defective in appropriate cases. Upon binding to its receptor, IFN-γ induces pleiotropic effects, including the upregulation of major histocompatibility complex (MHC) class II expression and TNF-α production by monocytes. These effects are mediated by the binding of phosphorylated STAT1

to gamma-activating sequences (GAS) in gamma-responsive genes. Thus, IFN-γR deficiency may be diagnosed functionally by studying in vitro responses to IFN-γ. A simple whole-blood assay was used to demonstrate defective responses to IFN-γ in the Maltese kindred (Levin et al., 1995), and this technique was modified to study PBMC responses in a patient with partial IFN-γR1 deficiency (Jouanguy et al., 1997). MHC class II expression is easily studied by flow cytometry (Altare et al., 1998b), whereas nuclear translocation and phosphorylation of pSTAT1 in response to IFN-γ can be assessed using electrophoretic mobility shift assays (Bach et al., 1997; Dupuis et al., 2001) or, more simply, by flow cytometry with a STAT1-specific monoclonal antibody (Fleisher et al., 1999). Cellular responses to IFN-γ should be tested at low and high concentrations of IFN-γ to differentiate between partial and complete receptor deficiency. In vitro studies in patients with IL-12p40 deficiency show defective IFN-γ production by PBMCs or whole blood following stimulation with BCG. This defect was restored by the addition of recombinant IL-12 to the culture medium. IL-12Rβ1–deficient patients also have diminished mitogen-induced IFN-γ production, but IL-12 p70 production in response to lipopolysaccharide (LPS), tuberculin, or mycobacteria is normal. A flow-cytometric assay that detects phosphorylated STAT4 has also been developed (Uzel et al., 2001). Notably, children with complete IFN-γR deficiency have low in vitro production of IFN-γ because of impaired production of IL-12 (Holland et al., 1998).

Recurring mutations are seen in the dominant *IFNGR1* hot-spot mutations, IRF8 hot-spot mutations, GATA2 hot-spot mutations, some recessive hypomorphic IFNGR1 mutations, and the two *IL12B* mutations (founder effects). The majority of the rest of the MSMD mutations are unique. It is not cost-effective to set up mutation screening assays looking only for known mutations. A combination of in vitro phenotyping (flow cytometry for surface expression of the IFN-γR1 and IL-12Rβ1 and functional studies) followed by direct gene sequencing is recommended. GATA2 deficiency is suggested by markedly low numbers of circulating monocytes, B cells, and NK cells. Once the causative mutation has been established in a family, other family members can be screened directly for the mutation. Accurate molecular diagnosis by biochemical, functional, and genetic studies is of the utmost importance for guiding treatment and predicting prognosis.

GENETIC COUNSELING AND PRENATAL DIAGNOSIS

Defects in the IL-12/IFN-γ pathway may be inherited either as dominant or recessive disorders, depending on the mutation. All mutations reported in *IFNGR2*, *IL12RB1*, and *IL12B* are recessive: many patients are homozygous, reflecting the high frequency of parental consanguinity within this group of patients. *IFNGR1* mutations were initially identified as homozygous recessively inherited traits, but dominant mutations have subsequently been identified as well. Compound heterozygotes have also been reported. Most *STAT1* mutations identified to date are dominant loss- or gain-of-function mutations, but complete recessive cases have also been recognized. Mutations in IRF8 are recessive or dominant, while those in GATA2 are transmitted in a dominant pattern but cause disease because of haploinsufficiency. Finally, X-linked recessive inheritance has been shown to be due to mutations in NEMO (Frucht and Holland, 1996; Frucht et al., 1999; Holland et al., 1994) and more recently in gp91^{phox} (NOX2) (Bustamante et al., 2011a).

Given the heterogeneity of MSMD, coupled with its rarity, carrier detection or screening using functional assays is not currently feasible. In one family with recessive IFN-γR1 deficiency, heterozygous carriers had an intermediate cellular phenotype in vitro (Levin et al., 1995; Newport et al., 1996), although this may have been dependent on the assay used. To date, there is no clinical phenotype associated with heterozygosity for any of the recessive alleles. Once the molecular basis is known within a family, it is simplest to screen other members by directly sequencing their DNA. Counseling within families in which the mutation is known is straightforward in terms of the risk of inheriting a "susceptible" genotype (25 percent risk of an affected child if recessive, 50 percent risk of an affected child if dominant inheritance). However, any discussion must also take into account the following: (1) the clinical phenotype depends on the gene affected and whether the mutation leads to complete or partial protein deficiency; (2) development of disease is dependent on pathogen exposure (e.g., BCG); and (3) there are individuals who have inherited a susceptible genotype without developing disease, presumably thanks to the impact of modifier genes that result in residual antimycobacterial immune function or lack of exposure or both. To date, there are no known individuals with complete IFN-γR1, IFN-γR2, IRF8, or STAT1 deficiency who have not been clinically affected. Complete IFN-γR1 or IFN-γR2 deficiency is the most severe phenotype and is frequently lethal despite the use of antibiotics. BCG vaccination must be withheld from potentially affected children until IFN-γR status is clarified. Bone marrow transplantation (BMT) has proved very difficult and less successful than would be anticipated (see below), perhaps because transplantation has typically been attempted after disseminated mycobacterial disease occurred.

Once a molecular diagnosis has been established, prenatal diagnosis can be offered to affected families with severe disease (i.e., complete IFN-γR deficiency). The role of prenatal diagnosis for other mutations is less obvious as the phenotype is less severe, disease is preventable, and many individuals carrying mutations are disease-free.

TREATMENT AND PROGNOSIS

The treatment of defects in the IL-12/IFN-γ axis should be tailored to the individual patient according to the mutation, the clinical pattern of disease, and the pathogens involved (Holland, 2000b). Established infection should be treated with appropriate antimicrobial drugs as determined by the genus and species. Thus, microbiological isolation and characterization of the causative pathogen at an early stage are desirable. The role for in vitro susceptibilities in directing treatment of NTM infections is still unproven and poorly defined.

NTM infections are notoriously resistant to a number of antimicrobials. Cytokine therapy has helped clear mycobacterial infection in patients with full or partial function of the IFN-γ receptor (Holland, 2000a; Holland et al., 1994), and patients with IL-12B (IL-12p40), IL-12Rβ1 deficiency or partial STAT1 deficiency respond well to IFN-γ treatment. It may also work in patients with the dominant IRF8 mutations and the mycobacteria-predisposing mutations in gp91^{phox} (NOX2). However, intestinal, mesenteric, and splenic infections can be resistant to antibiotics and IFN-γ. Splenectomy was helpful in two children with splenic sequestration (IFN-γ induced in one child); on occasion abdominal lymph node resection may be indicated (Kaufman et al., 1998; J. L. Casanova, unpublished observation). Overall, patients with partial IFN-γR/STAT1 deficiency or complete IL-12Rβ1 deficiency can achieve prolonged clinical remission after antibiotics and IFN-γ are discontinued. Relapses may occur years after the initial episode. Treatment with antibiotics and IFN-γ should be prolonged, even after clinical remission is obtained.

In contrast, children with complete IFN-γR deficiency achieve full clinical remission less often, and mycobacterial infections often relapse weeks to months after antibiotics are discontinued (Dorman et al., 2004). Therefore, successful antibiotic therapy should not be discontinued. Because of the lack of specific receptors, IFN-γ therapy is not indicated. The role for other cytokines, such as IFN-α, granulocyte-macrophage colony-stimulating factor (GM-CSF), or IL-12, is undefined. The only curative treatment available for patients with complete IFN-γR deficiency is BMT (Reuter et al., 2002; Chantrain et al., 2006; Moilanen et al. 2009). An international survey identified eight unrelated patients with complete IFN-γR1 deficiency who underwent BMT (Roesler et al., 2004). The results were disappointing: BMT in patients with complete IFN-γR1 deficiency is associated with high morbidity and mortality. The only child receiving a human leukocyte antigen (HLA)-haploidentical transplant died after the second transplant (HLA identical) of EBV-induced lymphoproliferative disease. Of the seven patients transplanted with an HLA-identical related graft, despite an initial full engraftment in most cases, four are alive but only two have a functional graft and are free of infection. There appears to be a selective advantage of IFN-γR–deficient over wild-type hematopoietic progenitors in IFN-γR–deficient children (which makes gene therapy for patients with IFN-γR deficiency challenging) (Rottman et al., 2008). Moreover, chronic NTM/MAC infection before and during stem cell transplantation carries an unfavorable outcome. The expression of IFN-γ itself appears to inhibit marrow engraftment and success of transplant, which is greatly aggravated in the setting of ongoing active infection. Prevention of infection is desirable, although many pathogens to which these individuals are susceptible are ubiquitous in the environment. BCG should be avoided and mycobacterial infection (both primary and secondary) may be prevented by the routine daily use of a macrolide such as clarithromycin or azithromycin. In patients with mild MSMD, prophylactic antibiotics are not required, as infectious episodes are relatively infrequent and can be controlled by IFN-γ and antibiotics if treated promptly. However, physicians and patients should weigh carefully the risks and benefits of recurrence of infection, especially if it recurs in bone, as is often the case with the dominant form of IFN-γR1 deficiency (Dorman et al., 2004). In these patients recurrence of infection can have serious consequences, despite curative therapy.

In patients with complete IFN-γR deficiency, antibiotics should be continued indefinitely after therapy for acute infections. There is considerable diversity of pathogenic NTM (particularly rapidly growing species), making absolute recommendations difficult. Most NTM are susceptible to macrolides, and these should be strongly considered for long-term prophylaxis regardless of cure of other acute infections. Immunosuppressive agents such as corticosteroids should be avoided as a rule, particularly in children with complete IFN-γR deficiency, although in some circumstances they may be helpful. Children with MSMD should be treated on an individual basis, and treatment should be undertaken in close collaboration with experts.

ANIMAL MODELS

The study of gene-disrupted mice has greatly enhanced our understanding of the IL-12/IFN-γ pathway. Although not completely concordant, the phenotypic similarities between these animal models and patients with mutations in this axis are striking (Jouanguy et al., 1999a). Mice lacking *Ifngr1* are highly susceptible to BCG infection, with poorly defined granuloma formation and death (Kamijo et al., 1993). Mice lacking Ifn-γ also fail to control BCG, *M. avium*, or *M. tuberculosis* (Cooper et al., 1993; Dalton et al., 1993). More recently, *Ifngr2* knockout mice were shown to have defective Ifn-γ production and susceptibility to *L. monocytogenes* infection (Lu et al., 1998). *Il12b* (il-12p40) knockout mice are more susceptible to *M. tuberculosis* infection than normal mice, leading to higher bacterial loads and disseminated disease (Cooper et al., 1997). Granulomata were poorly formed and multibacillary. *Il12rb1* knockout mice have defective Ifn-γ responses to mitogens and LPS (Wu et al., 1997). Disruption of *Ifng* in mice also leads to lethal infection with an attenuated strain of *S. typhimurium*, whereas wild-type mice clear infection within 4 weeks (Bao et al., 2000; Hess et al., 1996). However, comparisons between mice and humans are limited in several ways: most of the infections in MSMD patients are naturally occurring, whereas those in mice are experimental and often administered intravenously, and the strain and dose of pathogen are controlled. There are certain infections, such as *Toxoplasma gondii* and *Cryptococcus neoformans*, to which *Ifng/Il-12* knockout mice have increased susceptibility that are less observed in humans (Decken et al., 1998; Yap et al., 2000). This may reflect lack of exposure, experimental design, or the fact that knockout mice are generated in highly inbred strains. Genetic variation at other immunity-modifying loci is low in inbred mice whereas humans are outbred, even in the setting of consanguinity. Experimental infections in mice probably highlight even minor effects of the Il-12/Ifn-γ axis. Alternatively, mice and humans may differ in their handling of some of these nonmycobacterial infections.

CONCLUDING REMARKS AND FUTURE CHALLENGES

Mutations in eight genes involved in the IL-12/IFN-γ axis, the NADPH oxidase pathway, or early hematopoiesis have been associated with the syndrome of MSMD, which encompasses a range of clinical presentations. The severity of the clinical phenotype depends primarily on the gene involved and the specific mutation. IFN-γ–mediated immunity appears to be a genetically controlled quantitative trait that determines the outcome of mycobacterial invasion (Dupuis et al., 2000). IFN-γ immunity to mycobacteria is dependent on IL-12 stimulation and mediated by STAT1 and its homodimeric complex GAF. These defects are most pronounced with respect to mycobacteria and, to a lesser extent, intramacrophagic fungi, *Salmonella*, and viruses (Casanova and Abel, 2002). The investigation of more patients is necessary to broaden our knowledge of these genotype–phenotype correlations. Clinically, molecular diagnosis guides rational treatment based on pathophysiology.

ARE THERE OTHER MSMD GENES?

There remain patients with the clinical syndrome of MSMD who do not have mutations in *IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB1, NEMO, CYBB, IRF8*, or *GATA2* (approximately 20 percent at our centers, S. Holland and J. L. Casanova, unpublished observations). Characterization of the molecular defects in these patients will help in the identification of other MSMD genes and contribute further to our understanding of human mycobacterial immunity. Relevant genes upstream of IL-12 and downstream of IRF8 are expected to expand and define the limits of the IL-12/IFN-γ axis, especially the inducer and effector mechanisms of immunity to mycobacteria.

DEFINITION OF CLINICAL BOUNDARIES OF MSMD

The genetic defects of the IL-12/IFN-γ axis were identified by investigating patients with disseminated, often lethal, BCG/NTM disease. Subsequently, it was found that some affected individuals have recurrent local disease, whereas others are asymptomatic. The clinical boundaries of IL-12Rβ1 deficiency (de Beaucoudrey et al., 2010; Fieschi et al., 2003) and IFN-γR1 deficiency (Dorman et al., 2004; Solugren et al., 2011) were made possible thanks to international collaboration. Other international surveys are currently under way to define the clinical features of each inherited disorder on the basis of the clinical history of the patients identified. The question arises as to whether patients with unexplained local BCG/NTM disease may suffer from these or related genetic defects. However, NTM lung disease in the elderly appears to be due to other predisposing factors and does not appear to be due to impaired hematopoietic IFN-γ synthesis or response. NTM adenitis in childhood is currently unexplained but does not appear to have its origin in immune defects in this pathway (Haverkamp et al., 2010). Because of these considerations, patients with various forms of BCG/NTM disease should be studied in terms of the IL-12/IFN-γ axis to define the clinical frontiers of each genetic defect.

ROLE OF MSMD GENES IN SUSCEPTIBILITY TO TUBERCULOSIS AND LEPROSY

It is estimated that approximately 2 billion individuals worldwide are infected with *M. tuberculosis* (Dolin et al., 1994). The World Health Organization estimates that there were 8 million new cases of tuberculosis and 1.7 million deaths from the disease in 2009. The fact that only 10 percent of individuals infected with *M. tuberculosis* go on to develop clinical disease suggests that exposure to virulent mycobacteria alone is not sufficient and that the host immune response is an important determinant of susceptibility (or resistance) to disease (Murray et al., 1990). Several studies demonstrate a role for host genetic factors as determinants of susceptibility to tuberculosis (Casanova and Abel, 2002, 2004). However, the identification of specific genes involved in susceptibility to infectious diseases in outbred human populations is difficult. Complex interactions among the pathogen, which also has a genome, the environment, and host factors determine whether an individual is resistant or susceptible to disease. It is likely that a number of genes are involved, but it is not known exactly how many or how they interact. Population-based studies have reported associations between candidate genes and tuberculosis, but the effects have been modest and the functional relevance of these findings is yet to be established (Abel and Casanova, 2000; Casanova and Abel 2002, 2004; Newport and Levin, 1999; Wilkinson et al., 1999).

There is a spectrum of disease within the MSMD syndrome ranging from severe disease that is fatal in early childhood (complete IFN-γR deficiency) to moderate disease in individuals with partial IFN-γR1 deficiency (Jouanguy et al., 1997). The IL-12p40/IL-12Rβ1 mutations have a less severe clinical course. Mutations in *IL12RB1* and *IL12B* have been identified as a susceptibility factor for the development of abdominal *M. tuberculosis* infection (Altare et al., 2001; Haerynck et al., 2008) and tuberculous adenitis (Picard et al., 2002). Furthermore, four families have been observed whose affected members lacked IL-12β1 and suffered from disseminated tuberculosis; however, none of them had a history of clinical disease caused by BCG/NTM (Altare et al. 2001; Boisson-Dupuis et al., 2011; Caragol et al., 2003; Özbeck et al., 2005). Disorders of the IL-12/IFN-γ axis should thus be considered in selected children with severe tuberculosis, even in the absence of infection with poorly virulent mycobacteria or *Salmonella*. Partial deficiency of either IL-12p40 or IL-12Rβ1 would be expected to have a less severe phenotype than complete deficiency and to show susceptibility to only the most virulent pathogens. More subtle polymorphisms in the MSMD genes identified thus far could result in impaired expression of a normal protein or normal expression of a slightly altered, less efficient protein. It is also likely that mutations or polymorphisms will be identified in other genes known to be involved in mycobacterial immunity that may play a different role and cause a different immune defect. Such individuals may retain immunity to organisms of low virulence while remaining susceptible to more virulent species.

INBORN ERRORS OF NF-κB IMMUNITY: GENETIC, IMMUNOLOGICAL, AND CLINICAL HETEROGENEITY

Capucine Picard, Jordan S. Orange, Anne Puel, Shen-Ying Zhang, and Jean-Laurent Casanova

The 10 human Toll-like receptors (TLRs) act as receptors for pathogens and, as such, are involved in innate immune recognition (Akira and Takeda, 2004). Agonists of TLR homodimers and heterodimers include triacetylated bacterial lipopeptides for TLR1/TLR2, diacetylated bacterial lipopeptides for TLR2/TLR6, peptidoglycan and lipoteichoic acid for TLR2, double-stranded RNA for TLR3, lipopolysaccharide (LPS) for TLR4, bacterial flagellin for TLR5, single-stranded RNA for TLR7 and TLR8, and CpG-DNA for TLR9 (Kawai and Akira, 2010). No TLR10 agonist has yet been identified. TLR1, 2, 4, 5, 6, and 10 are expressed on the cell surface. By contrast, TLR3, 7, 8, and 9 are expressed in the endoplasmic reticulum (ER), from which they may be transported to other intracellular compartments, such as endosomes. UNC-93B is an essential molecule in the signaling pathway of these receptors because it delivers the nucleotide-sensing receptors TLR3, 7, 8, and 9 from the ER to endolysosomes (Fig. 36.1) (Kim et al., 2008).

TLRs and IL-1Rs all have an intracellular Toll and interleukin-1 receptor (TIR) domain. The presence of this domain defines the TIR superfamily (O'Neill, 2008). Humans have up to 10 members of the IL-1R family, including a decoy receptor without a TIR domain (IL-1RII) and 9 TIR-domain-containing receptors, including 6 receptors (IL-1R1, IL-18Rα, IL-33Rα, TIGIRR-1, TIGIRR-2, and IL-1Rrp2), 2 co-receptors (IL-1RAcP and IL-18Rβ), and an inhibitory receptor TIR8/SIGIRR (Arend et al., 2008; Dinarello, 2009; Sims and Smith, 2010). The six receptors include those for three potent proinflammatory cytokines: (1) IL-1β (IL-1RI and IL-1RAcP also recognize the less-inflammatory IL-1α) (Arend et al., 2008; Dinarello, 2009, Sims and Smith, 2010), (2) IL-18 (IL-18Rα and IL-18Rβ also recognize the less-well-defined IL-1F7) (Arend et al., 2008; Nakanishi et al., 2001), and (3) IL-33 (IL-33Rα and IL-RAcP) (Arend et al., 2008; Haraldsen et al., 2009). Historically, IL-1Rs have been seen as key innate immune system receptors, because IL-1β, IL-18, and IL-33 have been shown to be key cytokines in the early steps of the inflammatory response (Arend et al., 2008; Dinarello, 2009; Sims and Smith, 2010). These three cytokines, IL-1β, IL-18, and IL-33, are thought to play an important role in various immune responses contributing to host defense.

TIR-domain-containing TLRs and IL-1Rs recruit the TIR-containing cytosolic adaptors MyD88, TRIF, TIRAP (also known as MAL), TRAM, and SARM (Kenny and O'Neill, 2008; O'Neill and Bowie, 2007). The canonical TIR pathway is dependent on MyD88, which is used by all TLRs other than TLR3 and at least three IL-1Rs: IL-1R, IL-18R, and IL-33R. The alternative pathway is controlled by another key adaptor, TRIF, the only known TLR3 adaptor, which is also used by MyD88 via TLR4 (Fig. 36.1). The other three adaptors act as co-adaptors. The sorting adaptor TIRAP recruits MyD88 to TLR2 and 4, whereas TRAM recruits TRIF to TLR4. The role of SARM is less well defined (Carty et al., 2006; Casanova et al., 2011). The adaptors, in turn, recruit cytosolic kinases, including the IL-1R–associated kinase (IRAK) complex, which is recruited by MyD88 and seems to be the most TIR-specific kinase used in these pathways (Lin et al., 2010; Ringwood and Li, 2008). The classical TIR pathway results in the activation of both nuclear factor-κB (NF-κB) and mitogen-activated protein kinases (MAPKs), via the IRAK complex, which comprises two active kinases (IRAK-1 and IRAK-4) (Fig. 36.1) and two noncatalytic subunits (IRAK-2 and IRAK-3/M). The alternative pathway results in the activation of NF-κB and interferon regulatory factor 3 (IRF3).

NF-κB is a transcription factor sequestered in the cytoplasm of resting cells through associations with the inhibitor of NF-κB (IκB) proteins. Signaling via both the classical and alternative pathways can lead to the activation of NF-κB. Upon cell stimulation, IκBs are phosphorylated at two conserved

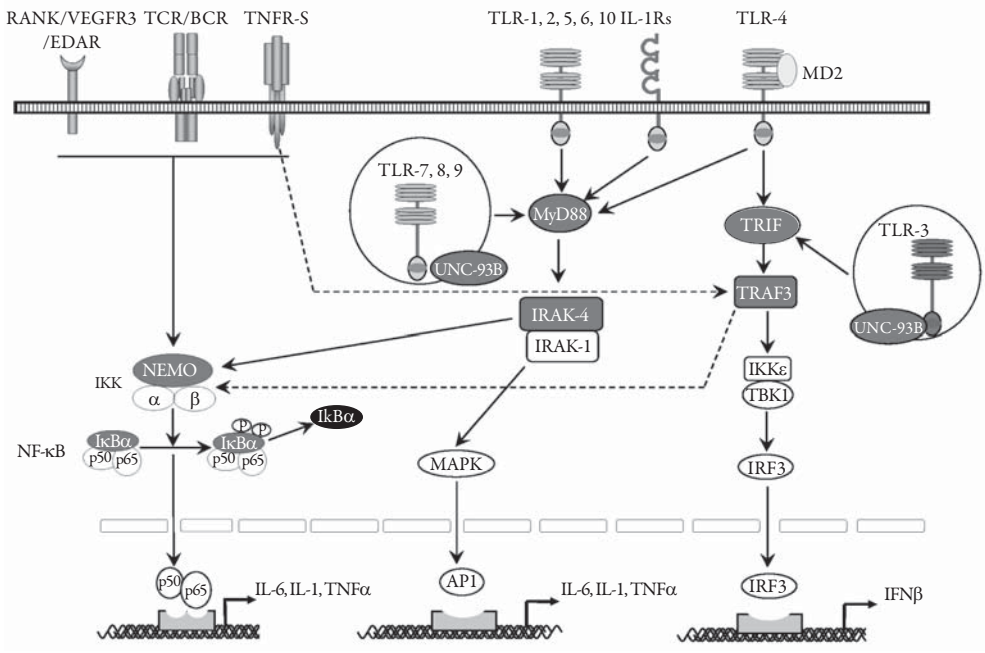

Figure 36.1 *Human defects involving NF-κB pathways.* Immune receptor signaling pathways leading to NF-κB activation can be grouped into four categories on the basis of the surface receptors involved: developmental receptors RANK, VEGFR3, and EDAR; antigen receptors (TCR and BCR); members of the TNF receptor superfamily (TNF-Rs); and members of the TIR superfamily (IL-1Rs/TLRs). The two proteins of the TIR signaling pathway (MyD88, IRAK-4) and the two proteins of the NF-κB signaling pathway (NEMO and IκBα) responsible for primary immunodeficiency are shown in gray. The defect in UNC-93B abolishes cellular responses to TLR3, TLR7, TLR8, and TLR9 agonists. The defect in TRAF3 impairs cellular responses to TLR3 and other pathways. The four proteins of the TLR3 signaling pathway (TLR3, UNC-93B, TRIF, and TRAF3) responsible for immunodeficiency selective for herpes simplex virus 1 encephalitis (HSE) are shown in gray.

critical amino-terminal serine residues by the IκB kinase (IKK) complex, leading to their ubiquitination and subsequent degradation (Fig. 36.1; Puel et al., 2004). The IKK complex consists of at least three related catalytic subunits, IKKα, IKKβ, and IKKγ/NEMO (for NF-κB essential modulator) (Israel, 2010). The degradation of IκBs results in the translocation of NF-κB dimers to the nucleus, where they bind to DNA at cognate binding sites and regulate gene transcription (Puel et al., 2004). The classical proinflammatory TIR signaling pathway leads to the synthesis of inflammatory cytokines and chemokines, such as IL-1β, -6, -8, and -12, and tumor necrosis factor α (TNF-α) (Fig. 36.1; Kawai and Akira, 2010). The alternative pathway is controlled by TRIF, which is used by TLR-3 and TLR-4, leading to activation of the transcription factors IRF3 and NF-κB (Fig. 36.1; Kawai and Akira, 2010). TRIF recruits TRAF6 and activates TAK1 for NF-κB activation. TRIF also recruits a signaling complex involving TBK1 and IKKε via TRAF3 for IRF3 activation (Kawai and Akira, 2010). This signaling pathway induces the production of type I and type III IFNs and inflammatory cytokines and is important in antiviral immunity (Kawai and Akira, 2010).

Four primary immunodeficiencies (PIDs) associated with impaired signaling via the TIR canonical pathway have been reported, with mutations in *IRAK4*, *MYD88*, *NEMO*, and *IKBA* (Fig. 36.1) (Courtois et al., 2003; Doffinger et al., 2001; Hanson et al., 2008; Picard et al., 2003, 2010; von Bernuth et al., 2008). The mutations in *NEMO* and *IKBA* also impair the alternative, TRIF-dependent pathway. The principal infectious phenotype of patients with any of these four defects is the occurrence of pyogenic bacterial infections. Conversely, four genetic defects affect primarily the alternative pathway, with mutations in *TLR3*, *UNC93B1*, *TRIF* and *TRAF3* (Fig. 36.1; Casrouge et al., 2006, Perez de Diego et al., 2010; Zhang et al., 2007) (Sancho-Shimizu et al.2011). *UNC93B1* and *TRAF3* defects also impair the TLR7-9 pathway, but with no known clinical consequences. The predominant infectious phenotype of patients with any of these three defects is herpes simplex virus 1 encephalitis (HSE) in childhood. Collectively, these seven disorders were initially thought to be rare, but they have since been diagnosed in about 200 patients around the world. They have very little in common except that they all impair at least one arm of NF-κB–involved immunity. We summarize here the infectious diseases seen in patients with mutations impairing the canonical pathway and the alternative pathway. We also discuss the diagnostic and therapeutic options in such patients, in an attempt to propose tentative guidelines for clinicians.

INBORN ERRORS OF THE TLR AND IL-1R CANONICAL PATHWAY (MYD88 AND IRAK-4)

HUMAN IRAK-4 DEFICIENCY

Molecular Basis of the Disease

Autosomal recessive IRAK-4 deficiency was discovered in 2003 (Picard et al., 2003). Up to 52 patients have since been identified,

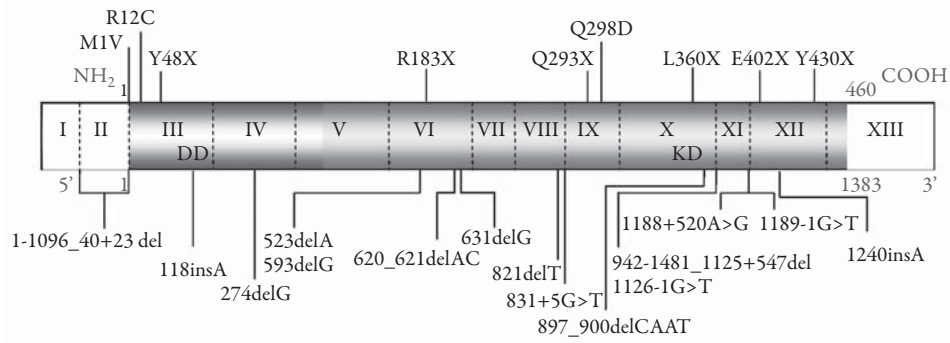

Figure 36.2 *Schematic diagram of the structure of the IRAK4 gene and the mutations identified.* Human *IRAK4* has 13 exons (Roman numerals), including two noncoding first exons, and encodes a protein (shown in gray) including a death domain (DD) and a kinase domain (KD). The position of all known mutations is represented (amino-acid nomenclature at the top, nucleotide nomenclature at the bottom).

from 33 kindreds, in 14 countries (Bouma et al., 2009; Cardenes et al., 2006; Chapel et al., 2005; Currie et al., 2004; Davidson et al., 2006; Day et al., 2004; Enders et al., 2004; Hoarau et al., 2007; Krause et al., 2009; Ku et al., 2007a, 2007b; Lavine et al., 2007; McDonald et al., 2006; Medvedev et al., 2003; Picard et al., 2010; Takada et al., 2006; van Bruggen et al., 2010; von Bernuth et al., 2006; Yang et al., 2005; and unpublished data). IRAK-4–deficient patients have homozygous or compound heterozygous mutations in the *IRAK4* gene (Fig. 36.2). Up to 17 cases have been identified as sporadic, with 35 cases considered familial (16 kindreds). The 33 affected families originated from 14 countries, from several different continents: the Americas (Canada, El Salvador, United States of America), Asia (Israel, Japan, Saudi Arabia, Turkey), Australia, and Europe (France, Hungary, Portugal, Slovenia, Spain, United Kingdom) (Fig. 36.3). Most of the patients and their families were living in their countries of origin, with the exception of a Portuguese family living in France, a Turkish family living in Germany, and a family from El Salvador living in the United States. The patients with IRAK-4 deficiency from 19 kindreds carried homozygous mutations, whereas those from 14 other kindreds were compound heterozygous for *IRAK4* mutations (Picard et al., 2010, and unpublished data). One patient was compound heterozygous for the Q293X mutation and for a large de novo deletion encompassing the *IRAK4* gene (Ku et al., 2007b). The mutations identified were nonsense mutations, missense mutations, splice mutations, and frameshift insertions or deletions (Fig. 36.2). All the mutations were loss of expression and loss of function, with the possible exception of two missense mutations, G298D and R12C, which seemed to be associated with residual IRAK-4 protein production (Picard et al., 2010).

Laboratory Findings and Immunological Features

In whole-blood assays, leukocytes from IRAK4-deficient patients do not produce IL-6, and CD62L shedding from

Figure 36.3 *Countries of origin of the 33 kindreds with IRAK-4 deficiency identified* (in dark gray). The number of patients identified in each country is indicated.

granulocytes does not occur in response to activation with the TLR and IL-1R agonists tested, with the exception of TLR3, which uses an IRAK-4–independent pathway (von Bernuth et al., 2006, 2008; Zhang et al., 2007). The defects observed abolished all TLR responses (with the exception of those to TLR3 and a few TLR4 responses), and all IL-1R responses (at least IL-1β, IL-18, and IL-33) tested, in all hematopoietic and nonhematopoietic cells from all patients tested (J. E. Sims, personal communication). However, there seems to be no overt defect of leukocyte development in IRAK-4–deficient patients and these patients have normal antigen-specific T- and B-cell responses, as shown by normal findings for immunological analyses, with three notable exceptions (Ku et al., 2007b; von Bernuth et al., 2008). First, the IgM+IgD+CD27+ cells but not switched B-cells were strongly reduced in IRAK-4-deficient patients (Weller el al. 2012). Second, the glycan-specific IgG and IgM antibody response to pneumococcal and AB glycans has been shown to be impaired in up to 50 percent of the patients explored (Picard et al., 2010). Third, serum IgE and IgG4 concentrations have been found to be high in 70 percent and 38 percent, respectively, of the patients tested (Picard et al., 2010). Nevertheless, none of the IRAK-4–deficient patients suffers from allergic asthma, and a chronic eczematous skin disease was reported in only one patient. IRAK-4 deficiency confers a predisposition to severe bacterial infection, with impairment of the ability to increase plasma C-reactive protein (CRP) concentrations and to mount fever at the beginning of infection. However, pus formation has been observed at various sites of infection. Finally, delayed separation of the umbilical cord is observed in 20 percent of IRAK-4–deficient patients.

Clinical and Pathological Manifestations

Despite their broad and profound immunological phenotype, patients with IRAK-4 deficiency display surprisingly narrow susceptibility to invasive pyogenic bacterial infections (meningitis, sepsis, arthritis, osteomyelitis, and abscesses). They also have normal resistance to common fungi, parasites, viruses and to many bacteria. Meningitis has been reported in 65 percent of IRAK-4–deficient patients, sepsis in 37 percent, arthritis in 27 percent, osteomyelitis in13 percent, and deep inner organ/tissue abscesses in 29 percent (Table 36.1). Only five IRAK-4–deficient patients have never developed invasive bacterial infection, and four of these patients were diagnosed at birth and have remained asymptomatic on prophylactic treatment. The invasive bacterial infections observed were mostly caused by *Streptococcus pneumoniae, Staphylococcus aureus*, and *Pseudomonas aeruginosa,* in particular. In IRAK-4–deficient patients, *S. pneumoniae* was involved in 54 percent of documented invasive episodes, whereas *S. aureus* and *P. aeruginosa* were found in 14 percent and 20 percent of such episodes, respectively (Table 36.2). Other gram-positive (*Streptococcus agalactiae, S. milleri, S. pyogenes*, and *S. parasanguis*) and gram-negative (*Shigella sonnei, Neisseria meningitidis*, *Haemophilus influenzae* type b, and *Clostridium septicum*) bacteria have been shown to cause invasive disease in IRAK-4–deficient patients

Table 36.1 PERCENTAGE OF IRAK-4- AND MYD88-DEFICIENT PATIENTS WITH INFECTIONS AT VARIOUS SITES

	TOTAL NUMBER OF PATIENTS (N = 74)	IRAK-4–DEFICIENT PATIENTS (N = 52)	MYD88-DEFICIENT PATIENTS (N = 22)
Meningitis	59%	65%	45%
Sepsis	41%	37%	50%
Arthritis	23%	27%	14%
Osteomyelitis	12%	13%	9%
Abscess	24%	29%	14%

Skin infection	35%	44%	14%
Pneumonia	19%	21%	14%
ENT	27%	33%	14%

Data from Conway et al., 2010; Picard et al., 2010; unpublished data.

(Table 36.2). Most IRAK-4–deficient patients (90 percent) suffered from their first bacterial infection before the age of 2 years. Twenty patients (38 percent) died from invasive bacterial infections, all before the age of 8 years and most before the age of 2 years (Picard et al., 2010; and unpublished data). Eleven of these patients died of invasive pneumococcal disease. However, this PID improved with age, and patients with IRAK-4 deficiencies do not seem to be particularly susceptible to invasive bacterial infection after their teens (Picard et al., 2010).

IRAK-4–deficient patients present also with noninvasive pyogenic bacterial infections, mostly of the skin and upper respiratory tract. Necrotizing infections are particularly common at these two sites. Recurrent localized skin infections (furunculosis, folliculitis, cellulitis, omphalitis, and orbital cellulitis or endophthalmitis) have been found in 44 percent of patients, lymphadenitis in 29 percent, and ear, nose, and throat (ENT) infections (otitis, sinusitis, tonsillar abscesses, necrotizing epiglottitis, pharyngitis, and palate infection) in 33 percent of patients (Table 36.1). Intriguingly, only 21 percent of patients have had pneumonia, and none has developed chronic bronchopulmonary disease. Of note, a pair of twins with this deficiency developed pneumonia during primary infection with cytomegalovirus (CMV) at the age of 3 months (unpublished data). The principal bacterial strains found during noninvasive infections were *S. aureus* in 43 percent of episodes, *P. aeruginosa* in 22 percent of episodes, and *S. pneumonia* in 16 percent of episodes in IRAK-4–deficient patients (Table 36.2). Other gram-positive (*S. pyogenes, S. intermedius,* β-hemolytic streptococci, and *S. equi*) and gram-negative (*E. coli, Serratia marcescens, M. catarrhalis*, and *Citrobacter freundii*) bacteria have also been reported to cause noninvasive disease in IRAK-4–deficient patients. Only one IRAK-4–deficient patient developed otitis and pneumonia due to *Mycobacterium avium*. All IRAK-4–deficient patients had noninvasive bacterial infections, and more than half the

patients suffered from their first noninvasive bacterial infection before the age of 2 years. All patients continued to suffer from skin infections, sinusitis, or pneumonia, including those who had reached adulthood.

HUMAN MYD88 DEFICIENCY

Molecular Basis of the Disease

Autosomal recessive MyD88 deficiency was discovered in 2008 (von Bernuth et al., 2008). Up to 22 patients have since been identified, from seven kindreds in six countries (Conway et al., 2010; Picard et al., 2010; and unpublished data). MyD88-deficient patients have homozygous or compound heterozygous mutations in the *MYD88* gene (Fig. 36.4). Only 1 case has been described as sporadic, with 21 cases described as familial (six kindreds). The seven families originated from six countries in the Americas (United States of America), Asia (Turkey), and Europe (France, Portugal, Serbia, Spain). All patients and their families were living in their countries of origin, with the exception of a Serbian family living in Switzerland (Fig. 36.5). The patients of six kindreds with MyD88 deficiency were homozygous, and one patient was compound heterozygous (Picard et al., 2010; von Bernuth et al., 2008). The mutations identified in patients were one nonsense mutation, two missense mutations, and one frameshift deletion (Fig. 36.4). All the mutations identified are loss of function, but only one *MYD88* mutation (E66X) is loss of expression (Conway et al., 2010). Two mutant *MYD88* alleles have been shown to lead to the production of very small amounts of a nonfunctional protein (E65del and L106P), whereas the R209C mutant allele is associated with quantitatively normal production of a nonfunctional protein (Picard et al., 2010; von Bernuth et al., 2008).

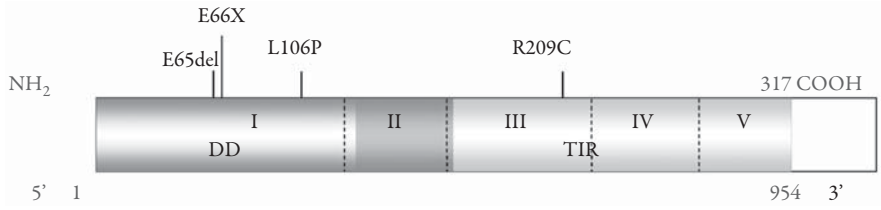

Figure 36.4 *Schematic diagram of the structure of the MYD88 gene and the mutations identified.* Human *MYD88* has five exons (Roman numerals) encoding a protein (shown in gray) with TIR and DD domains. The position of all known mutations is represented in amino-acid nomenclature at the top.

Laboratory Findings and Immunological Features

MyD88-deficient patients display a lack of production of IL-6 by whole blood, and CD62L shedding from granulocytes is absent following activation with most of the TLR and IL-1R agonists tested, with the exception of TLR3, which uses a MyD88-independent pathway (von Bernuth et al., 2006, 2008; Zhang et al., 2007). Thus, there seems to be no overt defect of leukocyte development in MyD88-deficient patients, and antigen-specific T- and B-cell responses appear to be normal in most cases, as shown by routine immunological analyses with three notable exceptions (Ku et al., 2007b; von Bernuth et al., 2008). First, the IgM+IgD+CD27+ cells but not switched B-cells were strongly reduced in MyD88-deficient patients (Weller el al. 2012). Second, serum IgE and IgG4 concentrations were high in up to half and in 28 percent, respectively, of the patients tested (Picard et al., 2010). Third, some of the modest subclinical abnormalities of B-cell responses, such as the production of low levels of antibodies against carbohydrates in some patients, may thus reflect impaired TACI responses rather than impaired TLR and IL-1R responses. Indeed, MyD88 has recently been shown to control signaling downstream of TACI (He et al., 2010). MyD88 deficiency confers a predisposition to severe bacterial infection, with impairment of the ability to increase plasma CRP concentrations and to mount fever at the beginning of infection. However, pus formation has been observed at various sites of infection.

Clinical and Pathological Manifestations

Patients with MyD88 deficiency present a narrow susceptibility to invasive pyogenic bacterial infections (meningitis, sepsis, arthritis, osteomyelitis, and abscesses) and have normal resistance to common fungi, parasites, viruses and many bacteria. Meningitis has been found in 45 percent of MyD88-deficient patients, sepsis in 50 percent, arthritis in 14 percent, osteomyelitis in 9 percent, and deep inner organ/tissue abscesses in 14 percent (Table 36.1) (Conway et al., 2010; Picard et al., 2010; and unpublished data). Only two MyD88-

Figure 36.5 *Countries of origin of the seven kindreds with MyD88 deficiency identified* (in light gray). The number of patients identified in each country is indicated.

deficient patients have never developed invasive bacterial infection (Conway et al., 2010). In MyD88-deficient patients, *S. pneumoniae* was involved in 41 percent of the documented invasive episodes, whereas *S. aureus* and *P. aeruginosa* were found in 20 percent and 16 percent of such episodes, respectively (Table 36.2). Other gram-positive bacteria (group A, B, and β-hemolytic streptococci) and gram-negative (*S. enteritidis, H. influenzae* type e, and *M. catarrhalis*) have been found to cause invasive disease in MyD88-deficient patients (Table 36.2) (Conway et al., 2010; Picard et al., 2010; and unpublished data). Most MyD88-deficient patients suffered from their first bacterial infection before the age of 2 years. Nine patients (41 percent) died from invasive bacterial infections, all before the age of 4 years and most before the age of 1 year (Conway et al., 2010; Picard et al., 2010; and unpublished data). Seven of these patients died from invasive pneumococcal disease (Conway et al., 2010; Picard et al., 2010; and unpublished data). However, MyD88 deficiencies seem to improve with age, and none of the patients has presented with invasive bacterial infection after adolescence (Picard et al., 2010).

MyD88 deficiencies also confer a predisposition to noninvasive pyogenic bacterial infections, mostly affecting the skin and upper respiratory tract. Necrotizing infections are particularly common at these two sites. Recurrent localized skin infections (furunculosis, folliculitis, cellulitis, and endophthalmitis) have been found in 14 percent of patients, lymphadenitis in 23 percent, and ENT infections (otitis, sinusitis, tonsillar abscesses, necrotizing epiglottitis, pharyngitis) in 14 percent of patients (Table 36.1) (Conway et al., 2010; Picard et al., 2010; and unpublished data). Only 14 percent of the patients had pneumonia, and none developed chronic bronchopulmonary disease. The principal bacterial strains found during noninvasive infections were *S. aureus* in 53 percent of patients, *S. pneumoniae* in 20 percent of patients, and *P. aeruginosa* in 13 percent of patients (Table 36.2). Other gram-negative bacteria (*E. coli* and *K. pneumoniae*) have been found to cause noninvasive disease in MyD88-deficient patients (Table 36.2). Severe mycobacterial, viral, parasitic, or fungal diseases have not been reported. Most MyD88-deficient patients have had noninvasive bacterial infections, with half the patients suffering from their first noninvasive bacterial infection before the age of 2 years. MyD88-deficient patients continue to suffer from skin infections, sinusitis, or pneumonia, including those who have reached adolescence.

TREATMENT OF IRAK-4 AND MYD88 DEFICIENCIES

MyD88 and IRAK-4 deficiencies are phenocopies in terms of their immunological and clinical phenotypes (von Bernuth et al., 2008), so the management of these two deficiencies can be discussed together. Patients with IRAK-4 and MyD88 deficiencies should be immunized with conjugated and nonconjugated *S. pneumoniae* vaccines, conjugated *H. influenzae* vaccine, and conjugated and nonconjugated *N. meningitidis* vaccines. A preventive treatment regimen, including antibiotic prophylaxis with cotrimoxazole plus penicillin V (or equivalent), is required throughout the patient's life, with empirical intravenous (IV) or subcutaneous (SC) immunoglobulin injections until at least the age of 10 years. This prophylaxis seems to have an impact on the incidence of invasive bacterial infections (Picard et al., 2010). Both clinical status and outcome improve with age, and prophylactic treatment appears to be beneficial in these patients. This dramatic improvement with age may be accounted for by the development of adaptive antigen-specific T- and B-lymphocyte responses.

INBORN ERRORS OF THE CORE NF-κB–MEDIATED SIGNALING PATHWAY

HUMAN NEMO DEFICIENCY

Molecular Basis of the Disease

X-linked recessive (XR) anhidrotic ectodermal dysplasia (EDA) with immunodeficiency (ID) due to hypomorphic *IKBKG/NEMO* mutations was described in 2000 (Zonana et al., 2000) and in 2001 (Doffinger et al., 2001) as a disorder caused by an impairment of NF-κB immunity. NEMO is a regulatory subunit of the IKK complex (Puel et al., 2004). Approximately 100 male patients with hemizygous hypomorphic mutations of *NEMO* have been reported to date, and about 47 different mutations have been identified. All mutations functionally investigated have been found to result in at least some impairment of NF-κB activation (Aradhya et al., 2001; Chang et al., 2008; Dai et al., 2004; Devora et al., 2010; Doffinger et al., 2001; Dupuis-Girod et al., 2002; Filipe-Santos et al., 2006; Fusco et al., 2008; Hanson et al., 2008; Haverkamp et al., 2004; Jain et al., 2001; Ku et al., 2005, 2007a; Lee et al., 2005; Martinez-Pomar et al., 2005; Mooster et al., 2010; Niehues et al., 2004; Orange et al., 2002, 2004a, 2004b, 2005; Orstavik et al., 2006; Pachlopnik Schmid et al., 2006; Puel et al., 2006; Roberts et al., 2010; Salt et al., 2008; Smahi et al., 2000; Zonana et al., 2000, and unpublished data). Two female patients with defective X chromosome lyonization have also been reported (Kosaki et al., 2001; Martinez-Pomar et al., 2005). Patients with this deficiency have been identified in 14 countries from various continents, including Africa (South Africa), the Americas (Canada, United States of America), Asia (Japan, Turkey), and Europe (Belgium, France, Germany, Italy, Poland, Netherlands, Norway, Switzerland, United Kingdom), including missense, nonsense, splice-site mutations, and frameshift insertions and deletions (Figs. 36.6 and 36.7). NF-κB dimers are involved in several pathways, including those triggered by the many members of the TNF-R, IL-1R, T-cell receptor (TCR), B-cell receptor (BCR), and TLR families (Fig. 36.1). In cases of NEMO deficiency, the impairment of the various immunological pathways depends on the mutation concerned (type and location), with between one and all the pathways impaired (Filipe-Santos et al., 2006; Hanson et al., 2008; Mooster et al., 2010; Puel et al., 2004). There is considerable allelic heterogeneity, accounting for the tremendous variability of cellular and clinical phenotypes.

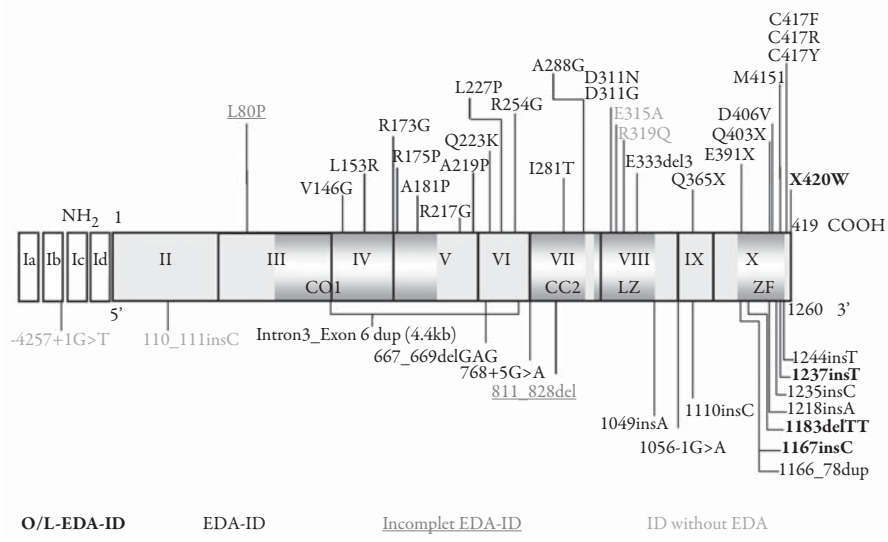

Figure 36.6 *Schematic diagram of the structure of the NEMO gene and the mutations identified.* Human *NEMO* has 10 exons (Roman numerals), including four noncoding alternative exons. *NEMO* encodes a protein (shown in gray) with two coil-coiled (CC) domains, one leucine zipper (LZ) and one zinc-finger (ZF) domain. The position of all mutations reported is represented (amino-acid nomenclature at the top, nucleotide nomenclature at the bottom). Mutations responsible for the osteopetrosis/lymphedema-EDA-ID phenotype are shown in black bold, mutations responsible for the EDA-ID phenotype are shown in black, mutations responsible for an incomplete EDA-ID phenotype (conical teeth only) are shown in light gray underline, and mutations responsible for ID without an EDA phenotype are shown in light gray.

Laboratory Findings and Immunological Features

NEMO-deficient patients generally display a lack of IL-10 production in response to activation with TNF-α in whole-blood assays (Doffinger et al., 2001; Hanson et al., 2008; Puel et al., 2004). TLR and IL-1R signaling pathways have been explored in only a few patients and have been shown to be impaired in patients with the most severe clinical infectious phenotype, with a high degree of susceptibility to infection (Hanson et al., 2008). However, they may be intact in certain individuals. Almost all patients bearing mutations in *NEMO* have an impaired antibody response, to glycans, including pneumococcal capsules, in particular (Hanson et al., 2008; Puel et al., 2004). Half the patients also have hypogammaglobulinemia, presumably

Figure 36.7 *Countries of origin of the patients with NEMO deficiency identified* (in gray).

secondary to a CD40 signaling impairment found in most patients with mutations affecting the zinc-finger domain (Hanson et al., 2008). High serum IgM concentrations have been found in 15 percent of patients with hyper-IgM–like phenotype, and high levels of IgA have been found in 37 percent of patients (Hanson et al., 2008). More than 10 patients have been explored for natural killer (NK) function, and all were found to have impaired NK-cell cytotoxicity, despite having normal numbers of peripheral blood NK cells (Hanson et al., 2008; Orange et al., 2002; and unpublished data). Other immunological parameters used for diagnosis, such as the numbers of blood phagocytes, B and T lymphocytes, lymphocyte subset distribution (CD4, CD8), and T-cell proliferation in response to mitogens and antigens, are generally normal in most patients tested (Hanson et al., 2008). However, one NEMO-deficient patient with somatic reversion mosaicism in T, B, and NK cells revealed the critical role of NEMO in lymphocyte development and/or survival (Nishikomori et al., 2004). The severity and diversity of the infectious phenotype of NEMO-deficient patients and the diversity of signaling pathways potentially affected by mutations in the corresponding gene thus contrast with the small number of detectable abnormalities identified in routine immunological examination of affected patients.

Clinical and Pathological Signs

The broad and profound immunological phenotypes of patients with NEMO deficiencies are responsible for a high degree of susceptibility to invasive pyogenic bacterial infections (meningitis, sepsis, arthritis, osteomyelitis, and deep organ abscesses), environmental mycobacteria, parasites, viruses, and fungal infections. One third of the patients have had sepsis, one third have had a deep tissue abscess, one third have had recurrent pneumonia with bronchiectasis, 20 percent have had meningitis or encephalitis, about 23 percent have had gut infection, and 11 percent have had osteomyelitis and sinusitis (Table 36.3) (Doffinger et al., 2001; Hanson et al., 2008; Puel et al., 2004). Pyogenic bacterial infection has been identified in about 86 percent of NEMO-deficient patients and has been attributed to several species, including *S. pneumoniae*, *H. influenzae*, and *S. aureus*. Mycobacterial infection is found in about 44 percent of NEMO-deficient patients (cellulitis, osteomyelitis, lymphadenitis, pneumonia, and disseminated infections) and is mostly caused by *M. avium* or *M. kansasii* (Doffinger et al., 2001; Hanson et al., 2008). The presence of mycobacterial infection in patients with NEMO deficiency is indicative of a particularly poor prognosis. Serious viral infection has occurred in 21 percent of NEMO-deficient patients (herpes simplex virus encephalitis, severe adenoviral gastroenteritis, severe cytomegalovirus infection) (Table 36.4) (Doffinger et al., 2001; Hanson et al., 2008; Niehues et al., 2004; Puel et al., 2006). Finally, opportunistic infections, *Pneumocystis jirovicii* infections, and chronic mucocutaneous candidiasis (CMC) have been reported, but in less than 10 percent of patients (Doffinger et al., 2001; Hanson et al., 2008; Orstavik et al., 2006). However, the number of *Pneumocystis* infections recognized as associated with NEMO deficiency and even as a presenting infection has increased in recent years (Hanson et al., 2008; Salt et al., 2008). In summary, the spectrum of infectious diseases is broad in NEMO-deficient patients, as most patients present with multiple infections (Bustamante et al., 2008). Almost all patients report infections caused by pyogenic bacteria (*S. pneumoniae*, *S. aureus*, *P. aeruginosa*, and

Adapted from Hanson et al., 2008.

H. influenzae), and only some patients suffer from opportunistic infectious diseases caused by mycobacterial, fungal, and/or viral infections.

About 80 percent of the NEMO-deficient patients reported to date have had isolated EDA characterized by the presence of sparse hair, dental abnormalities (conical teeth, tooth agenesis), and hypohidrosis with lack of sweating and a tendency to develop hyperpyrexia (Hanson et al., 2008; Puel et al., 2004). These features result from defective signaling via the ectodysplasin receptor signaling pathway, the normal functioning of which is required for normal ectodermal development. Unrelated mutations in the genes encoding the ectodysplasin receptor or its ligand result in other forms of EDA, not associated with immunodeficiency. In some other NEMO-deficient patients, osteopetrosis and lymphedema have been found associated with the EDA phenotype (Doffinger et al., 2001; Hanson et al., 2008; Roberts et al., 2010) This is particularly true for those associated with a frameshift run-on mutation resulting in elongation of the NEMO protein. Some patients also have dysmorphia with mild frontal bossing (Dupuis-Girod et al., 2002; Mancini et al., 2008; and unpublished data). About 10 percent of NEMO-deficient patients have none of the features of the EDA phenotype (Hanson et al., 2008; Mooster et al., 2010; Puel et al., 2006). Inflammatory conditions are also frequent, with cutaneous inflammation and colitis. Some patients develop a disseminated skin eruption, dermatitis, eczema, and/or erythema early in life (Fish et al., 2009; Mancini et al., 2008; Minakawa et al., 2009; Permaul et al., 2009; Roberts et al., 2010; Tono et al., 2007; and unpublished data). Histological studies of the skin have revealed acanthosis, spongiosis of the epidermis, and a perivascular lymphohistiocytic infiltrate with necrotic keratinocytes (Mancini et al., 2008; Tono et al., 2007). Colitis was also found in 21 percent of patients, and some had intractable diarrhea with failure to thrive (Hanson et al., 2008; Orange et al., 2002, 2004a; Pai et al., 2008; Roberts et al., 2010; and unpublished data). There seems to be some evidence for a genotype–phenotype correlation in NEMO deficiency. Given the large number of mutations reported to date, it is difficult to be certain that some of the findings attributed to particular genotypes are relatively consistent. For example, mutations affecting specific regions of the NEMO protein tend to be associated with particular types of infection, the absence of an EDA phenotype, autoinflammation, osteopetrosis/lymphedema, and certain immune phenotypes, such as antibody defects and TLR impairments. A summary of the most frequently identified genotypes and their associated phenotypes is provided in Table 36.5. In conclusion, the developmental and immunological phenotype of NEMO-deficient patients is variable and probably relates to the biological function of each mutation.

HUMAN MUTATIONS IN *IKBA* GENE

Molecular Basis of the Disease

In 2003, an autosomal dominant (AD) form of EDA-ID was identified that was caused by a hypermorphic heterozygous mutation of *NFKBIA/IKBA*, impairing the phosphorylation and degradation of NF-κB inhibitor α (IκBα) (Fig. 36.1) (Courtois et al., 2003). Seven patients with four different hypermorphic mutations of *NFKBIA/IKBA* have since been identified (Fig. 36.8) (Courtois et al., 2003; Janssen et al., 2004; Lopez-Granados et al., 2008; McDonald et al., 2007; Ohnishi et al. 2012; and E. Renner and T. Torgerson, personal communication). The patients originated from five countries: North America (United States of America), Asia (Japan) and Europe (Italy, Netherlands, Germany). Two of the mutations identified were missense mutations and three were nonsense mutations (Fig. 36.8). The same heterozygous 94G>T mutation was identified in two unrelated kindreds. This mutation is responsible for the replacement of a serine residue important for the phosphorylation of IκBα with an isoleucine residue (S32I). The S32I,

Q9X and Q14X mutations are gain-of-function mutations, as they increase the inhibitory capacity of IκBα by preventing its phosphorylation and degradation, resulting in the impairment of NF-κB activation (Courtois et al., 2003; Janssen et al., 2004; Lopez-Granados et al., 2008; and Ohnishi et al. 2012). The W11X nonsense mutation is responsible for haploinsufficiency and less severe clinical, immunological, and functional phenotypes in the patient bearing this mutation (McDonald et al., 2007). Functional studies are currently under way for the M37K mutation (E. Renner and T. Torgerson, personal communication). One IκBα-mutated adult patient with a S32I mutation presented a complex partial mosaicism; his son also presents the same mutation of *IKBA*, but with no mosaicism (Janssen et al., 2004). IκB molecules are involved in several pathways, including those triggered by the many members of the TNF-R, IL-1R, TCR, BCR, and TLR families. IκBα mutations leads to a particularly severe impairment of TCR signaling.

Laboratory Findings and Immunological Features

The three children bearing AD mutations (two patients bearing S32I and one bearing W37K) in the *IKBA* gene without mosaicism had hypogammaglobulinemia with hyper-IgM and no production of specific antibodies (Courtois et al., 2003; Janssen et al., 2004; and E. Renner, personal communication). These three patients and the pediatric patient with the Q14X mutation had low proportions of memory CD4 and CD8 T cells and no TCR gamma/delta T cells. Five patients displayed severe impairment of T-cell proliferation in response to anti-CD3 or PHA, but antigen-mediated T-cell proliferation was impaired only in the two patients carrying the S32I mutation without mosaicism (Courtois et al., 2003; Janssen et al., 2004; Lopez-Granados et al., 2008; Ohnishi et al. 2012; and E. Renner and T. Torgerson, personal communication). The child with the W11X mutation presented only a defect of glycan antibody production (McDonald et al., 2007). No immunological abnormalities were found in the adult patient with complex mosaicism and the S32I mutation, but the production of specific glycan antibodies was not explored in this patient (Janssen et al., 2004).

Clinical and Pathological Signs

The broad and profound immunological phenotypes of patients with *IKBA* mutations are responsible for broad susceptibility to severe pyogenic bacterial infections (meningitis, sepsis, arthritis, enteritis, abscesses, and pneumonia) and fungi. All seven patients have developed recurrent pyogenic bacterial infections. All presented with recurrent bacterial pneumonia, three have had sepsis or meningitis, and one has had arthritis (Table 36.3) (Dupuis-Girod et al., 2006; Janssen et al., 2004; Lopez-Granados et al., 2008; McDonald et al., 2007; Ohnishi et al. 2012; and E. Renner and T. Torgerson, personal communication). Pyogenic bacterial infections were identified in all IκBα-deficient patients, due to β-hemolytic type A streptococci, *S. aureus*, *P. aeruginosa*, *K. pneumoniae*, *S. marcescens*, and *S. typhimurium*. Patients are also prone to opportunistic infections, with three having had *P. jirovicii* infections. Four patients has had CMC and one has had hepatitis caused by CMV (Table 36.4). Finally, six of these patients presented with recurrent diarrhea and/or colitis. The patient with the W11X mutation responsible for haploinsufficiency and the adult patient with complex partial mosaicism and the S32I mutation did not develop opportunistic infections, chronic diarrhea, or failure to thrive (Janssen et al., 2004; McDonald et al., 2007). All IκBα-deficient patients had EDA, with sparse hair, abnormal teeth (conical teeth, tooth agenesis), and hypohidrosis (Dupuis-Girod et al., 2006; Janssen et al., 2004, Lopez-Granados et al., 2008; McDonald et al., 2007; Ohnishi et al. 2012; E. Renner and T. Torgerson, personal communication), with the exception of the adult patient with complex partial mosaicism, who did not display features of EDA (Janssen et al., 2004).

TREATMENT AND PROGNOSIS OF PATIENTS WITH *IKBA* AND *NEMO* MUTATIONS

Prophylactic antibiotic treatment with cotrimoxazole and penicillin V (or equivalent) for preventing pyogenic bacterial infection, and with azithromycin (or equivalent) to prevent atypical mycobacterial infection, should be offered to all patients with mutations in *IKBA* and *NEMO* genes. IV or SC immunoglobulin substitution should also be considered, given the frequency and range of impaired B-cell immunity. Patients with mutations in *IKBA* and *NEMO* genes with functional B-cell immunity can be immunized with conjugated and nonconjugated *S. pneumoniae* vaccines, conjugated *H. influenzae* vaccine, and conjugated and nonconjugated *N. meningitidis* vaccines, irrespective of the provision of Ig therapy. Hematopoietic stem-cell transplantation (HSCT) has been reported in two children mutated

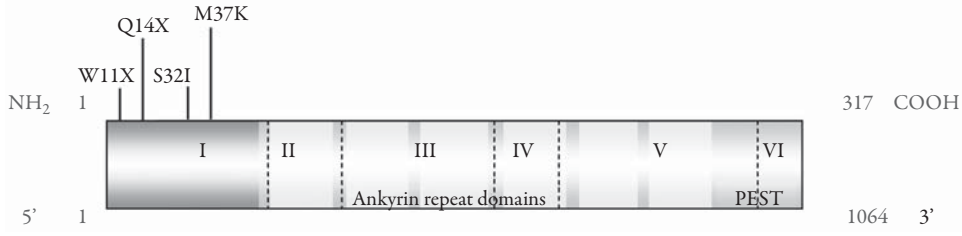

Figure 36.8 *Schematic diagram of the structure of the IKBA gene and the mutations identified.* Human *IKBA* has six exons (Roman numerals) encoding a protein (shown in gray) with ankyrin repeat domains (light gray) and PEST (proline/glutamic acid/serine/threonine) domains. The position of all mutations reported is represented in amino-acid nomenclature at the top.

in *IKBA* gene with combined immunodeficiency (Dupuis-Girod et al., 2006; Fish et al., 2009). One of these patients is alive and well in the absence of treatment, 8 years after parental haploidentical HSCT, whereas the second patient died of bacterial sepsis during the aplasia period (Dupuis-Girod et al., 2006; Fish et al., 2009). Seven NEMO-deficient patients with severe clinical and immunological phenotypes have undergone transplantation with various conditioning regimens (ranging from myeloablative to reduced-intensity conditioning) and with a matched related donor or a partially matched unrelated donor (Dupuis-Girod et al., 2006; Fish et al., 2009; Minakawa et al., 2009; Pai et al., 2008; Permaul et al., 2009; Tono et al., 2007; and unpublished data). Two patients died after HSCT, one from veno-occlusive disease and the other from *Parainfluenza* type III viral infection (Dupuis-Girod et al., 2002; Fish et al., 2009). Five NEMO-deficient patients displayed engraftment and correction of their immunodeficiency, but the preexisting colitis in two of these patients was either exacerbated or not cured (Fish et al., 2009; Pai et al., 2008; Permaul et al., 2009; Tono et al., 2007; and unpublished data). HSCT can correct these immunodeficiencies, but some inflammatory signs may persist or even become worse and the EDA phenotype is not corrected. This difficult procedure should be proposed only for selected patients with severe immunodeficiency, with the most closely matched donor available. A large international clinical survey of NEMO-deficient patients is currently under way to improve definition of the clinical and immunological outcome of these patients (Picard and Orange, in progress). This study may facilitate the formulation of guidelines for the treatment of this heterogeneous genetic disorder.

INBORN ERRORS OF THE TLR3-IFN-A, IFN-B, AND IFN-Λ PATHWAY

HUMAN TLR3 DEFICIENCY

Molecular Basis and Laboratory Findings

In 2007, an autosomal dominant form of TLR3 deficiency (Fig. 36.1) due to a heterozygous mutation of *TLR3* with dominant-negative effect was identified (Zhang et al., 2007). Seven patients from two unrelated kindreds with the same missense P554S mutation of *TLR3* have been reported, (Fig. 36.9). Both kindreds originate from France. Two of them had developed herpes simplex encephalitis (HSE) during childhood. Blood leukocytes (monocyte-derived dendritic, NK, and CD8 T cells) from TLR3-deficient patients have an impaired response to stimulation with TLR3 agonist. The fibroblast cells of the patients produce low levels of the antiviral molecules IFN-β and IFN-λ in response to TLR3 agonist, herpes simplex virus 1 (HSV-1), and vesicular stomatitis virus (VSV), leading to higher levels of viral replication and virus-induced cell death than for healthy control cells. All standard immunological parameters, such as the numbers of blood phagocytes, B and T lymphocytes, lymphocyte subset distribution (CD4 T, CD8 T), NK cells, antibody production, and T-cell proliferation in response to the mitogens and antigens tested, were normal in all patients tested. These observations suggest that the TLR3-dependent generation of IFN-α, IFN-β, and IFN- λ is critical for primary immunity to HSV-1 in the central nervous system (CNS) but redundant for immunity to most other viral infections (Zhang et al., 2007).

The recent report of an autosomal recessive form of complete TLR3 deficiency in a young adult who had developed HSE during childhood further illustrates the crucial importance of TLR3 signaling in fibroblasts for protective immunity to HSV-1 in the CNS (Guo et al. 2011). While the TLR3 activation in leukocytes from the TLR3-deficient patient resulted in normal antiviral IFN production.

Clinical and Pathological Manifestations and Treatment

Only one child from each of the two kindreds with autosomal dominant TLR3 deficiency (two of the seven individuals bearing the TLR3 mutation) developed HSE. The first patient developed HSE at 5 years of age, during primary infection with HSV-1. HSE was diagnosed on the basis of the intrathecal synthesis of specific anti–HSV-1 antibodies. The patient was treated with IV acyclovir and recovered well. Nineteen months later, HSE recurred, with the detection of HSV-1 nucleic acid in cerebrospinal fluid (CSF), associated with recent left temporal lesions detected by cerebral imaging. The patient was treated again with acyclovir, IV at first and then orally. The second patient presented an episode of meningoencephalitis at the age of 5 months, diagnosed

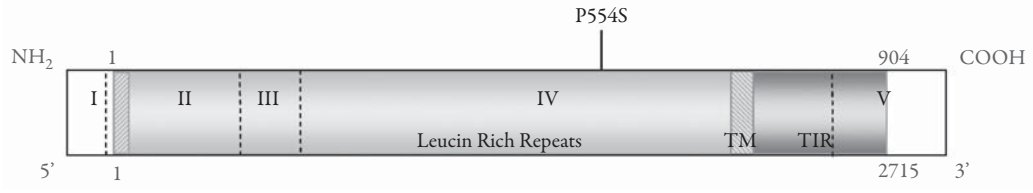

Figure 36.9 *Schematic diagram of the structure of the TLR3 gene and the mutation identified.* Human TLR3 has five exons (Roman numerals) encoding a protein (shown in gray) with a leucine-rich repeat (LRR) domain, a transmembrane (TM) domain, and a Toll/interleukin-1 receptor (TIR) domain. The position of the mutation reported is represented with amino-acid nomenclature.

following the detection of HSV-1 antigen and IFN-α in the CSF sample. The patient was treated with IV acyclovir and recovered well, with no recurrence. Both patients have been exposed to other viruses during 8 and 20 years of follow-up, respectively, as shown by the positive serological results obtained for other herpes viruses, including varicella zoster virus (VZV) and Epstein-Barr virus (EBV), with no subsequent acute events. The patients were also immunized with live mumps/rubella/measles and poliovirus vaccines, with no adverse effect. They did not experience infections caused by agents other than viruses, such as pyogenic bacteria or mycobacterial, parasitic, and fungal agents. None of the other five individuals with the dominant *TLR3* mutation developed HSE, despite serologically documented HSV-1 infection. TLR3 deficiency thus displayed complete penetrance at the cellular level but incomplete penetrance at the clinical level. Multiple factors may affect clinical penetrance, including age at infection with HSV-1, the viral inoculum, and human modifier genes.

HUMAN UNC-93B DEFICIENCY

Molecular Basis and Laboratory Findings

In 2006, autosomal recessive UNC-93B deficiency was identified as the first genetic etiology of isolated HSE (Casrouge et al., 2006). UNC-93B is a 12-transmembrane domain protein present in the ER. In mice, UNC-93B delivers the nucleotide-sensing receptors TLR3, 7, and 9 from the ER to endolysosomes (Fig. 36.1; Kim et al., 2008). Three individuals, from two European countries (Portugal and France) and originating from two consanguineous kindreds of Gypsy origin, have been found to carry homozygous mutations in *UNC93B1*. A homozygous 1034del4 mutation is carried by one HSE patient of Portuguese origin, and a homozygous 781G>A mutation was identified in two individuals from a Gypsy family living in France, one of whom developed HSE (Fig. 36.10; Casrouge et al., 2006, and unpublished data). Both mutations created a frameshift and a premature stop codon in the mRNA of *UNC93B1*. The leukocyte and fibroblast cells of patients with UNC-93B deficiency do not respond to TLR3, 7, 8, or 9 agonists in terms of IFN-α, IFN-β, and IFN-λ production, in particular. Impaired TLR7, 8, and 9 responses probably play no more than a moderate role in the pathogenesis of HSE, as patients with IRAK-4 and MyD88 deficiencies do not respond to TLR7, TLR8, or TLR9 either but did not suffer from HSE (Picard et al., 2003; von Bernuth et al., 2008). The fibroblast cells of UNC-93B–deficient patients displayed abnormal high levels of viral replication and cell death after infection with HSV-1 or VSV. All immunological parameters, such as the numbers of blood phagocytes, B and T lymphocytes, and NK cells, lymphocyte subset distribution (CD4 T, CD8 T), antibody production, and T-cell proliferation in response to mitogens and antigens tested, were normal in the two patients evaluated.

Clinical and Pathological Manifestations and Treatment

Two of the three UNC-93B–deficient individuals developed HSE. The first patient presented with his first episode of HSE at the age of 11 months, during HSV-1 primary infection. HSE was diagnosed on the basis of meningitis, necrotic bilateral temporal lesions on CT scan, and an increase in anti-HSV-1 antibody titers in the CSF. The patient was treated with IV acyclovir and initially recovered well. Three months later, encephalitis recurred, without the detection of HSV-1. IV acyclovir treatment was administered, followed by oral acyclovir for 2 months. At the age of 3.5 years, the patient presented a new episode of encephalitis, with coma and meningitis, together with new lesions on CT scan, but PCR tests for HSV-1 carried out on CSF were negative. IV acyclovir treatment was given for 1 month, leading to an improvement in his clinical status. During 14 years of follow-up, the patient has experienced no subsequent acute events. The second patient developed her first episode of meningoencephalitis at the age of 5 years. HSE was diagnosed on the basis of meningitis, right frontoparietal necrosis on MRI, and positive PCR tests for the presence of HSV-1 in CSF samples. The patient's clinical status improved on IV acyclovir treatment. She was admitted again at the age of 17 years for a second episode with meningitis, a strongly positive HSV-1 PCR, and intrathecal IFN-α production. Her clinical status improved with IV acyclovir therapy. She is now 21 years old and her clinical status has not worsened since the second episode of HSE. One sibling of the second patient, who carries the same homozygous 781G>A mutation in *UNC93B1*, is now 30 years old and did not develop HSE despite serologically documented HSV-1 infection. The two patients with UNC-93B deficiency and HSE have been exposed to other viruses without obvious clinical manifestations, including CMV, VZV, EBV, HHV6 parvovirus B19, respiratory syncytial virus, and parainfluenza-1, influenza A, and B viruses. They have also been immunized with live mumps/rubella/measles and poliovirus vaccines with no adverse effect (Casrouge et al., 2006).

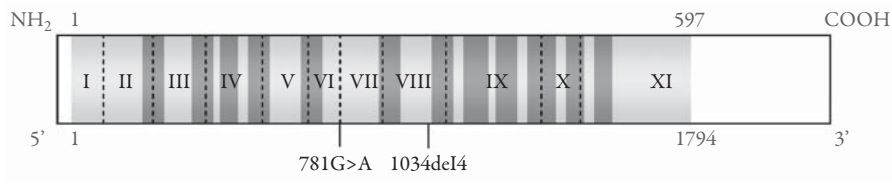

Figure 36.10 *Schematic diagram of the structure of the UNC93B1 gene and the mutations identified.* Human *UNC93B1* has 11 exons (Roman numerals), encoding a protein with 12 predicted transmembrane domains (shown in gray). The position of all mutations reported is shown in nucleotide nomenclature at the bottom.

HUMAN TRAF3 DEFICIENCY

Molecular Basis and Laboratory Findings

A French patient with autosomal dominant tumor necrosis factor (TNF) receptor-associated factor 3 (TRAF3) deficiency and HSE has recently been identified (Perez de Diego et al., 2010). TRAF-3 has functions downstream of multiple TNF receptors as well as downstream of TLR-3 and controls IFN-α, IFN-β, and IFN-λ production (Fig. 36.1). The de novo germline heterozygous R118W missense mutation results in loss of expression, loss of function, and a dominant-negative effect (Fig. 36.11). Leukocytes and fibroblasts from the patient displayed impaired responses to TLR3 agonist stimulation, in terms of IFN-β and IFN-λ production, in particular. The fibroblast cells of the patient displayed higher levels of viral replication and cell death after VSV infection than the control cells. Monocyte-derived dendritic cells and monocyte-derived macrophages from the patient were found to produce only small amounts of IFN-α, IL-12p40, TNF-α, and IL-6 in response to stimulation with TLR4 and TLR7–8 agonists. The responses to activation with RIG-I and MDA-5 in the patient's SV40-fibroblast cells also seemed to be partially impaired. Moreover, TRAF3 deficiency affects the TNF-R pathways, including the CD40, LTβR, and BAFF-R pathways. However, the lack of a corresponding overt clinical phenotype in the patient is consistent with an incomplete functional defect. All standard immunological parameters, such as the number of blood phagocytes, B and T lymphocytes and NK cells, lymphocyte subset distribution (CD4 T, CD8 T), antibody production, and T-cell proliferation in response to mitogens and antigens tested, were normal in the patient. In conclusion, various TRAF3-dependent pathways are impaired in the patient's cells, including the IFN-α/-β, -λ-inducing, and TNF-R-responsive pathways. However, residual TRAF3-dependent signaling is sufficient for most defects to remain clinically silent. By contrast, the impaired TLR3 response is symptomatic and causes HSE, implying that the TLR3 pathway is critically dependent on TRAF3 and essential for immunity to HSV-1 in the CNS.

Clinical and Pathological Manifestations and Treatment

The first clinical manifestations of HSE in the TRAF3-deficient patient appeared at the age of 4 years. The patient had persistent fever and convulsions, and HSV-1 was detected on CSF analysis. CT scan showed hypodensity in the left frontal temporal lobe. She was treated with IV acyclovir (60 mg/kg/d for 3 weeks) and initially recovered. The patient had chickenpox 1 to 2 months before HSE, her mother had cold sores, and one brother had also suffered from cold sores, viral meningitis, and gingivostomatitis, but none of her grandparents, parents, or brothers had developed HSE and none of these relatives carried the TRAF3 mutation. The patient with TRAF3 deficiency and HSE described here is now 18 years old and has otherwise remained healthy with no prophylaxis. She shows normal resistance to other infectious diseases, including viral diseases in particular, despite serologically documented EBV, VZV and HSV-2 infection.

HUMAN TRIF DEFICIENCY

Molecular Basis and Laboratory Findings

Two kindreds with childhood HSE associated with TRIF deficiency (Fig. 36.1) were recently identified (Sancho-Shimizu et al., 2011). The only affected member of family 1 is one of five offspring of consanguineous parents from Saudi Arabia and was found to have a homozygous nonsense mutation (R141X) in the N-terminal region of the *TRIF* gene resulting in complete absence of protein. Most of the other family members were heterozygous for the R141X mutation and none had a history of encephalitis. This loss of expression/function of TRIF resulted in the abolition of TLR3-mediated signaling and TRIF-dependent TLR4 responses as measured by IFN-β and IFN-λ production.

Patient 2, from a nonconsanguineous European family, has a heterozygous missense mutation (S186L) in the N-terminal part of the *TRIF* gene, suggesting that this hypomorphic S186L allele of TRIF is dominant negative and responsible for autosomal dominant TRIF deficiency resulting in HSE, although with incomplete penetrance as only one of the three S186L TRIF heterozygotes (mother and maternal grandfather) developed HSE following HSV-1 infection (Sancho-Shimizu et al., 2011).

Clinical and Pathological Manifestations

The affected boy from family 1 with the homozygous R141X mutation had no infectious problems until age 2, when he developed HSE complicated by seizures, EEG abnormalities, atrophy of the left temporal lobe, and delayed speech. The

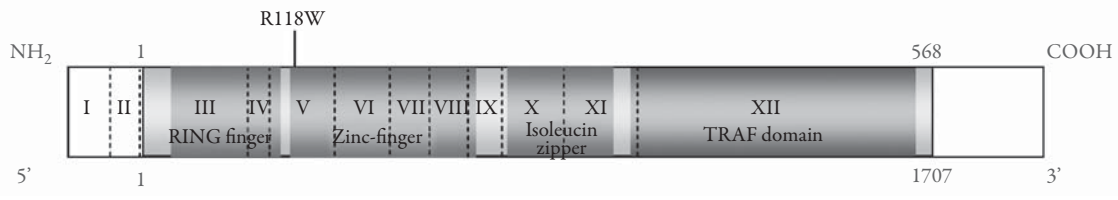

Figure 36.11 *Schematic diagram of the structure of the TRAF3 gene and the mutations identified.* Human *TRAF3* has 12 exons (Roman numerals), encoding a protein with a ring-finger and five zinc-finger domains in the N-terminal region, followed by an isoleucine zipper and a TRAF domain in the C-terminal region. The position of the mutations reported is represented with amino-acid nomenclature at the top.

affected offspring of family 2 was healthy until she developed HSE at age 21 months. She responded to treatment with acyclovir and never relapsed but has neurologic sequelae (blindness and epilepsy).

CONCLUSIONS

Human IRAK-4 and MyD88 deficiencies cause a selective predisposition to pyogenic bacterial diseases (mainly caused by *S. pneumoniae*, *S. aureus*, and *P. aeruginosa*) in early childhood but become asymptomatic after adolescence. Autosomal recessive mutations in the *IRAK4* or *MYD88* gene selectively impair TLRs other than TLR3 and most IL-1R responses. The MyD88- and IRAK-4–dependent pathway is essential for protective immunity to a few pyogenic bacteria in childhood but is otherwise redundant in host defense. X-linked hypomorphic mutations in *NEMO* and autosomal hypermorphic mutations in *IKBA* impair NF-κB–mediated signaling, at least in response to the stimulation of TLRs, IL-1Rs, and TNF receptors, and confer a broad predisposition to infections and PIDs with no improvement during life. Finally, clinical genetic studies have revealed that rare mutations in the TLR3-TRIF alternative pathway underlie HSE in otherwise healthy children: autosomal recessive UNC-93B, autosomal dominant and recessive TLR3, autosomal dominant TRAF3, and autosomal recessive and dominant TRIF deficiencies. These six disorders confer predisposition to HSE, consistent with the abundant and almost selective expression of TLR3 in resident cells from the CNS, including neurons, oligodendrocytes, astrocytes, and microglial cells (Lafaille et al. 2012). The lack of TLR3 responses results in the impaired production of antiviral IFN-α/-β and -λ, enhanced viral replication, and high levels of cell death. It seems likely that new inborn errors of immunity in these NF-κB–involved pathways will soon be discovered in patients with these or other infectious diseases (Alcais et al., 2010; Casanova and Abel, 2007; Casanova et al., 2011).

ACKNOWLEDGMENTS

CARTILAGE-HAIR HYPOPLASIA

Outi Mäkitie

DESCRIPTION

Cartilage-hair hypoplasia (CHH), or metaphyseal chondrodysplasia, McKusick type (MIM 250250), is an autosomal recessive skeletal dysplasia in which immunodeficiency is a constant feature (McKusick et al., 1965). Skeletal dysplasias comprise a large group of clinically distinct and genetically heterogeneous conditions characterized by abnormalities in patterning, linear growth, differentiation, and maintenance of the human skeleton, beginning during the early stages of fetal development and evolving throughout life. In the 2006 revision of the International Nosology and Classification of Genetic Skeletal Disorders, 372 different conditions were listed in 37 groups defined by molecular, biochemical, and/or radiographic criteria (Superti-Furga and Unger, 2007). The metaphyseal chondrodysplasias constitute a subgroup of bone dysplasias with eight distinct disorders.

CHH is a pleiotropic skeletal dysplasia with symptoms arising also from several nonskeletal tissues (Makitie et al., 1995; Makitie and Kaitila, 1993; McKusick et al., 1965). In the original description of CHH, McKusick et al. observed an increased propensity to infections, caused by viruses in particular. Since then the defective immunity in CHH has been confirmed by clinical and laboratory studies (Makitie et al., 1998, 2000b; Polmar and Pierce, 1986). The disease-causing gene, *RMRP*, RNA component of mitochondrial RNA processing endoribonuclease, was identified in 2001, and a number of mutations have been found (Ridanpaa et al., 2001, 2002). However, the pathogenic mechanisms of the pleiotropic features, including the immunodeficiency, have remained elusive.

CHH is prevalent among the Amish in the United States and among the Finns in Europe, but affected families have been observed in most Caucasian and Asian populations (Nakashima et al., 2003; Ridanpaa et al., 2002).

CLINICAL MANIFESTATIONS

NONIMMUNOLOGICAL FEATURES

The clinical features include growth failure and hair hypoplasia (Makitie and Kaitila, 1993; Makitie et al., 1995), anemia (Juvonen et al., 1995; Makitie et al., 1992b), intestinal neuronal dysplasia or Hirschsprung's disease (HD) (Makitie et al., 2001a), defective spermatogenesis (Makitie et al., 2001c), and risk of malignancies (Makitie et al., 1999) (Table 37.1 and Fig. 37.1).

The marked short-limbed, short stature is due to metaphyseal dysplasia. The growth failure has its onset prenatally and progresses with age. In Finnish patients the mean birth length was 45.8 cm for boys and 44.9 cm for girls (range, 38–51 cm), and the median adult height was 131.2 cm (range, 110–158 cm) for males and 122.5 cm (range, 103–137 cm) for females (Makitie et al. 1992a; Makitie and Kaitila, 1993).

The radiographic skeletal abnormalities include short and broad tubular bones with splaying and an irregular metaphyseal border of the growth plate (Fig. 37.2). The costochondral junctions are similarly splayed and irregular; the vertebrae are usually normal. These findings develop and are diagnostic by the age of 6 to 9 months. In adults the tubular bones remain short and thick but are otherwise unspecific (Makitie and Kaitila, 1993; Makitie et al., 1995).

The characteristic hair hypoplasia in CHH presents as fair, thin, and sparse hair growth. However, variation is marked and individuals with normal hair have been observed (Bonafe

Table 37.1 PLEIOTROPIC FEATURES IN CARTILAGE-HAIR HYPOPLASIA

FEATURE	FREQUENCY (%)
Short stature, –4 SD or <5th percentile	100
Hair hypoplasia	93
Immunodeficiency	56
Propensity to infections	56
In vitro immunodeficiency	88
Hypoplastic childhood anemia	79
Gastrointestinal dysfunction	18
Hirschsprung's disease	9
Defective spermatogenesis	100
Metaphyseal chondrodysplasia on childhood skeletal radiographs	100
Overall risk of malignancies (standardized incidence ratio)	7.0
Non-Hodgkin's lymphoma (standardized incidence ratio)	90
Basal cell carcinoma (standardized incidence ratio)	33

Data from Makitie and Kaitila, 1993; Makitie et al. 1999, 2001b; Taskinen et al., 2008.

et al., 2002; Makitie and Kaitila, 1993; Makitie et al., 1995; Verloes et al., 1990).

Gastrointestinal problems, such as neuronal dysplasia of the intestine, are common in CHH. Congenital HD was found in 13 of 147 Finnish patients with CHH (9 percent), all of whom had an overall severe form (Makitie et al., 2001a). Eight patients had the classic form of HD with rectosigmoid involvement, two had long-segment colonic disease, and three had total colonic aganglionosis. Six of the patients had episodes of enterocolitis, two with colonic perforations prior to the first surgery; 11 patients had postoperative enterocolitis and some died of enterocolitis-related septicemia (Makitie et al., 2002).

Defective erythrogenesis in early childhood presenting as refractory hypoplastic anemia is a common feature in CHH and was found in 54 of 74 Finnish patients (73 percent). In approximately 6 percent of CHH patients severe anemia is persistent and resembles Diamond-Blackfan anemia (Makitie et al., 1992b, 2000a; Williams et al., 2005). Thrombocytopenia and autoimmune hemolytic anemia have also been reported (Ashby and Evans, 1986; Berthet et al., 1996).

IMMUNOLOGICAL FEATURES

McKusick et al. (1965) observed an increased rate of infections in patients with CHH. Varicella occasionally resulted in a prolonged and severe disease with hemorrhagic vesicles, high fever, and even fatality. They showed in two Amish

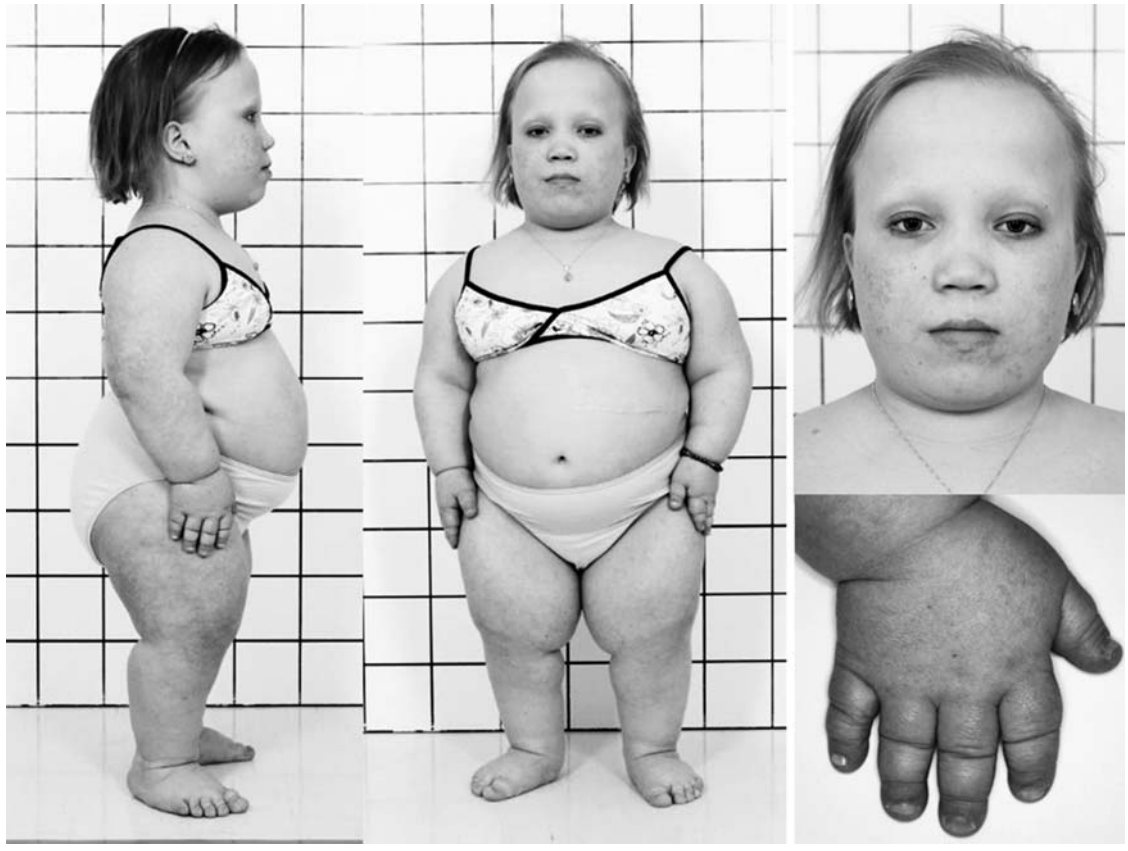

Figure 37.1 Patient with CHH. (See Color Plate.)

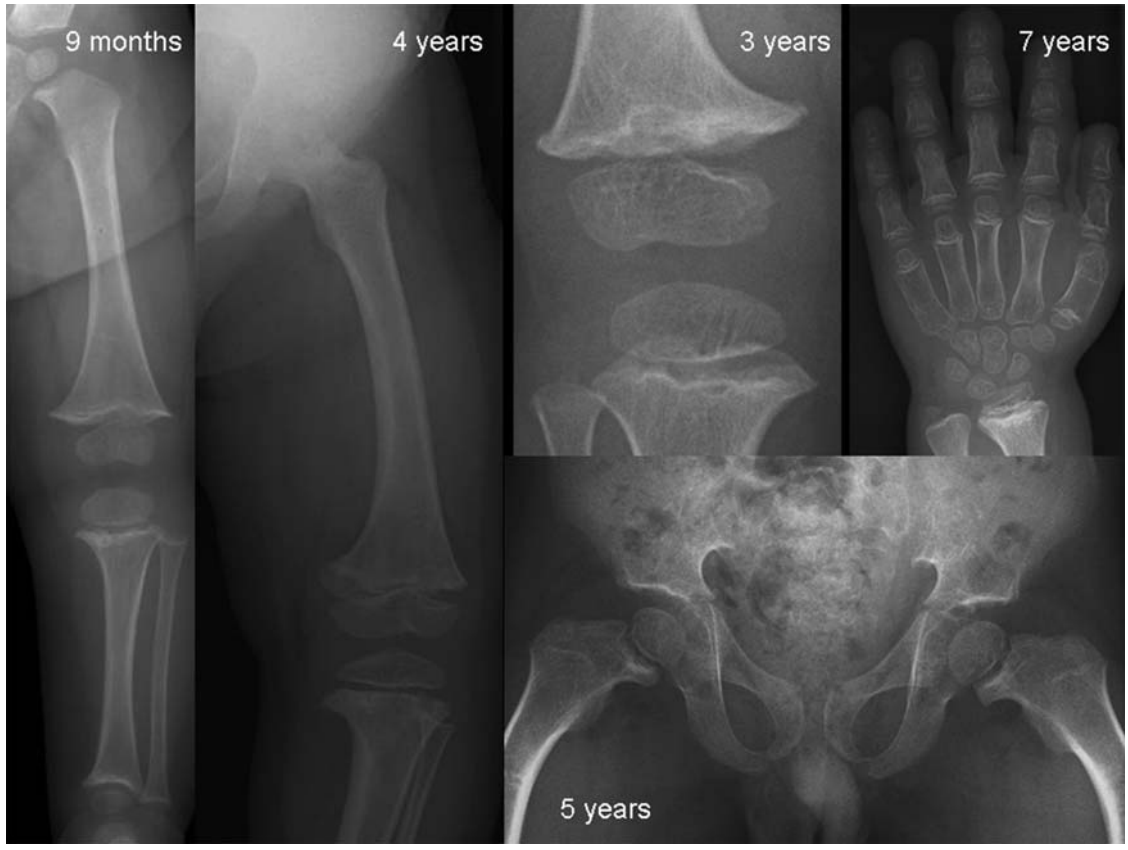

Figure 37.2 Radiographs showing the characteristic features. (See Color Plate.)

patients mild to moderate lymphopenia, decreased delayed hypersensitivity, and impaired lymphocyte responses to mitogens, whereas immunoglobulin concentrations and antibody synthesis were normal (Lux et al., 1970). Subsequent studies confirmed cell-mediated immune deficiency to be an integral feature of CHH (Pierce and Polmar, 1982; Pierce et al., 1983; Polmar and Pierce, 1986; Ranki et al., 1978; Rider et al., 2009; Trojak et al., 1981; Virolainen et al., 1978). The absolute lymphocyte count was about half that of normal controls. The results of allogeneic stimulations indicated an intrinsic T-cell defect, whereas antigen-presenting cells were not affected. The IL-2 production by CHH lymphocytes was reduced, but exogenous IL-2 did not correct the defect in proliferation (Kooijman et al., 1997; Pierce and Polmar, 1982; Pierce et al., 1983; Polmar and Pierce, 1986).

In the Finnish patients, a reduction of 50 percent in the $CD4^+$ cell count and a reduction of 30 percent in the $CD4^+/CD8^+$ cell ratio have been reported. The B-lymphocyte count was usually normal, whereas the NK-cell count was often elevated (Makitie et al., 1998). On the basis of increased expression of Fas (CD95), CD95L, and Bax, and decreased expression of Bcl-2 and inhibitor of apoptosis protein (IAP) in both $CD4^+$ and $CD8^+$ cells, it has been suggested that the lymphopenia might be due to increased apoptosis of these cells (Yel et al., 1999). In another study, the levels of mRNA encoding c-myc, IL-2Rα, IL-2, and IFN-γ were decreased in stimulated CHH lymphocytes, whereas those of other early activation gene products, such as c-fos and c-jun, were not impaired, suggesting a lymphocyte intracellular signaling defect (Castigli et al., 1995). Transcriptional profiling of CHH patient RNAs identified several upregulated and downregulated genes that play a role in the immune system, cell-cycle regulation, and signal transduction (Hermanns et al., 2005).

In contrast to earlier studies, we found that one third of the Finnish CHH patients also had partially defective humoral immunity presenting as isolated IgA and IgG subclass deficiencies (Makitie et al., 2000b; Toiviainen-Salo et al., 2008). Impaired antibody production has been observed (Rider et al., 2009). Several CHH patients with combined immune deficiency have been reported also from other populations (Guggenheim et al., 2006; Kavadas et al., 2008; Rider et al., 2009).

A number of patients with chronic, severe, and even fatal infections due to viruses, bacteria, and fungi have been reported (Berthet et al., 1996; Castigli et al., 1995; Guggenheim et al., 2006; Hong, 1989; Kainulainen et al., 2008; Lux et al., 1970; Polmar and Pierce, 1986; Saulsbury et al., 1975; Steele et al., 1976). CHH patients, particularly those with defective humoral immunity, have an increased risk for bronchiectasis (Toiviainen-Salo et al., 2008). Despite severe clinical presentations in occasional patients, most patients do clinically relatively well (Makitie et al., 1998, 2000b; Rider et al. 2009).

MOLECULAR BASIS

On the basis of molecular linkage studies on Finnish multiplex CHH families, the disease-causing gene was mapped to

9p12 in 1993 (Sulisalo et al., 1993). The location was refined by disequilibrium analysis; finally, the mutated gene, *RMRP*, was detected through physical mapping and sequencing (Ridanpaa et al., 2001). Several *RMRP* mutations have been detected (Bonafé et al., 2005; Ridanpaa et al., 2002). Most are base substitutions, insertions, or short duplications that alter conserved nucleotide sequences in the transcribed region. Insertions or duplications in the promoter region between the TATA box and the site of initiation of transcription, or in the 5′ end of the transcribed region, are also common.

The most common CHH-causing mutation is 70A > G, found in 92 percent of Finnish CHH patients and probably all Amish patients (Ridanpaa et al., 2003). The same mutation accounts for 48 percent of the mutations among patients from other parts of Europe, North and South America, the Near East, and Australia (Ridanpää et al., 2001, 2002).

The human *RMRP* gene encodes the 267 bp RNA molecule of the RNase MRP complex, which consists of protein components and the RNA molecule. Thus, unlike most of the known disease-associated genes, the *RMRP* is an untranslated gene. The RNase MRP is a ribonucleoprotein endoribonuclease involved in the processing of precursor ribosomal RNA and in priming of the RNA for mitochondrial DNA replication. It has been suggested that the RNase MRP also carries other important biological functions, such as control of cell proliferation (Clayton, 2001; Maida et al., 2009). In situ hybridization experiments have indicated the presence of RNase MRP in both mitochondria and nucleoli, the majority being localized to the latter. The pathogenetic mechanisms of the *RMRP* mutations are still unknown.

TREATMENT AND PROGNOSIS

Children with CHH should not be vaccinated with live or attenuated bacteria or viruses. Antibiotic and antiviral treatment of infections, as well as prophylactic antibiotics, should be recommended on a case-by-case basis. Immunoglobulin treatment is indicated in patients with combined immune deficiency.

Profound T-cell deficiency similar to that seen in severe combined immunodeficiency has been demonstrated in some patients with CHH. Anecdotal CHH patients with such severe presentation have undergone bone marrow transplantation with successful long-term reconstitution of immunity; no improvement was observed in longitudinal growth, however (Berthet et al., 1996; Guggenheim et al., 2006)

Patients with CHH have significantly increased mortality rates compared with their parents and nonaffected siblings (Makitie et al., 2001b). While infections predispose younger children to premature death, malignancies predominate as the cause of death in the older age groups (Makitie et al., 1999, 2001b). A recent follow-up study including 123 Finnish CHH patients identified 14 cases of cancer (standardized incidence ratio [SIR] 7.0). Non-Hodgkin's lymphoma was the most frequent cancer type (9 patients, SIR 90.2). Nine of the 14 cancers were diagnosed in patients less than 45 years of age. In addition, 10 patients had basal cell carcinoma of the skin (SIR 33.2) (Taskinen et al., 2008). Kaplan-Meier estimation of cancer events gave a probability of a cancer event (excluding basal cell carcinoma) of 41 percent by the age of 65 years (Taskinen et al., 2008).

HYPER-IGE RECURRENT INFECTION SYNDROMES

Alexandra F. Freeman, Bodo Grimbacher, Karin R. Engelhardt, Steven Holland, and Jennifer M. Puck

Hyper-immunoglobulin E recurrent infection syndrome (HIES; MIM #147060, #243700) has been recognized as a primary immunodeficiency characterized by recurrent staphylococcal skin abscesses, pneumonias with pneumatocele formation, extreme elevations of serum IgE, eosinophilia, and distinct abnormalities of the connective tissue, skeleton, and dentition (Belohradsky et al., 1987; Buckley et al., 1972; Davis et al., 1966; Donabedian and Gallin, 1983a; Erlewyn-Lajeunesse, 2000; Grimbacher et al., 1999a; Hill and Quie, 1974). The majority of cases of autosomal dominant HIES (AD-HIES; MIM #147060) are caused by mutations in signal transducer and activator of transcription 3 (STAT3) (Holland et al., 2007; Jiao et al., 2008; Minegishi et al., 2007; Renner et al., 2008). A distinct hyper-IgE syndrome, described as autosomal recessive hyper-IgE syndrome (AR-HIES; MIM #243700), was described by Renner et al. in 2004. Mutations in DOCK8 account for the majority of these patients, characterized by sinopulmonary infections, viral infections of the skin, allergy, and predisposition to malignancy (Engelhardt et al., 2009; Zhang et al., 2009).

AD-HIES

HISTORY

"So went Satan forth from the presence of the Lord, and smote Job with sore boils from the sole of his foot unto his crown." With this citation from Job II: 7, Davis, Schaller, and Wedgewood coined the term *Job syndrome* in 1966 (Davis et al., 1966). They reported two red-haired, fair-skinned girls who had frequent sinopulmonary infections, severe dermatitis, and recurrent staphylococcal skin infections that were remarkable for their lack of surrounding warmth, erythema, or tenderness. The syndrome was further defined and clarified by Buckley et al. (1972), who noted similar infectious problems in two boys with severe dermatitis, distinctive facial appearance, and elevated IgE levels, leading to the term *Buckley syndrome*. Following this report, elevated levels of IgE and a defect in neutrophil chemotaxis were reported in the two girls from the initial report (Hill and Quie, 1974), showing that Job syndrome and Buckley syndrome represented the same condition. To avoid further confusion, the name *hyper-immunoglobulin E recurrent infection syndrome* (HIES) is now widely used. In 1999 a group at the U.S. National Institutes of Health (NIH) undertook to define further the phenotype of HIES, noting that the syndrome was heritable as an autosomal dominant condition (hence referred to in this chapter as AD-HIES, even though many cases are sporadic due to new mutations, as discussed below) with both immune and nonimmune features.

CLINICAL PRESENTATION

The clinical features of AD-HIES include the immune system, the connective tissues and skeleton, the vasculature, and dentition. Table 38.1 shows the frequency of the most consistent clinical and laboratory findings in AD-HIES. These 19 clinical features associated with AD-HIES were published based on a cohort of 30 patients with the disease (Grimbacher et al., 1999a) and have since been confirmed in many more individuals. Multivariate analysis of these features in AD-HIES patients revealed that IgE greater than 1,000 IU plus five of the features—recurrent pneumonia, newborn rash, pathological bone fractures, characteristic face, and high palate—were highly indicative of a STAT3 mutation (Woellner et al., 2010).

Table 38.1 INCIDENCE OF CLINICAL FINDINGS ASSOCIATED WITH HYPER-IGE RECURRENT INFECTION SYNDROME

	% of cases
Findings Related to Infections and Immune System	
Moderate to severe eczema	100
Serum IgE >2,000 IU/mL	97
Eosinophilia (>2 SD above normal mean)	93
Recurrent pneumonia, X-ray proven	85
Recurrent skin abscesses	85
Recurrent (>3 per year) upper respiratory infections	80
Mucocutaneous candidiasis	80
Pneumatoceles	75
Newborn rash	75
Other serious infections	50
Lymphoma, other cancer	3
Findings Related to Bones, Teeth, and Connective Tissue	
Characteristic face	80
Retained primary teeth	70
Hyperextensibility of joints	70
Increased nasal width (interalar distance >1 SD above normal value for age, race)	65
Scoliosis >10 degrees	60
Recurrent fractures following minor trauma	55
High-arched palate	50
Congenital skeletal anomalies	10
Focal hyperintensities on brain MRI	80
Chiari type I malformation	40
Coronary vasculature abnormalities	60

IMMUNE SYSTEM

Eczema, abscesses, pneumonia, mucocutaneous candidiasis, elevated serum IgE, and eosinophilia are the most common features of immunodeficiency and immune dysregulation in AD-HIES patients. The initial presentation is a newborn rash, which may even be present at birth (Color Plate 38.I). Scrapings of this rash typically show eosinophils. The newborn rash may improve or progress to an eczematoid dermatitis. The dermatitis of AD-HIES is usually driven by *Staphylococcus aureus* and improves with control of *S. aureus* with antistaphylococcal antibiotics or antiseptics. The dermatitis is in a distribution somewhat atypical for atopic dermatitis, involving the posterior auricular areas, back, buttocks, and scalp (Color Plate 38.II). Furuncles or boils are almost universal in AD-HIES unless staphylococcal colonization is well controlled with prophylactic antibiotics and/or antiseptics. The boils may be "cold" and nontender and are usually not associated with fever or signs of local or generalized inflammation (Erlewyn-Lajeunesse, 2000). However, despite the outward appearance of diminished inflammation, these abscesses are typically filled with pus and almost always grow *S. aureus*. Surgical drainage of these lesions is commonly required, and they typically resolve without spreading through the dermis and fascia. With diagnosis earlier in life and institution of prophylactic antibiotics, we have seen mostly impetiginized eczema and fewer boils than previously described. In our cohort, 85 percent of AD-HIES patients had recurrent skin abscesses, and over half had a history of more than four abscesses.

Sinopulmonary infections are frequent in AD-HIES. Individuals have a high palate, which in addition to the immunodeficiency may interfere with clearance of sinus and ear drainage and lead to chronic infections. The majority of patients report four or more episodes of upper respiratory tract infections such as sinusitis per year.

A clinical hallmark of AD-HIES is recurrent pneumonia. The great majority of patients have had at least one bout of pneumonia in their lifetime, but more than half have had three or more. The most common pathogens of acute pneumonia are *S. aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. For reasons still unclear, lung parenchymal abnormalities frequently complicate these pneumonias. About three quarters of AD-HIES patients develop long-term pulmonary complications, including bronchiectasis and pneumatoceles (Fig. 38.1). The cycle of infection and lung destruction is further exacerbated by superinfection of the cavities and bronchiectatic lung with *Pseudomonas aeruginosa* and *Aspergillus fumigatus*. The pulmonary fungal and *Pseudomonas* superinfections are a major source of morbidity and mortality in this disease (Freeman et al., 2007). Pulmonary infections less commonly seen in HIES include *Pneumocystis jiroveci* (Freeman et al., 2006), which may occur in infancy as the first lung infection, and nontuberculous mycobacteria (Melia et al., 2009).

Chronic candidiasis of mucosal sites and the nail beds affects about 80 percent of AD-HIES patients, including children (Color Plate 38.III). Although primary invasive fungal infections are relatively uncommon, focal extrapulmonary infections with *Cryptococcus* and *Histoplasmosis*, such as of the genitourinary tract and gut, occur infrequently (Hutto et al., 1988; Jacobs et al., 1984).

SKELETAL AND CONNECTIVE TISSUE ANOMALIES

Skeletal and facial abnormalities associated with HIES were recognized in the original reports by Davis et al. (1966) and Buckley et al. (1972). They noted characteristic facies and hyperextensibility of the joints. The facies in HIES are often asymmetrical, with a prominent forehead and mild prognathism, increased interalar width of the nose, wide-set eyes, thickening of the soft tissue of ears and nose, and a high-arched palate (Borges et al., 1998; Grimbacher et al., 1999a). The facial features progressively develop over childhood and become almost universal by late adolescence (Color Plate 38.IV). Sixty percent have an increased interalar distance (width across the bottom of the nose) and almost half have a high-arched palate

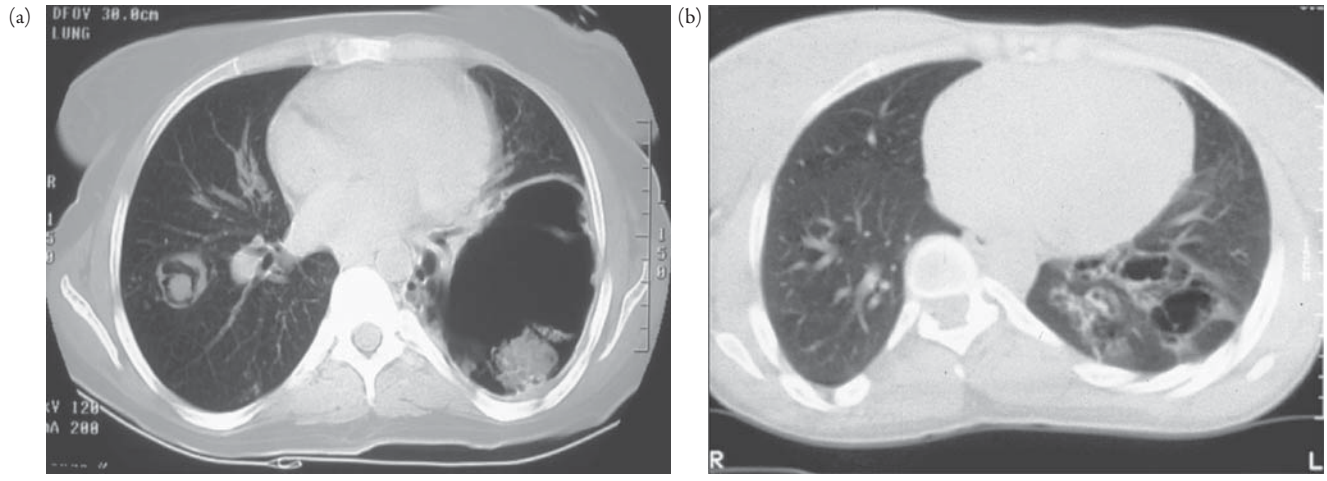

Figure 38.1 Pulmonary complications of hyper-IgE syndrome. (a) Postinflammatory cysts containing aspergillomas. (b) Scoliosis evident in angle of vertebra. (c) Degenerative spine disease in an adult with HIES.

(Color Plate 38.V, top right). Craniosynostosis has also been reported in a few cases of HIES (Gahr et al., 1987; Höger et al., 1985; Smithwick et al., 1978), and Chiari I malformations occur in about 20 percent of patients (Freeman et al., 2007). The Chiari malformations have been largely asymptomatic and have not required surgical correction.

Recurrent fractures with only minimal trauma occur in about half of patients, confirming the multisystem nature of AD-HIES. Fractures occur most commonly in the long bones and ribs (Fig. 38.2A). Although osteopenia is common and may be cytokine driven (Cohen-Solal et al., 1995; Leung et al., 1988), the fractures that occur are not at the same sites typical of osteoporosis in postmenopausal females and the osteopenia does not correlate directly with the number of minimal-trauma fractures. Scoliosis has been seen in about 60 percent of patients: over half had a curvature of more than 15 degrees, and one third had more than 20 degrees (Fig 38.2B). Although many cases of scoliosis are idiopathic, diverse contributing factors have been noted, such as leg-length discrepancy, prior thoracotomy (e.g., for lung cyst removal), and vertebral body anomalies. Several patients have had severe scoliosis requiring surgical correction with rod placement. Hyperextensibility of the joints was noted in the initial reports and was found in 68 percent of our patients. Degenerative bone disease, primarily of the spine, often appears with increasing age and can result in significant pain (Fig. 38.2C). Spinal fusions and other surgical procedures have ameliorated symptoms for some individuals.

DENTITION AND ORAL FINDINGS

In our cohort of AD-HIES patients older than age 6, about 70 percent had delayed shedding of three or more primary teeth (Color Plate 38.V). Reduced resorption of primary tooth roots may lead to prolonged retention of the primary teeth, which in turn prevents the appropriate eruption of the permanent successors (O'Connell et al., 2000). The mechanism underlying this unique abnormality is unknown. We currently recommend that, after checking by radiography for the existence and developmental age of the secondary teeth, children with AD-HIES undergo extraction of retained primary teeth. This procedure is usually followed by normal eruption of the permanent teeth. Abnormalities of oral mucosa have been described, including central ridges and fissures of the palate, central depressions of the tongue, and oral mucosal variants of the cheek (Domingo et al., 2008).

VASCULAR FINDINGS

Vascular abnormalities are increasingly recognized in AD-HIES. One individual was found to have a large coronary artery aneurysm after suffering a myocardial infarction (Ling et al., 2007). This finding and other reported cases of aneurysms led to more systematic imaging of coronary arteries (Alomar-Melero et al., 2008; Young et al., 2007). Abnormalities are common and manifest as tortuosity, dilation, and less frequently aneurysm of the coronary arteries. Aneurysms have also been reported in the brain, though these vessels have not been studied as closely as the coronary arteries. Brain magnetic resonance imaging has shown an increase in lacunar infarcts at a younger age than expected, as well as focal hyperintensities of unclear etiology frequently in all age groups (Freeman et al., 2007).

OTHER ASSOCIATED CONDITIONS

Several malignancies have been reported in AD-HIES, which suggests that these patients may be at increased risk of both lymphomas and other tumors (Bale et al., 1977; Buckley and Sampson, 1981; Einsele et al., 1990; Gorin et al., 1989; Huber et al., 1987; Kowalchuk, 1996; Nester et al., 1998; Takimoto et al., 1996). In the NIH cohort, two patients developed non-Hodgkin's lymphoma and both were successfully treated; another was successfully treated for nodular sclerosing Hodgkin's disease. One patient developed metastatic squamous cell carcinoma of the tongue. Autoimmune phenomena such as systemic lupus erythematosus and rheumatoid arthritis occur infrequently in HIES (Brugnoni et al., 1998; Leyh et al., 1986; North et al., 1997; Schopfer et al.,

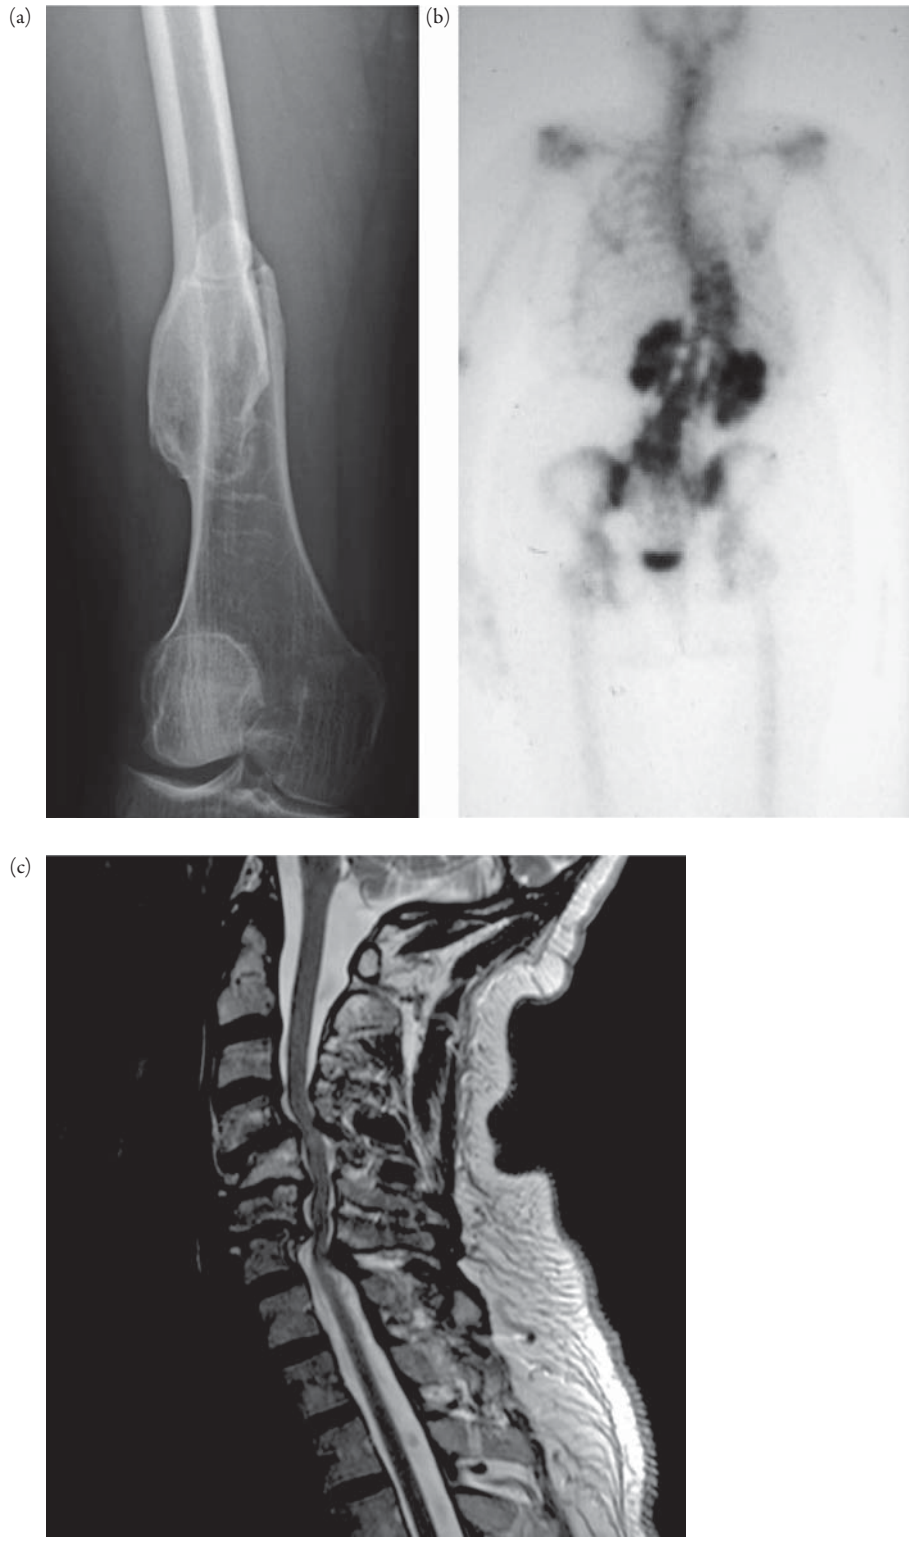

Figure 38.2 Skeletal manifestations of Job syndrome. (a) Healed pathological distal femoral fracture suffered while wading in the ocean. (b) Bone scan showing marked scoliosis. (c) Cervical spine magnetic resonance image of a 53-year-old with AD-HIES, demonstrating severe degenerative changes and spinal column narrowing.

1983). Autoimmune vasculitis (Kimata, 1995), dermatomyositis (Min et al., 1999), and membranoproliferative glomerulonephritis (Tanji et al., 1999) have been described in reports preceding genetic diagnosis, and may occur, but likely very infrequently.

LABORATORY FINDINGS

The syndrome takes its name from marked polyclonal elevations of IgE in serum, with an IgE of more than 2,000 IU/mL often being used as an arbitrary diagnostic level. However,

because IgE levels are very low in utero and climb only after birth in normal infants, infants affected with AD-HIES may not achieve a diagnostic level of 2,000 IU/mL early in life, and the levels may normalize or significantly decrease in adulthood (Grimbacher et al., 1999a). In affected infants the IgE is consistently elevated over the age-adjusted value, and a level 10 times the age-appropriate level has been a reasonable guide. Serum IgE levels are not static, and substantial fluctuations in serum IgE concentrations have been noted over time without any obvious relationship to the clinical status. Therefore, although a high IgE level is part of the diagnostic criteria for HIES, authentic cases may lack this particular feature at some point in their course, and the level of serum IgE apparently is not correlated with disease activity or severity. IgE production is thought to be elevated because of an increased number of B cells making subnormal levels of IgE (Garraud et al., 1999; King et al., 1991) and potentially impaired catabolism (Dreskin et al., 1987a). But the driving force for this abnormality is still unclear. In addition, the tropism of the elevated IgE is still unclear. Anti–*S. aureus* and anti–*Candida albicans* IgE titers have been noted to be raised in HIES, but any relationship to the severity of the disease is not known (Berger et al., 1980; Walsh et al., 1981). Unfortunately, raised anti-staphylococcal IgE titers are also seen in atopic patients and are therefore not helpful in the diagnosis of HIES. Anaphylaxis and allergies in general are not thought to be increased in AD-HIES.

White blood cell counts are typically in the normal range but have been reported to range from 1,700 to 60,000/μL (Buckley and Becker, 1978; Donabedian and Gallin, 1983a). Chronic leukopenia with borderline neutropenia has been observed in several patients (Donabedian and Gallin, 1983a). Eosinophilia is seen in more than 90 percent of HIES patients. This eosinophilia is at least 2 standard deviations above normal, usually above 700 cells/μL, may fluctuate over time, and is not correlated with the extent of IgE elevation.

DIAGNOSIS

An HIES scoring system (Table 38.2) was initially developed at NIH to assist in gene linkage studies (Grimbacher et al., 1999). Because for the majority of cases of AD-HIES the genetic etiology is now known to be mutations in STAT3, an alternative STAT3 score has been put forward (Woellner et al., 2010) to distinguish between STAT3 mutated and STAT3 wild-type patients. Individuals who have a similar phenotype but do not have a STAT3 mutation may still be classified with the original NIH scoring system, which is based on the frequency and severity of characteristics exhibited. In contrary to the STAT3 score, it includes an age correction, since older patients are likely to have collected more points, and some clinical features, such as shedding of primary teeth, cannot be evaluated in very young patients. For the NIH system, AD-HIES is considered highly likely if the score exceeds 40 points and unlikely if the score is below 20 points. Between 20 and 40 points is an indeterminate zone: patients with these scores may be suspected of having AD-HIES and followed over time to gather more conclusive data, or they may have other genetic forms of HIES (see below). If both immunological and nonimmunological features are present and contribute to the score, there is an increased likelihood of AD-HIES due to STAT3 mutations.

ETIOLOGY

The majority of cases of AD-HIES are caused by dominant-negative mutations in STAT3 (Holland et al., 2007; Jiao et al., 2008; Minegishi et al., 2007; Renner et al., 2008; Woellner et al., 2010). Most mutations are missense, resulting in one amino acid change, or short in-frame deletions. Mutations are largely concentrated in the SH2 and DNA binding domains of STAT3, with several mutational hot spots in each region. The SH2 domain mediates protein–protein binding, and the DNA binding domain mediates protein–DNA interactions. Despite the difference in functions of the two regions, and some differences in vitro in their effects on STAT3 signaling, clinically significant genotype–phenotype associations are absent.

Although HIES is thought to be rare, the exact incidence is unknown. Over 200 cases have been published. Although first described in Caucasians with red hair, STAT3 mutations have been found in all races and many ethnic groups, with equal frequency between genders. Transmission is autosomal dominant, with many sporadic cases reported. Penetration of the mutation is complete, and all family members carrying a specific mutation have the HIES phenotype, although there may be a variation in severity and phenotypic expressivity. Laboratory constructs of STAT3 mutations demonstrate a dominant-negative effect on STAT3 functioning. This is supported by the lack of null alleles in HIES, and the fact that mice with a complete heterozygous deletion of only one STAT3 allele are phenotypically normal. It is also noteworthy in this context that complete STAT3 knockout mice die in utero (Takeda et al., 1997).

IMMUNOLOGY AND PATHOGENESIS

The pathogenesis of both the immunological and nonimmunological features of AD-HIES are still not well understood. The most consistent immunological findings in HIES have been the elevated serum IgE, eosinophilia, diminished memory T- and B-cell populations, and greatly diminished Th17 cells and IL-17 production ex vivo (de Beaucoudrey et al., 2008; Ma et al., 2008; Milner et al., 2008; Speckmann et al., 2008). Many studies have also focused on other cytokine production and responsiveness, as well as neutrophil chemotaxis, with conflicting results.

STAT3 is one of the STAT family of major signal transducers and is involved in many diverse pathways, including cancer, wound healing, angiogenesis, and immunity. Many cytokines, including IL-6, IL-10, IL-21, IL-22, and IL-23, signal through STAT3 (Fig. 38.3). That both proinflammatory cytokines (such as IL-6) and anti-inflammatory cytokines (such as IL-10) signal through STAT3 likely explains in part the dichotomy of AD-HIES being a disease of both too much and too little inflammation, as it is characterized by the exuberant local inflammation found in abscesses and pneumonia but the lack of systemic signs of illness such as fever and acute phase reactants (C-reactive protein, CRP).

Table 38.2 NIH HYPER-IGE SYNDROME SCORING SYSTEM

POINTS										
CLINICAL FINDING	0	1	2	3	4	5	6	7	8	10
Highest IgE (IU/mL)	<200	200–500			501–1,000				1,001–2,000	>2,000
Skin abscesses (total)	None		1 or 2		3 or 4				>4	
Pneumonias (X-ray proven, total)	None		1		2		3		>3	
Parenchymal lung abnormalities	Absent						Bronchiectasis		Pneumatocele	
Other serious infection	None				Severe					
Fatal infection	Absent				Present					
Highest eosinophils/μL	<700			700–800			>800			
Newborn rash	Absent				Present					
Eczema (worst stage)	Absent	Mild	Moderate		Severe					
Sinusitis, otitis (no. of times in worst year)	1 or 2	3	4–6		>6					
Candidiasis	None	Oral, vaginal	Fingernail		Systemic					
Retained primary teeth	None	1	2		3				>3	
Scoliosis, maximum curvature (degrees)	<10		10–14		15–20				>20	
Fractures with little trauma	None				1 or 2				>2	
Hyperextensible joints	Absent				Present					
Characteristic face	Absent		Mild			Present				
Increased nose width (interalar distance)	<1 SD	1–2 SD		>2 SD						
High palate	Absent		Present							
Congenital anomaly	Absent					Present				
Lymphoma	Absent				Present					

Leukocyte microarray data at rest and after stimulation and in vitro cytokine stimulation assays show increased levels of proinflammatory cytokines such as TNF-alpha and interferon-gamma (Holland et al., 2007; Yeganeh et al., 2008). Animal data support this finding, as mice with a conditional myeloid STAT3 knockout have increased proinflammatory cytokines (Takeda et al., 1999). However, in other aspects, AD-HIES is associated with diminished inflammatory cytokine and chemokine production. For instance, IL-6 leads to monocyte chemoattractant protein (MCP)-1 production, and this is disrupted in STAT3 deficiency, leading to decreased MCP-1 in vitro.

The immunodeficiency of STAT3 defects may be explained in part by a lack of differentiation of T lymphocytes into Th17 cells and subsequent IL-17 production. Both STAT3-deficient individuals as well as STAT3-deficient mice have impaired Th17-cell synthesis and IL-17 production. The role of IL-17 in human immunity is still being delineated, but mice with abnormal IL-17 signaling are prone to both *Candida* and extracellular bacterial infections (Aujla et al., 2008; Huang et al., 2004). In part, the immunity of IL-17 is thought to be due to regulation of IL-22, a key cytokine in human beta-defensin production (Dong et al., 2008). The antimicrobial peptide beta-defensin and neutrophil-recruiting chemokines, which are both important for protection against bacterial infection, are poorly produced by keratinocytes and lung epithelial cells when stimulated by T cells from HIES patients. Those cells, unlike other cell types, need the synergistic action of Th17 cytokines and classical proinflammatory cytokines to produce antibacterial factors. This might explain why HIES patients with impaired Th17 but normal proinflammatory cytokine production are susceptible to bacterial infections particularly in the skin and lung (Minegishi et al., 2009).

The greatly increased serum IgE in HIES remains poorly understood (Vercelli et al., 1990). Although IL-21 receptor knockout mice have elevated IgE, and IL-21 signals through STAT3, this finding does not appear to translate from mice to human, and impaired IL-21 signaling may actually result in less IgE in humans (Avery et al., 2008; Ozaki et al., 2002).

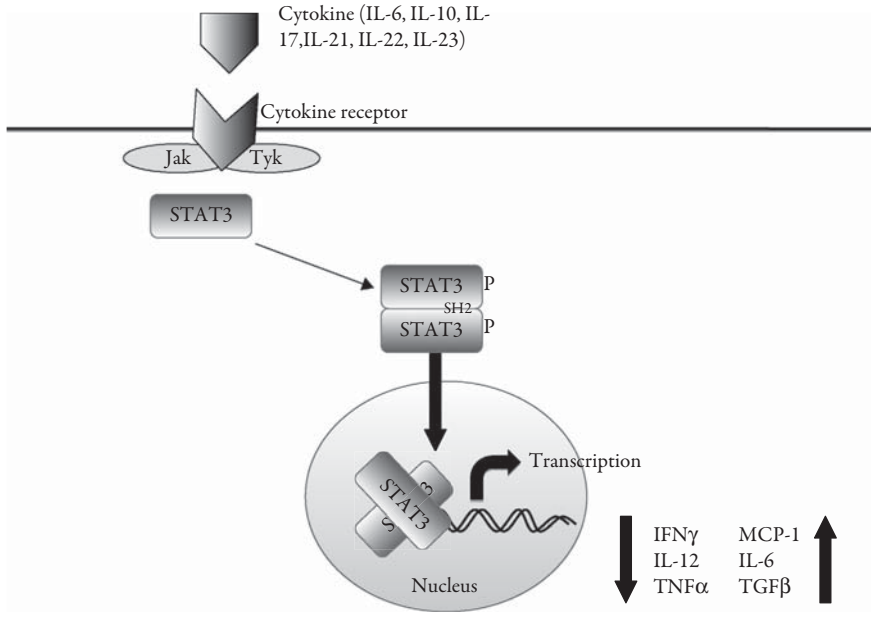

Figure 38.3 STAT3 signaling pathway. Multiple cytokines signal through transmembrane receptors that activate STAT3. The cytokine receptor activates the Janus kinase (Jak) family proteins leading to STAT3 phosphorylation and dimerization through the STAT3 SH2 domains. The STAT3 phosphodimer then enters the nucleus and binds to DNA to change the transcription program. Some of the regulatory effects of STAT3 are shown in the lower right corner.

B-cell development in mice with STAT3-deficient bone marrow have abnormal B-cell development, but again the translation into humans is not clear, and abnormal B-cell development has not been shown in AD-HIES. In general, people with AD-HIES have normal levels of B cells, normal-appearing lymph nodes, and normal IgG, IgM, and IgA. The only consistent B-lymphocyte abnormality has been deficient memory B cells and variable specific antibody responses (Speckmann et al., 2008).

PATHOGENESIS OF SOMATIC FINDINGS

How diminished STAT3 signaling leads to the many somatic features of HIES is still poorly understood. STAT3 knockout mice are embryologically lethal, but organ-specific STAT3 knockouts show evidence that STAT3 deficiency in mice does correlate with some of the somatic features. Mice with STAT3-deficient bone marrow have osteopenia with evidence of increased osteoclastogenesis, likely similar to the osteopenia and minimal-trauma fractures in AD-HIES (Zhang et al., 2005). Mice with STAT3-deficient astrocytes have evidence of astrocytosis and demyelination after brain injury, which may relate to the role of IL-6 in astrocyte development and be similar to the focal hyperintensities seen on brain magnetic resonance imaging in HIES (Datta et al., 2008; Okada et al., 2006). Mice with STAT3-deficient pulmonary epithelium have alveolar enlargement and excessive inflammation after injury, which may be similar to the residual pneumatoceles present in AD-HIES patients after lung infection (Hokuto et al., 2004). STAT3-deficient mouse keratinocytes have poor wound healing, which may be similar to the porous, doughy skin of human STAT3 deficiency as well as the oral mucosal variants (Sano et al., 1999). Other phenotypes of organ-specific STAT3 knockouts are not observed in humans, such as colitis and cardiomyopathy. The phenotype of transgenic mouse models with STAT3 mutations found in human AD-HIES is just being delineated and will add to our understanding of the pathogenesis of the somatic and immunological features.

TREATMENT

Aggressive skin care and prompt treatment of infections are the main pillars of management of all types of HIES. The dermatitis is heavily dependent on ongoing infection, typically with *S. aureus*. Therefore, antibiotic treatment is often an essential part of management of HIES eczema, in association with topical moisturizing creams and occasionally topical steroids. We have also used topical antiseptic treatments such as bathing in a dilute bleach solution or swimming in chlorinated pools to reduce the bacterial burden in the skin. Skin abscesses are a common complication of HIES and may require incision and drainage. Interestingly, after the introduction of prophylactic antibiotics, skin abscesses are unusual. The role of prophylactic antibiotics has not been rigorously investigated in this setting, but there is general consensus in favor of their use to prevent the skin and lung infections. Most physicians cover *S. aureus* with trimethoprim-sulfamethoxazole, a semisynthetic penicillin (e.g., dicloxacillin), or a first-generation cephalosporin. With increasing rates of community-acquired methicillin-resistant *S. aureus* (MRSA) in the community, cultures of eczematoid regions or of the nares can be helpful in selecting a prophylactic antibiotic. If parenchymal lung disease is present, such as bronchiectasis or pneumatoceles, then expansion of antibacterials may be necessary.

The other major recurrent infectious problem in HIES is mucocutaneous candidiasis. This typically manifests as onychomycosis and oral and/or vaginal thrush. *Candida* disseminates typically only when indwelling intravenous catheters are present. Oral antifungals, such as fluconazole, are quite effective in controlling the mucocutaneous candidiasis in HIES and may be used as prophylaxis. Anti-*Aspergillus* antifungals, such as voriconazole, posaconazole, and itraconazole, should be considered for individuals with pneumatoceles as molds are a significant cause of morbidity and mortality for these individuals. Although the overuse of antibiotics and antifungals is currently discouraged in general practice because of concerns about selection for resistant organisms, there is no clear demonstration of increasingly resistant organisms in HIES patients or other patients with primary immunodeficiencies on prolonged prophylactic and suppressive antibiotic therapy; on the contrary, the benefits of this approach are readily appreciated.

One remarkable feature of HIES is the enormous infectious burden with which patients often present. By the time the patient or parent is aware of illness, there is usually nothing subtle about the diagnosis. One of the most difficult problems in the management of HIES is that even in the presence of obvious auscultatory and radiographic evidence of pneumonia, patients do not feel unwell and may be unwilling to undergo invasive diagnostic testing or prolonged courses of therapy. In addition, the hesitance of physicians to believe that patients who appear no different from their baseline are really on the verge of collapse is difficult to overcome. However, aggressive therapy is necessary to try to lessen parenchymal lung damage.

As in most of medicine, the firm establishment of a microbiological diagnosis cannot be overemphasized. Bronchoscopy may help in both obtaining the specimen and mobilizing secretions. Thick inspissated secretions typically plug ectatic bronchi and are tenacious and difficult to clear. High-dose intravenous antibiotics or highly active oral antibiotics may be needed for a prolonged course to eradicate infection and to prevent bronchopleural fistula formation and bronchiectasis. Empirical acute coverage should consider *S. aureus*, *H. influenzae*, and *S. pneumoniae*, and then antibiotics can be tailored to the microbiological findings.

One of the typical features of AD-HIES is that following the resolution of acute pneumonias, pulmonary cysts and bronchiectasis may form. These parenchymal abnormalities then serve as the focus for colonization with *P. aeruginosa*, *Aspergillus* and other fungal species, and nontuberculous mycobacteria. These superinfections are the most difficult aspect of long-term management of HIES. Similar to cystic fibrosis, eradication of *Pseudomonas* and molds is very difficult, but the goal should be to diminish the degree of colonization and disease and treat exacerbations aggressively. The role of surgery to remove infected pneumatoceles and areas of parenchymal abnormalities remains unclear. *Aspergillus* and *Pseudomonas* infections in these areas of parenchymal abnormalities are a major source of morbidity and mortality, but thoracotomy and lung resection appear to have increased complications. The remaining lung may fail to expand normally, and soiling of the pleural space may occur, leading to chronic empyema. Surgery often results in a need for very prolonged chest tube drainage, thoracoplasty, or pneumonectomy, along with intensive parenteral antibiotic treatment. Therefore, pulmonary surgery in HIES should not be undertaken lightly and should be performed at a center with experience with the disease where possible and in most cases after failure of control of infection with antimicrobials.

The role for immune modulators in HIES is unproven. Levamisole was tried in a double-blind, placebo-controlled trial and actually caused an increase in infectious complications in the treatment arm (Donabedian et al., 1982). This is the only published double-blind, placebo-controlled trial of any management intervention in HIES. Immune globulin therapy, either intravenously or subcutaneously, is used for some patients, with anecdotal improvement for at least a subset of patients (Kimata, 1995; Wakim et al., 1998). A blinded study of immunoglobulin replacement in HIES is therefore warranted.

It has been previously supposed that since immunodeficiency is a central part of HIES, the underlying defect in HIES must reside in the leukocytes; thus, bone marrow transplantation has been suggestive as a curative treatment. Cases of bone marrow transplantation in HIES have been reported (Gennery et al., 2000; Nester et al., 1998). The first was a 46-year-old man with HIES who had experienced many bouts of pneumonia from childhood onward. Two of his four children were also affected. He developed a B-cell lymphoma that was treated with a peripheral stem cell transplant from his HLA-identical sister, preceded by total body irradiation. He was maintained on prednisolone and cyclosporine A after the transplant. Serum IgE fell to normal values following transplant and no infections were reported. However, he died 6 months later from interstitial pneumonitis.

The second patient was a 7-year-old girl who was transplanted in an effort to treat her severe HIES. She received marrow from a matched unrelated donor after cytoreductive therapy. Cyclosporine A was used for prophylaxis of graft-versus-host disease. Initially the skin lesions cleared, but 4 years after transplant, she developed recurrent infections, although perhaps more mild, despite full engraftment, and her IgE returned to pretransplant levels. The high IgE is particularly surprising in view of the reported full engraftment of the B-cell compartment, suggesting that the features that led to IgE elevation in this patient may have been somatic, and that the features that made her susceptible to infection may not have been confined to the hematopoietic system.

More recently, successful bone marrow transplants of two unrelated boys with sporadic HIES due to STAT3 mutations have been reported (Goussetis et al., 2010). Both patients had developed high-grade non-Hodgkin's lymphoma in addition to HIES symptoms. After myeloablative conditioning, both received bone marrow from their respective healthy, HLA-identical sibling. Acute or chronic graft-versus-host disease was prevented by the administration of cyclosporine and methotrexate. Initially, severe adenoviral hemorrhagic enteritis occurred, but it ceased after stable engraftment was achieved. Full donor chimerism led to complete immunological correction. Ten and 14 years after transplant, respectively,

serum IgE levels remained normal, no respiratory and skin infections were reported, and even nonimmune manifestations like osteoporosis in one patient resolved. Furthermore, bone marrow transplantation prevented the development of later-occurring complications such as coronary artery aneurysms, brain lesions, or degenerative joint disease.

Now that the genetic etiology of AD-HIES is known, the pathogenesis of both the somatic and immunological manifestations will be delineated. Understanding the various manifestations of this rare disease will help to expand our knowledge of more common disease processes such as staphylococcal susceptibility, eczema, idiopathic scoliosis, and coronary artery disease. In addition, understanding the pathway of STAT3 deficiency will help us to learn the etiology and pathogenesis of related, still poorly understood hyper-IgE syndromes. These advances are expected to lead to further possibilities for treatment.

AR-HIES

In 2004, 13 HIES patients from six consanguineous families with severe recurring infections (pneumonia and abscesses), eczema, high IgE, and eosinophilia were described who fulfilled the criteria for diagnosis of HIES, here designated autosomal recessive (AR)-HIES (Renner et al., 2004). These patients lacked many of the connective tissue and skeletal abnormalities associated with AD-HIES and had increased viral skin infection susceptibility, as well as more neurological symptoms and autoimmune phenomena. A single patient with AR-HIES was reported to have deficiency of the tyrosine kinase-2, or Tyk2 gene, TYK2 (MIM #611521) (Minegeshi et al., 2006). This Tyk2-deficient patient had a unique clinical phenotype. In contrast to other AR-HIES patients, he had Bacillus Calmette-Guérin (BCG) and *Salmonella* infections, which are classically associated with defects of the IL-12/IFN-gamma pathway. However, he did exhibit other clinical features of AR-HIES, including eczema, recurrent sinopulmonary infections, and viral infections. He was found to have a homozygous 4 nucleotide deletion in Tyk2 leading to a premature stop codon (Minegishi et al., 2006). Tyk2 was sequenced in several of the other reported cases of AR-HIES and mutations were not found (Woellner et al., 2010). Recently, a second Tyk2-deficient patient has been described who presented with mycobacterial and cutaneous viral infections but, unlike HIES patients, not with pyogenic bacterial infections (Kreins et al., 2010). This finding suggests that Tyk2 deficiency may predispose to infections with mycobacteria and other intracellular pathogens, while the HIES phenotype may be a less consistent finding that could possibly be explained by other loci that were homozygous in the Japanese patient.

In 2009, mutations in the dedicator of cytokinesis-8 gene (DOCK8) were found to account for the disease of most patients with AR-HIES (Engelhardt et al., 2009; Zhang et al., 2009). DOCK8 deficiency is associated with elevated serum IgE, eosinophilia, eczema, food allergies, sinopulmonary infection, viral skin infections, staphylococcal skin infections, mucocutaneous candidiasis, and a predisposition to malignancy. One of the most distinguishing characteristics between DOCK8 deficiency and AD-HIES is the viral skin infections. Patients with DOCK8 deficiency have had severe chronic therapy-resistant molluscum contagiosum infections, warts, herpes zoster, and recurrent herpes simplex mucosal and skin infections. Malignancies have included squamous cell carcinomas, thought to be related to the human papillomavirus (HPV) infection, and lymphomas. Mortality is frequently at a younger age than with AD-HIES, often occurring in the first and second decades. Connective tissue and skeletal characteristics common in AD-HIES such as retained primary dentition, minimal-trauma fractures, and the characteristic facial appearance are infrequent in DOCK8 deficiency.

Although both AD- and AR-HIES have elevated serum IgE and eosinophilia, there are distinguishing laboratory features. DOCK8 deficiency may be associated with lymphopenia, with most patients having decreased CD4 and CD8 T lymphocytes, B lymphocytes, and natural killer cells, although in other patients lymphocyte subsets have been normal. Another distinguishing feature is diminished serum IgM in DOCK8 deficiency. Serum IgG and IgA levels are variable but frequently normal; specific antibody production has been variable. Lymphocyte proliferation, especially of CD8 T cells, appears abnormal.

DOCK8 is one of 11 members of the DOCK180 family of proteins that are thought to be involved in cytoskeletal rearrangements allowing cell migration, adhesion, and growth. The exact function of DOCK8 remains unknown but is proposed to be involved with cytoskeletal rearrangements important for T-cell activation and effector responses. Most of the reported patients with DOCK8 deficiency have had greatly diminished or absent production of DOCK8 protein. Both homozygous and compound heterozygous mutations have been reported, and large deletions have been frequent.

TREATMENT OF DOCK8 DEFICIENCY

As the genetic etiologies of AR-HIES are elucidated, optimal therapies will be determined. Currently, therapies are largely supportive and similar to those utilized in AD-HIES. As eczema can be severe, involvement of a dermatologist is important to maximize skin care. Treatment of recurrent staphylococcal skin infections is frequently with antiseptic therapies such as dilute bleach baths and chronic antistaphylococcal antibiotics. Prophylactic antimicrobials are also frequently helpful to control sinopulmonary infections. Allergies and asthma are more frequent than in AD-HIES and may require antihistamines as well as inhaled corticosteroids. Although serum IgG is often normal, specific antibodies are variable and immunoglobulin replacement has been used in some of these patients, with anecdotal improvement of the sinopulmonary infections. Improvement of the skin viral infections has not been seen with replacement of immunoglobulin. The widespread molluscum and HPV that are frequently seen are often difficult to treat with standard measures such as salicylic acid, cryotherapy, and imiquimod. There has been some anecdotal evidence with mixed results with interferon-alpha therapy. Hematopoietic stem cell transplantation leading to the cure of DOCK8-deficient patients was reported in 2010.

In the first report, two patients with recurrent respiratory infections, eczema, and disfiguring molluscum contagiosum received transplants from a HLA-matched unrelated donor (Gatz et al., 2010). Patient 1, with additional chronic autoimmune anemia, developed no graft-versus-host disease due to prophylaxis and achieved complete donor cell chimerism until now, 4 years after transplant. His immune functions have normalized, with complete clearance of molluscum contagiosum and absence of bacterial infections. Patient 2, who additionally suffered from severe periodontitis, recurrent skin abscesses, and chronic ulcerative HSV infections, had a more troublesome transplant course. Among others, she developed brain abscesses and an acute Epstein-Barr virus infection despite full donor chimerism. Finally, like patient 1 her immunological functions normalized with complete clearance of molluscum contagiosum and absence of bacterial infections until her last follow-up 2 years after transplant. Both patients now lead a normal and healthy life.

Bittner et al. (2010) described a DOCK8-deficient patient 6 years after transplant. She received bone marrow from her HLA-identical father together with graft-versus-host disease prophylaxis. Only partial myeloablative preconditioning was applied due to severe pulmonary dysfunction. The transplantation was mainly uneventful and led to mixed donor chimerism. Before transplantation she presented with recurrent obstructive bronchitis, severe eczema, candidiasis, molluscum contagiosum infection, and multiple severe food allergies. Now she is alive and well with no findings of eczema and severe infections, decline of IgE levels, and improvement of pulmonary function. However, despite improvement of severity, she still suffers from food allergies.

A further DOCK8-deficient girl with AR-HIES symptoms complicated by Epstein-Barr virus–induced B-lymphoproliferative syndrome, abdominal vasculitis, and celiac trunk aneurysm received a hematopoietic stem cell transplant from her healthy, HLA-identical sister at 9.5 years of age (Barlogis et al., 2010). Total donor chimerism was achieved, together with a decrease of IgE levels and absence of viral infections and vasculitis.

These results suggest that bone marrow transplantation presents an excellent curative treatment option for DOCK8 deficiency, which is otherwise characterized by high morbidity and mortality.

HYPER-IGE OVERLAP SYNDROMES

Interestingly, in rare cases of other defined genetic diseases, the classical triad of HIES with recurrent skin abscesses, recurrent pneumonia, and extreme elevations of IgE is also fulfilled. Antoniades et al. (1996) reported the coexistence of HIES and Dubowitz syndrome, defined by postnatal growth retardation, microcephaly, and characteristic facial appearance. Boeck et al. (1999) reported the coexistence of pentasomy X and HIES. Boeck et al. (2001) further reported the coexistence of HIES and Saethre-Chotzen syndrome (defined by acrocephalosyndactyly, hypertelorism, and ptosis), caused by mutations in the *TWIST* gene. Prolidase deficiency has been associated with hyper-IgE, recurrent lung infections with residual structural abnormalities, and some of the connective abnormalities seen in AD-HIES. Common mechanisms between these syndromes and those of STAT3 and DOCK8 deficiency remain unknown.

ACKNOWLEDGMENTS

The authors are indebted to physicians and patients who contributed to facilitate better diagnosis and management of HIES and help unravel the pathogenesis of this enigmatic disease. A.F. and S.H. are supported by the NIH NIAID Division of Intramural Research. B.G. was a fellow of the Immune Deficiency Foundation (1998–1999), an Emmy-Nöther Fellow of the Deutsche Forschungsgemeinschaft (2001–2005), and a Marie-Curie fellow of the European Union (2006–2010). K.R.E. was a Marie-Curie fellow of the European Union (2006–2010). J.P. received support from the Jeffrey Modell Foundation and the NIH/NCRR Grant UL1 RR024131 to the UCSF Clinical and Translational Research Institute.

HEPATIC VENO-OCCLUSIVE DISEASE WITH IMMUNODEFICIENCY

Tony Roscioli and Melanie Wong

Veno-occlusive disease with immunodeficiency (VODI) (OMIM235550) is an autosomal recessive primary immunodeficiency disease associated with hepatic sinusoidal obstruction (also known as hepatic veno-occlusive disease [hVOD]) (Roscioli et al., 2006). The onset of VODI usually occurs prior to the age of 6 months. The immunodeficiency comprises severe hypogammaglobulinemia with absent lymph-node germinal centers and tissue plasma cells together with clinical evidence of T-cell immunodeficiency in the presence of normal numbers of circulating T cells. Opportunistic infections, including *Pneumocystis jirovecii*, mucocutaneous candidiasis, and enteroviral or cytomegalovirus infections, occur. The mortality rate for VODI was previously reported as 100% in the first year of life (Roscioli et al., 2006). In contrast, there have been only three deaths among 8 recently ascertained patients older than 1 year, representing a markedly improved prognosis with early recognition and treatment with intravenous immunoglobulin (IVIg) and *Pneumocystis carinii (jirovecii)* pneumonia (PCP) prophylaxis (Cliffe et al., 2012). The gene responsible for VODI, *SP110*, was identified by homozygosity mapping and candidate gene sequencing and represents the first monogenic disorder of a PML nuclear body (PML NB) protein. Targeted sequencing of exons 2, 4, and 5 of *SP110* has detected mutations in 100% of the 13 individuals with VODI evaluated to date (Cliffe et al., 2012; Roscioli et al., 2006).

CLINICAL DESCRIPTION

VODI is a rare disorder originally described in five Lebanese Australian children from three families (Mellis and Bale, 1976). The prevalence of VODI in the Lebanese population in New South Wales has subsequently been estimated to be 1:22,500, implying a carrier frequency of 1:75 (http://www.abs.gov.au/websitedbs/d3310114.nsf/home/Census+data). Two Italian children, one Hispanic child, and one Palestinian child with confirmed cases of VODI have also been identified (Cliffe et al., 2012; Wang et al., 2012; Ganaiem et al., 2013). There has, in addition, been an earlier case report in the Spanish literature of an individual with hVOD and combined immunodeficiency consistent with VODI (Manzanares Lopez-Manzanares et al., 1992).

The clinical features of 20 children with a clinical diagnosis of VODI and a subset of 13 with confirmed *SP110* mutations are summarized in Tables 39.1 and 39.2, respectively (Cliffe et al., 2012; Roscioli et al., 2006). All children in the Australian cohort presented prior to 6 months of age, either with sequelae of immunodeficiency or concurrently with hVOD. The children with VODI who presented without evidence of hepatic involvement were ascertained at a young age because of an affected sibling and were treated early in the disease course with IVIg.

IMMUNODEFICIENCY IN VODI

The immunological features of VODI involve both the B- and T-cell compartments. Serum immunoglobulin levels are low or undetectable, and most VODI patients have reduced circulating T-cell subsets and $CD19^+$ B-cell numbers (Cliffe et al., 2012). Memory B cells are reduced in almost all VODI patients. Further immunophenotyping in two patients with novel mutations (patients I and F in Table 39.2) demonstrated that $CD27^+CD10^-$ B cells were reduced significantly (7.07% ± 1.6%, vs. control 12.8% ± 2.4 %), while $CD27^-CD10^-$(Naïve) B cells were somewhat reduced (63.7% ± 16.2%, vs. control 77.5% ± 0.7%) and $CD27^-CD10^+$ (transitional) B cells were elevated (25.85% ± 15.2%, vs. control

Table 39.1 VODI CLINICAL AND IMMUNOLOGICAL FEATURES

	PHENOTYPE		
CLINICAL FEATURES	PATIENTS FROM SYDNEY WITH VODI (ROSCIOLI ET AL., 2006)	COMMENTS	NEWLY ASCERTAINED PATIENTS WITH VODI (CLIFFE et al., 2012) WITH NOVEL MUTATIONS*
Presenting <6 months	20/20 (100%)		7/8 (patient F > 6 months)
Hepatic failure at initial presentation	4/20 (20%)	1/12 post-HSCT 3/12 no obvious precipitant	0/8
Hepatomegaly at initial presentation	9/20 (45%)	3/6 *P. jirovecii* 2/6 hepatomegaly without hVOD	6/8 1/8 enterovirus & disseminated cytomegalovirus (F)
P. jirovecii infection	12/20 (60%)	7/12 proven; 5/12 suspected	1/8 suspected (F) 1/8 proven (I)
Mucocutaneous candidiasis	2/20 (10%)		1/8
Other features	1/20 (5%)	By age 19 years	1/8 lung fibrosis (H)
Death	19/20 (95%)		3/8 (38%)
Recovery from initial hVOD	4/20 (20%)	1 completely well 1 chronic liver disease requiring hepatic transplantation 1 hVOD post-HSCT 1 developmental disability, chronic aspiration	4/8
Neurological abnormalities	6/20 (35%)	4/7 cerebral infarction 2/7 Leukodystrophy	1/8 Leukodystrophy
Panhypogammaglobulinemia	19/19 (100%)	1/18 loss of normal immunoglobulins at age 4 months	5/5 tested 1/5 low normal levels of IgA and IgM after commencing IVIg
Normal number of lymphocytes	10/11 (92%)		8/8
Normal number of NK cells	12/12 (100%)		3/3
Decreased intracytoplasmic IFN-γ, IL-2, IL-4, IL-10	4/5 (80%)	Low levels at 4 hours, normal/increased levels at 48 hours	1/1 (F)
Decreased number of memory T and B cells	3/4 (75%)		2/3 These cells were present in the individual with the exon 4 duplication (F).

Table modified from Roscioli et al., 2006.

HSCT, hematopoietic stem cell transplantation; IVIg, intravenous immunoglobulin; hVOD, hepatic veno-occlusive disease.

* Patients I, F, 2, and 3 in Table 39.2: I = c.78_79delinsAT (p.Ile27Leu), F = c.319_325dup (p.Ser109TrpfsX5), 2 = c.667 + 1dup, 3 = c.373delA (p.Th r125LeufsX3)

8.49% ± 3.4%). Patients also showed a marked reduction in $CD27^{+}IgD^{-}$ (switched memory) B cells and an absence of IgG^{+} or IgA^{+} B cells. Histological studies have shown absence of both lymph-node germinal centers and tissue plasma cells (Roscioli et al., 2006). Immunocytochemistry of CD40L stimulated B cells in a representative sample of VODI patients demonstrated that their cells were unable to isotype switch to IgG or IgA. Furthermore, compared with normal controls, total B cells as well as naïve B cells from VODI patients, when activated in vitro with CD40L +/- IL-21, showed marked reduction in immunoglobulin production (IgM was 6-fold reduced; IgG and IgA were >100-fold reduced), demonstrating that *SP110* mutations compromise the intrinsic ability of B cells to differentiate into immunoglobulin-secreting cells and to undergo isotype switching in response to T-dependent stimuli (Cliffe et al., 2012).

VODI patients show a predisposition to *P. jirovecii* and mucocutaneous candidiasis, consistent with impaired T-cell immunity. While the numbers and percentages of circulating T-cell subsets are moderately decreased and T-cell proliferation assays are normal in VODI patients, the $CD45RO^{+}CD27^{-}$ (memory) T cells are almost absent, with resultant predominance of naïve T cells. Intracytoplasmic cytokine expression after stimulation with phorbol myristate acetate and ionomycin is significantly reduced: IFN-γ 1 to 4% (reference range 25–30v); IL2 1 to 3% (12–32%); IL4 1 to 2% (4–7%), and IL10 1 to 2% (1–6%). NK activity was normal in the seven patients with *SP110* mutations tested.

HEPATIC DISEASE IN VODI

Hepatic disease in VODI is characterized by hepatomegaly or hepatic failure. Ninety percent of the children with VODI

Table 39.2 CLINICAL FEATURES OF INDIVIDUALS HOMOZYGOUS FOR *SP110* MUTATIONS

PATIENT	SP110 MUTATION	PRESENTATION	SERUM Ig's	MEMORY T/B CELLS	T CELL CYTOKINES	CLINICAL FINDINGS	DECEASED?
AII.1[1] Lebanese	c.642delC exon 5	Age 5 months: immunodeficiency, thrombocytopenia, hVOD	↓	N/A	N/A	Left hemiparesis[3], recurrent hVOD with GVHD post-HSCT	Yes
BII.1[1] Lebanese		Age 7 months: immunodeficiency	↓	N/A	N/A	Chronic lung disease secondary to recurrent aspiration	Yes (age 19 years)
BII.2[1] Lebanese		Age 6 months: hepatosplenomegaly, ascites, hVOD	↓	↓	↓	Well	No
CII.1[1] Lebanese		Age 4 months: hepatosplenomegaly, ascites, hVOD, thrombocytopenia, mucocutaneous candidiasis	↓	↓	↓	Chronic liver disease, portal hypertension post-hepatic transplantation	Yes
DII.1[1] Lebanese		Age 3 months: hepatosplenomegaly, ascites, hVOD	↓[4]	↓	↓	Hemophagocytic syndrome post-hepatic transplantation	Yes
G[1] Lebanese		Age 3 months: hepatosplenomegaly, ascites, hVOD	↓	↓	↓	Pulmonary hemorrhage, multi-organ failure	Yes
J[1] Lebanese		Age 3 months, respiratory distress	↓	↓	N/A	SIADH, idiopathic cerebrospinal leukodystrophy	No
6[2] Lebanese		Age 3 months: chronic cough, diarrhea hepatosplenomegaly 8 years, hVOD > 12 years	↓	N/A	N/A	Idiopathic left frontal lobe calcified cyst, Epilepsy, CMV colitis, post-diarrheal encephalomyelitis with lower limb paralysis, cerebrospinal leukodystrophy, oesophageal candidiasis, duodenal lymphocytic infiltrate	No
7[2] Lebanese	c.642delC presumed	Age 2 months: chronic diarrhea, failure to thrive, middle ear and respiratory infections, hepatosplenomegaly, thrombocytopenia	N/A	N/A	N/A	Microcephaly, Hepatic biopsy consistent with hVOD	Yes, 11 months diarrhea leading to septic shock
8[2] Lebanese	c.642delC presumed	Age 5 months: upper respiratory illness, age 8 months chronic diarrhea, hepatomegaly, thrombocytopenia	N/A	N/A	N/A	Hepatic biopsy consistent with hVOD	Yes, 3.5years, diarrhea leading to septic shock
9[2] Lebanese	c.642delC presumed	Age 2 months: ascites, hepatomegaly, anaemia, thrombocytopenia	N/A	N/A	N/A	Hepatic biopsy consistent with hVOD	Yes, 2.5 months otitis, diarrhea, pneumonia
EI.1[1] Lebanese	c.40delC in exon 2	Age 3 months: immunodeficiency, thrombocytopenia, hepatosplenomegaly without definite evidence of hVOD	↓	N/A	N/A	Enteroviral and *P. jiroveci* infection	Yes

(continued)

Table 39.2 (CONTINUED)

PATIENT	SP110 MUTATION	PRESENTATION	SERUM Ig's	MEMORY T/B CELLS	T CELL CYTOKINES	CLINICAL FINDINGS	DECEASED?
I[2] Hispanic	c.78_79delinsAT (p.Ile27Leu) exon 2	Age 3 months	↓	↓	↓	Stable and well	No
F[2] Italian	c.319_325dup GGTGCTT exon 4	Age 11 months: hepatosplenomegaly, disseminated cytomegalovirus infection, rotavirus gastroenteritis, vulvar abscesses, hVOD	↓initially	↓	N/A	Recovering from hVOD, well	No
2[2] Italian	c.667+1dup exon 5 splice site	Age 3 months: hepatosplenomegaly, failure to thrive, respiratory distress/lung fibrosis, diarrhea	↓	↓	N/A	Hepatic biopsy consistent with sinusoidal dilatation, moderate central vein and perivenular subsinusoidal fibrosis; stable with improvement	No
3[2] Palestinian Arabic	c.373del exon 4	Age 3 months: diagnosis of VODI confirmed with cascade testing prior to illness onset. No hepatomegaly or liver function abnormalities	N/A	N/A	N/A	Stable and well	No

Modified from Roscioli et al. (2006).

Although families A, B, and C are not known to be related, they are believed to have a common ancestor. Individuals AII.1, BII.1, BII.2, CII.1, G, and J were included in the initial homozygosity mapping analysis.

GVHD, graft-versus-host disease, HSCT, hematopoietic stem cell transplantation; hVOD, sinusoidal obstruction syndrome; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

[1]Reported in Roscioli et al. (2006).

[2]Reported in Cliffe et al. (2012).

[3]Secondary to cerebral white matter abnormality.

[4]IgA and IgM serum concentrations increased to lower limit of normal while on IVIG.

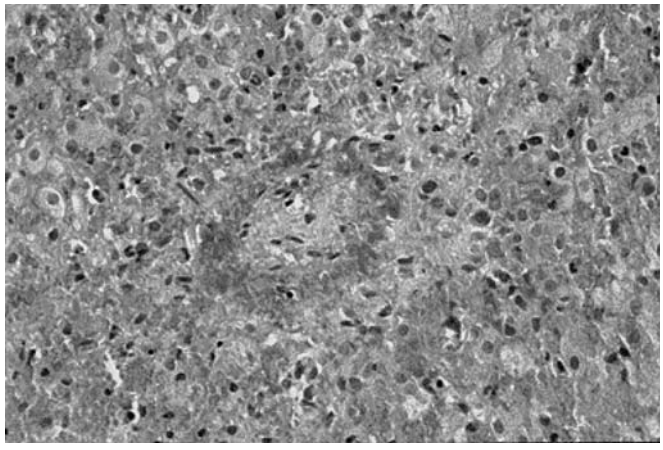

Figure 39.1 Hepatic biopsy showing vascular obliteration, perivenular fibrosis, zone 3 fibrosis, and hepatocyte dropout from a girl who presented at age 5 months with hepatomegaly and ascites (Picro-Mallory stain, ×100).

have presented either with hepatomegaly (83% with preceding infection) or hepatic failure (53% with preceding infection). A significant improvement in the hVOD recovery rate from 20% in the initially described cohort to 100% in the recently identified group has been observed. A typical hepatic biopsy from an affected individual that demonstrates the features of vascular obliteration, perivenular fibrosis, zone 3 fibrosis, and hepatocyte dropout that are diagnostic of hVOD is shown in Figure 39.1. It is currently unknown whether hVOD is a direct manifestation of *SP110* mutations or whether it is related to altered apoptosis in hepatic sinusoids or secondary to infection. It is unusual for primary or acquired immunodeficiencies to be associated with hVOD, and there are only isolated reports of such associations (Buckley and Hutchins, 1995; Washington et al., 1993). However, in children with VODI, hVOD appears to develop after infection. In hematopoietic stem cell transplantation (HSCT) the presence of hVOD prior to day 20 and before

engraftment also suggests that T- or B-cell–mediated mechanisms are not the primary cause of hVOD.

OTHER CLINICAL FEATURES

Thirty percent of children with VODI had neurological involvement. Four unrelated affected children had multiorgan failure associated with extensive cerebral necrosis on postmortem examination. A striking finding is the presence of cerebrospinal leukodystrophy in 3 (20%) VODI patients. Patient 5 (Table 39.2) had a leukodystrophy of unknown etiology and patient 6 developed this complication after a CMV-related gastroenteritis. In patient AII.1, the initial diagnosis of a cerebrovascular accident with a right-sided cerebral white matter lesion, presumed to be *Toxoplasma* or a porencephalic cyst was revised to being more consistent with cerebrospinal leukodystrophy. Child J developed a syndrome of inappropriate antidiuretic hormone secretion (SIADH) and an idiopathic cerebrospinal leukodystrophy, resulting in upper motor neuron lesions affecting the upper limbs and swallowing, which improved slowly. Lung fibrosis of unknown etiology was identified only in patient 2 (*SP110* c.667+1dupG).

OUTCOMES

VODI is associated with 100% mortality in the first year if unrecognized and untreated with IVIg and PCP prophylaxis. Improved recognition and early management have reduced mortality (Cliffe et al., 2012). Should hVOD recovery occur, recurrence appears to be prevented by continuation of IVIg and PCP prophylaxis. One child (AII.1, Table 39.2) died following recurrence of hVOD after HSCT at age 6 years. Chronic hepatic disease of unknown etiology resulting in hepatic failure occurred in one child in her teenage years after an disease-free period (CII.1, Table 39.2). She underwent a hepatic transplant but died as a result of multiple complications.

No significant difference in the clinical manifestations of VODI has been observed between individuals with *SP110* exon 2, exon 4, and exon 5 mutations. One individual with an exon 4 insertion/duplication had later onset of disease at 11 months, disseminated cytomegalovirus (CMV) infection, and normal numbers of memory T and B cells and intracellular cytokine production, differentiating her from the rest of the cohort.

DIFFERENTIAL DIAGNOSIS

The primary differential diagnosis for hVOD is environmental alkaloid or sinusoidal cell toxicity. However, hVOD has also been reported in association with alcoholic cirrhosis (Kishi et al., 1999), ataxia-telangiectasia (Srisirirojanakorn et al., 1999), osteopetrosis (Corbacioglu et al., 2006), and hypereosinophilic syndrome. hVOD associated with severe combined immunodeficiency (SCID) has been described (Washington et al., 1993) and was observed in a postmortem HIV cohort (Buckley and Hutchins, 1995). The lack of a strong association between immunodeficiencies and hVOD suggests that hVOD is a primary and specific feature of VODI.

MANAGEMENT

EVALUATIONS AT INITIAL DIAGNOSIS

Full blood count and biochemical assessment of hepatic function should be undertaken. A clinical assessment for portal hypertension, a coagulation profile, and a hepatic Doppler ultrasound examination are extremely helpful for identifying the presence of intrahepatic venous obstruction and should be undertaken prior to consideration of hepatic biopsy for the histological diagnosis of hVOD. Evidence of impaired clotting (if unable to be corrected) and/or significant portal hypertension are contraindications to hepatic biopsy.

The initial immune evaluation should include serum immunoglobulin levels, T- and B-cell numbers and percentages, and T-cell proliferative response to mitogen. Extensive immune testing for memory B- and T-cell numbers and intracellular cytokine responses to phorbol ester stimulation may be of interest. *SP110* molecular genetic testing should be done to confirm the clinical diagnosis and to assist with the genetic counseling process. Sequencing of the 19 *SP110* coding exons should be performed if no mutations are identified in exons 2, 4, and 5.

TREATMENT OF SYMPTOMS

IVIg administration and cotrimoxazole prophylaxis for PCP should commence at diagnosis, or in presymptomatic siblings after the confirmation of homozygous *SP110* mutations. Specific infections should be treated appropriately. Some evidence suggests that early treatment may reduce the risk of hVOD. It is unknown whether hVOD resolution and/or prevention with IVIg is due to an immunomodulatory role of IVIg or results from a decrease of infections.

SURVEILLANCE

Surveillance of hepatic function, platelet count, and hemoglobin in children with VODI should be undertaken on a regular basis as hepatic failure and portal hypertension may occur. In addition, routine monitoring of complete blood count and renal and hepatic function and periodic assessment of trough IgG levels are recommended. Pulmonary function testing may be indicated to monitor for the sequelae of significant lower respiratory tract infection. Continuing awareness and appropriate tests for the investigation of possible infection are essential, as in other patients with a significant combined immunodeficiency.

Agents known to predispose to hVOD such as cyclophosphamide and senecio alkaloids/bush teas should be avoided in VODI. hVOD has been reported in the Australian cohort of

VODI patients following HSCT, so individuals with VODI were thought to have, at very minimum, the population risk of hVOD after HSCT, suggesting that this form of transplantation was contraindicated. Recently however, HSCT has been reported as a successful therapy for VODI in 3 out of 5 children with a specific mutation in *SP110* confirming that modified conditioning regimes pre-transplantation increase the chance of a successful outcome (Ganaiem et al., 2013). Hepatic transplantation may also have an increased risk of complications. One child with VODI (DII.1) is known to have developed hemophagocytic syndrome after hepatic transplantation. The safety of hepatic transplantation in VODI is not clear as it appears to have a high rate of complications in the VODI cohort studied to date.

GENETIC COUNSELING

VODI is inherited in an autosomal recessive manner, and parents of an affected child are asymptomatic obligate heterozygotes. The recurrence risk for siblings of an affected child is 25%. Carrier testing for at-risk relatives and prenatal (or preimplantation) genetic diagnosis for pregnancies at increased risk after genetic counseling are possible if both disease-causing mutations in a family are identified. Molecular genetic testing of siblings of a proband who are younger than age 12 months to allow early diagnosis and treatment should be discussed with the family. VODI immunodeficiency penetrance has been 100% in individuals with mutations in *SP110*, although it is possible that this risk is inflated due to ascertainment bias. Similarly, hVOD has been described in all probands or their affected siblings.

SP110 AND MOLECULAR GENETICS

The Sp110 nuclear body protein is a member of the Sp100/Sp140 PML NB protein family. The PML NB is a nuclear macromolecular complex deployed to areas of active host/viral DNA replication, transcription, and repair and has been reported to be involved in apoptosis, cell-cycle control, and the immune response (Hofmann and Will, 2003; Kiesslich et al., 2002; Muratani et al., 2002; Negorev and Maul, 2001; Rivera et al., 2003). Sp110 contains a Sp100 domain involved in dimerization with other Sp100 family proteins (amino acids [a.a.] 6–159), a nuclear localization signal (a.a. 288–306), and a nuclear hormone interaction domain (LXXLL type), which may act as an all-trans retinoic acid (ATRA) response element. Other domains facilitating chromatin-mediated gene transcription include a SAND domain (a.a. 452–532), a plant homeobox domain (a.a. 537–577), and a bromodomain (a.a. 606–674) (Bloch et al., 2000). Epstein-Barr virus (EBV)-transformed B cells from an individual with VODI have shown an absence of nuclear Sp110 expression but with maintenance of normal numbers of PML NBs, consistent with *SP110* having a role in the immune response without being essential for PML NB assembly (Roscioli et al., 2006).

Further evidence for the involvement of the PML NB and Sp100 in the immune response include their induction by IFN-γ (Chelbi-Alix et al., 1995; Guldner et al., 1992; Lavau et al., 1995; Stadler et al., 1995), inactivation by HSV-1 (Chelbi-Alix and de The, 1999; Negorev and Maul, 2001), the disruption of PML-NBs by the CMV early proteins IE1 and 2 (Rio et al., 1994), the EBV immediate-early protein BZLF1 (Adamson and Kenney, 2001), and a possible PML anti-Ebola virus and anti-rabies virus effect (Bjorndal et al., 2003; Blondel et al., 2002). The hepatitis C virus (HCV) core protein has been shown to interact with the Sp110b HCV core binding domain (a.a. 389–453), causing its inactivation and sequestration from the nucleus, resulting in ATRA-induced cell death (Watashi et al., 2003). These studies and the VODI phenotype are consistent with an *SP110* role in infectious disease resistance.

SP110 is expressed primarily in leukocytes and the spleen; it is induced by IFN-γ and ATRA. Expression microarray experiments have demonstrated altered levels of proteins affecting late B-cell differentiation pathways including decreased CD27 expression, down-regulation of the TNFR superfamily and SLAM pathways (SLAMF3/CD229 and SLAMF5/CD84) consistent with of the failure of production of memory B cells (Cliffe et al., 2012). The Sp110 nuclear body protein has three major isoforms: (1) NM_004509 (78.438 kd; lacking exon 17); (2) NM_004510 (61.940 kd; includes an alternate exon 15 and terminates within exon 15); and (3) NM_080424 (81.211 kd; includes exon 17 and terminating at exon 19). The Sp110b protein isoform has been described as showing activity as a potent transcriptional co-repressor of retinoic acid receptor alpha (RARα), perhaps via competitive exclusion of activators at receptor (Watashi et al., 2003).

PATHOLOGICAL ALLELIC VARIANTS

All reported mutations cluster within the first part of the gene (exons 2, 4, and 5), and so are predicted to affect all isoforms of the Sp110 mRNA. The majority of pathogenic mutations cause a frameshift with consequent protein truncation. The one exception to date is the c.78_79CA>AT mutation. This dinucleotide substitution mutation includes the silent third base of codon 26 (GCC>GCA, both of which encode Alanine) and the adjacent first base of codon 27 (ATA>TTA Isoleucine to Leucine). This predicted substitution is relatively conservative and ordinarily well tolerated by proteins; however, in this instance, the mutation is located within the highly conserved Sp140-Sp110 dimerization domain. A multispecies alignment of the protein sequence in this region shows that Isoleucine27 is almost absolutely conserved, suggesting that this residue may have a significant functional role in protein–protein interactions and may mediate the Sp140-related recruitment of Sp110 into the nuclear body. The dinucleotide deletion/insertion mutation has been shown to produce profound effects on Sp110 protein stability (Cliffe et al., 2012). The key pathogenic event in the development of VODI in all cases reported to date therefore appears to be of the lack of fully functional Sp110 protein.

OTHER *SP110* VARIANTS

No other Mendelian disorders for *SP110* or contiguous gene deletion disorders including the *SP110* region have been described. Tosh et al (2006) reported transmission disequilibrium for alleles of *SP110* in *Mycobacterium tuberculosis* infection in individuals of West African heritage. However, a replication study in a similar population did not identify the same association (Thye et al., 2006). A well-designed study by Szeszko et al. (2007) failed to detect a significant association between alleles of *SP110* and *M. tuberculosis* infection in Russian Caucasians. It is notable that the three studies cited compare Mantoux-positive and Mantoux-negative individuals rather than disease progression in individuals known to be exposed to *M. tuberculosis*.

Previous case-controlled studies using single-nucleotide polymorphisms (SNPs) have also reported associations between HSCT-induced hVOD and SNPs in the carbamyl phosphate synthetase 1 (*CPS1*), factor V Leiden (*FVL*), *HFE*, and glutathione S-transferase genes (*GSTM1* and *GSTT1*), with relative risks of 8.6 for the homozygous HFE C282Y allele and 4.12 for the *GSTM1* null allele (Kallianpur, 2005; Kallianpur et al., 2005; Srivastava et al., 2004). No independent replication of these findings has been performed. There has been no report of *SP110* mutations in individuals described to have hVOD alone.

SUMMARY

VODI is due to mutations in the *SP110* gene and is the first immunodeficiency to be associated with the PML NB. Although rare globally, it shows higher frequencies in some population isolates and has been reported in populations with Mediterranean ancestral admixture both in Europe and North America as well as Hispanic populations. The clinical pattern and lack of genetic heterogeneity thus far make VODI an important and specific differential diagnosis for immunodeficiency syndromes.

WHIM SYNDROME

George A. Diaz

CLINICAL FEATURES

The term "WHIM syndrome" was coined to describe a rare combined immunodeficiency disease characterized by the clinical features of *W*arts, *H*ypogammaglobulinemia, *I*mmunodeficiency, and *M*yelokathexis (Wetzler et al., 1990; Fig. 40.1). The latter manifestation is a form of peripheral neutropenia in the face of hypercellularity of mature neutrophils in the bone marrow (Zuelzer, 1964). The features described by Wetzler et al. in two sisters and, by history, in their deceased father included noncyclical neutropenia with transient elevation of neutrophil counts during infectious episodes, recurrent bacterial infections (otitis media, pneumonia, cellulitis, urinary tract infection), and extensive dermal and/or cervical warts with no specific human papillomaviral isotype susceptibility. Immunological investigation revealed depression of all immunoglobulin subtypes and profound lymphopenia, particularly of B cells. As additional cases have been ascertained, it has become apparent that the clinical expression of the disorder can be quite variable. The spectrum of disease manifestations, genetics, and disease pathophysiology will be reviewed in the following sections.

HEMATOLOGIC FEATURES

Neutropenia is marked in WHIM syndrome, with absolute neutrophil counts generally significantly below 1,000/mm^3. In contrast to neutropenic states caused by mutations in the *CSF3R* (Dong et al., 1994), *ELANE* (Dale et al., 2000; Horwitz et al., 1999), or *WAS* (Devriendt et al., 2001) genes, in which normal development of the myeloid lineage is arrested, neutrophil maturation is not defective in WHIM syndrome. Indeed, bone marrow samples are remarkable for hypercellularity of mature myeloid cells, but these often display morphological changes suggestive of apoptosis (nuclear hypersegmentation, pyknosis, cytoplasmic vacuolation). Vacuolation of eosinophils has also been described in a subset of cases (Gorlin et al., 2000; Latger-Cannard et al., 2006). Other less frequently reported quantitative abnormalities including deficits in peripheral blood monocytes (Balabanian et al., 2005; Siedlar et al., 2008) and increased natural kille (NK) cell counts (Wetzler et al., 1990) in a subset of patients.

An important diagnostic feature of the neutropenia of WHIM syndrome is the capacity of patients to transiently elevate their peripheral neutrophil counts in the setting of infection. These mobilized neutrophils appear to be functionally normal as assessed by tests of neutrophil migration, opsonization, and phagocytosis; functional deficits have been observed in patients manifesting isolated myelokathexis (Plebani et al., 1988; Weston et al., 1991). Myelokathexis is a genetically heterogeneous condition (see below), so these cases are not likely to represent *bone fide* WHIM cases. In addition to infection, neutrophil mobilization can also be triggered by epinephrine, glucocorticoids, and challenge with tetanus toxoid (Hord et al., 1997; Mentzer et al., 1977). The cytokines granulocyte- and granulocyte/monocyte-colony stimulating factor (G-, GM-CSF) have been used therapeutically to elevate neutrophil counts in individuals affected with isolated myelokathexis or WHIM syndrome (Bohinjec and Andoljsek, 1992; Cernelc et al., 2000; Hess et al., 1992; Weston et al., 1991; Wetzler et al., 1992).

In contrast to the myeloid hyperplasia, lymphocyte abundance is normal in bone marrow samples from WHIM syndrome patients. However, peripheral lymphopenia is a fairly consistent disease feature (Arai et al., 2000; Goddard et al., 1994; Gorlin et al., 2000; Hess et al., 1992). In particular, profound B lymphopenia is uniformly present, while

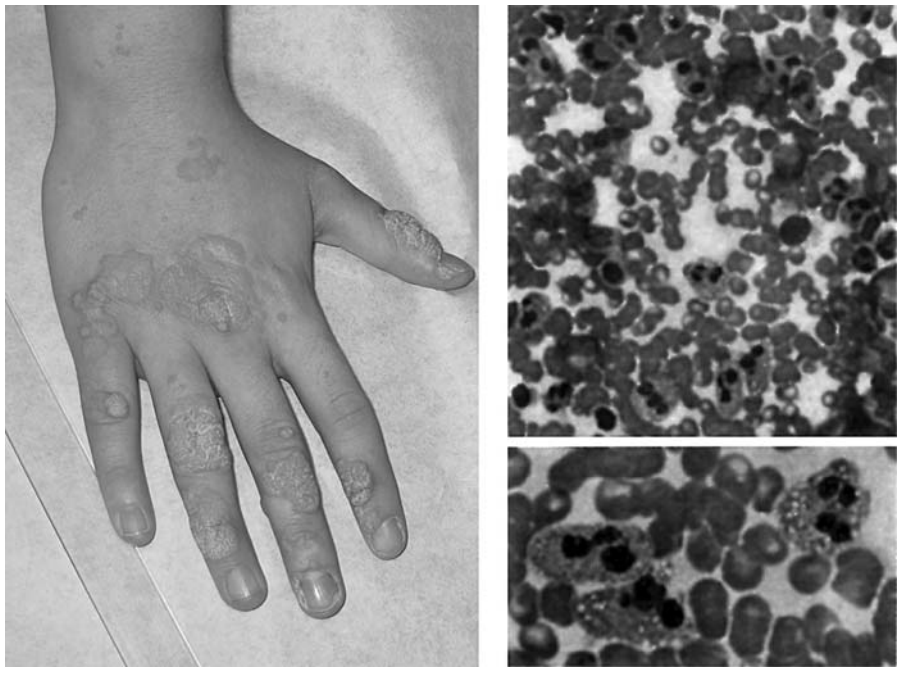

Figure 40.1 *Characteristic findings in WHIM syndrome.* The left panel shows an example of extensive and treatment-refractory HPV verrucosis on the hand of a young patient. The panels at right show the characteristic myeloid hyperplasia (*top*) and bizarre, hypersegmented nuclei and cytoplasmic vacuolation in a bone marrow aspirate sample from the original description characterizing the syndrome. (Panels at right adapted from Wetzler et al, 1990.) (See Color Plate).

T lymphopenia is present in some cases (Arai et al., 2000; Gorlin et al., 2000; Hess et al., 1992) but absent in others (Hord et al., 1997; Mentzer et al., 1977; Wetzler et al., 1990). Even when T lymphopenia is present, the CD4/CD8 ratio is generally been normal (Goddard et al., 1994; Taniuchi et al., 1999; Wetzler et al., 1990).

IMMUNOLOGICAL FEATURES

Even though hypogammaglobulinemia is included in the acronym defining the syndrome, this feature is relatively variable. Although immunoglobulin deficiencies have been reported in most cases in which levels were assessed, serial measurements have documented variation ranging from moderate deficiency to essentially normal levels (Arai et al., 2000; Christ and Dillon, 1997; Gorlin et al., 2000; Imashuku et al., 2002; Mentzer et al., 1977). Isolated IgG deficiency is most frequent, but additional deficiencies of IgM (Hord et al., 1997) or IgA and IgM (Wetzler et al., 1990) have been reported.

To date, little has been published about the effects of the disease on lymphoid organs. An inguinal lymph node biopsy performed after ipsilateral challenge with diphtheria–tetanus toxoid vaccine in a father and daughter with the full WHIM phenotype showed absent or hypoplastic lymphoid follicles and diminished numbers of plasma cells (Mentzer et al., 1977), although the genetic basis of the disease in this family has not been confirmed. Abdominal ultrasonography has demonstrated mild splenomegaly in several patients (Siedlar et al., 2008; Wetzler et al., 1990), but no histological data have been published to provide insight into the nature of the disease manifestations at the level of lymphoid organ organization. Of note, specific deficits in switched memory B cells ($CD27^+$, IgD^-) has been described in WHIM patients, consistent with disturbed B-cell maturation (Gulino et al., 2004).

Less information is available with regard to T-cell function, but abnormalities have been described in a number of patients. Tests of cell-mediated immune function by intradermal antigen challenge have been normal in most patients in which results were reported (Arai et al., 2000; Hord et al., 1997; Mentzer et al., 1977) but were impaired in some (Mentzer et al., 1977; Wetzler et al., 1990). In the same patients with a paucity of switched memory B cells, an increase was found in the number of memory effector T cells, particularly $CD8^+$ cells, but this increase was found to be associated with oligoclonal expansion of T-cell populations (Gulino et al., 2004).

DISEASE COMPLICATIONS

Although the neutropenia and lymphopenia present in most WHIM patients can be profound, the infectious complications of the disease can be relatively mild, as the reactive leukocytosis permits a good response to antibiotic therapy and resolution of infection. A significant proportion of reported cases have not been diagnosed until adulthood, and only a single case of mortality secondary to infection has been reported (Wetzler et al., 1992). However, most patients report recurrent bacterial infections from early childhood ranging from recurrent otitis media, sinusitis, and urinary tract infection at the mild end of the spectrum to pneumonia, thrombophlebitis, omphalitis, osteomyelitis, cellulitis, and abscesses at

the more severe end. Susceptibility to bacterial pathogens is not restricted, and infections have been reported with *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, and *Proteus mirabilis* species. Recurrent pneumonias may in some cases lead to severe bronchiectasis.

Despite some degree of T-cell lymphopenia or dysfunction in most WHIM patients, immunity to viral pathogens is generally robust. Live viral vaccines are well tolerated with no reported adverse outcomes, and even anergic individuals with low T-cell counts are not susceptible to opportunistic viral infections. The principal exception is a susceptibility to human papillomavirus (HPV). Onset of HPV infections can be from infancy to adolescence, with manifestations ranging from relatively few and scattered warts to extensive cutaneous and genital papillomatosis (Gorlin et al., 2000). Condyloma acuminata in affected females can be severe enough to require laser ablation and vulvectomy secondary to dysplastic changes (Wetzler et al., 1990). Of note, disseminated verrucosis is generally persistent and refractory to treatment with ablation or immunomodulatory therapies but can spontaneously resolve for prolonged periods (Hagan and Nguyen, 2007; Tarzi et al., 2005). A second family of viral pathogens that may cause more severe disease in WHIM patients are the herpesviruses, as several reports have documented severe recurrent herpes infections (Aprikyan et al., 2000; Balabanian et al., 2005; Goddard et al., 1994; Imashuku et al., 2002; Tarzi et al., 2005).

With the description of more cases, it has become apparent that viral-associated neoplastic disease represents a major clinical problem for WHIM patients. Three cases of early-onset B-cell lymphoma following Epstein-Barr virus (EBV) infection have been reported. In one report, an excellent response to chemotherapy was obtained (Chae et al., 2001), but the outcome was fatal in the two other cases (Imashuku et al., 2002; Tassone et al., 2009). In addition to EBV-associated cancer, mortality secondary to an HPV-associated vulval cancer has also been reported (Vinurel et al., 2008). Non–EBV-associated cancers described in WHIM patients include a fatal brain tumor (Montelibano et al., 2007) and a case of Kaposi sarcoma (Diaz, 2005). This latter tumor is associated with human herpesvirus 8, further reinforcing the suggestion that WHIM patients may have an additional susceptibility to herpesviruses.

Apart from infectious and neoplastic sequelae, other disease associations in WHIM syndrome include complex congenital heart disease in 2 patients out of approximately 50 reported, a significantly higher incidence than expected (Gulino et al., 2004; Taniuchi et al., 1999), and hypothyroidism and insulin-dependent diabetes in one patient (Takaya et al., 2009). Idiopathic mental retardation was described in another patient (Tassone et al., 2009). As discussed below, the mutant gene in these cases, *CXCR4*, plays an important role in the biology of cardiovascular and brain patterning and in normal immune function, raising the possibility that these developmental and autoimmune phenomena are a manifestation of abnormal CXCR4 receptor signaling.

Table 40.1 lists the clinical characteristics of a collection of WHIM syndrome patients with confirmed *CXCR4* mutations.

GENETIC STUDIES

By using familial WHIM cases with apparently dominant inheritance for genetic studies, the disease locus was linkage mapped to chromosome 2q21 and mutations were detected in the chemokine receptor gene *CXCR4*, thus identifying the molecular basis of the disease (Hernandez et al., 2003). *CXCR4* encodes a 352-amino acid G-protein–coupled receptor that binds to the chemokine CXCL12. The disease-associated mutations cluster very tightly at the terminus of the CXCR4 cytoplasmic tail domain. All mutations described to date are either nonsense or small deletions that truncate or frameshift the receptor at a point between 19 and 10 residues from the normally encoded stop codon, with one mutation generating a nonsense peptide that extends beyond the in-frame termination codon (Fig. 40.2). Recurrence has been documented for three mutations, R334X, S338X, and S339fs342X, with the former representing the preponderance of novel occurrences (11/21 unique families or individuals). The clinical features in the patients with the minimal 10-residue truncation, R343X (Hernandez et al., 2003; Hord et al., 1997), were not markedly different than those seen in patients with the more extensive 19-residue E334X truncation (Gorlin et al., 2000; Wetzler et al., 1990), suggesting that there is no strong genotype–phenotype correlation based on the extent of the truncation.

The clinical variability observed in WHIM syndrome, particularly within families known to carry mutant alleles, likely reflects the effects of modifier genes, but genetic heterogeneity may also contribute to the broad phenotypic spectrum. *CXCR4* mutations were excluded in a pedigree in which myelokathexis was inherited as an apparent autosomal recessive trait that was not associated with hypogammaglobulinemia or warts (Bohinjec, 1981; Hernandez et al., 2003). The existence of WHIM patients expressing the complete disease spectrum, but in whom *CXCR4* was wild type, confirmed genetic heterogeneity for the disease (Balabanian et al., 2005). Deficient transcriptional expression of the G-protein–coupled receptor kinase *GRK3*, a negative regulator of CXCR4 signaling, was demonstrated in one of these patients, representing the first non-*CXCR4*-mediated case of WHIM syndrome to be characterized at a molecular level (Balabanian et al., 2008). Mutations in additional genes involved in *CXCR4* signaling are likely be identified in other phenocopy cases in the future.

Table 40.2 lists the frequency of different genetic etiologies causing WHIM syndrome.

CXCR4 FUNCTION AND DISEASE PATHOPHYSIOLOGY

CXCR4 is a chemokine receptor that is important in hematopoietic and extrahematopoietic development and has a well-studied role as a co-receptor for HIV-1 (Feng et al., 1996). Like all chemokine receptors, CXCR4 has a conserved heptahelical transmembrane structure typical of G-protein–coupled receptors (GPCR) and mediates signal transduction via multiple pathways. In contrast to chemokines secreted in response to infection/inflammation, CXCR4 is considered a homeostatic chemokine that is expressed constitutively

in specific lymphoid compartments (Moser and Loetscher, 2001). The receptor has a single known cognate ligand, CXCL12 (formerly SDF-1). Both CXCR4 and CXCL12 are expressed widely in hematopoietic and nonhematopoietic tissues, including heart, vascular endothelium, and brain. Consistent with this expression pattern, homozygous null *Cxcr4-/-* mice displayed embryonic lethality with cardiac, cerebellar, and vascular malformations and deficits in neutrophil and B-cell production (Ma et al., 1998; Tachibana et al., 1998; Zou et al., 1998).

CXCR4 SIGNALING

CXCR4-mediated signaling involves several different pathways. These include the canonical Ga_i-coupled G-protein

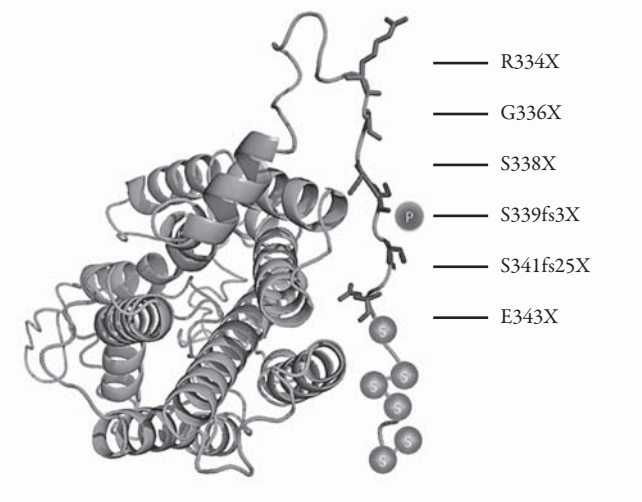

Figure 40.2 *Distribution of mutations in the cytoplasmic tail of CXCR4.* A model of CXCR4 is shown from the cytoplasmic face of the receptor parallel to the transmembrane helices in green. Helix 8, which runs parallel to the plasma membrane, is shown in orange. The positions of residues that are mutated to termination codons (red) or frameshifted to introduce missense peptides (blue) are indicated at right. A serine residue (S339) demonstrated to be phosphorylated by receptor activation (Woerner et al., 2005) is indicated by the purple sphere. Distal serines are indicated by green spheres. (See Color Plate.)

signaling (Bleul et al., 1998), signaling through phosphoinositide-3 kinase (PI-3K) isoforms (Ganju et al., 1998), and signaling through phospholipase C isoforms (Guinamard et al., 1999; Haribabu et al., 1997; Roes et al., 2003). CXCR4 dimerization following activation can also trigger the JAK2/JAK3/STAT signaling pathway (Vila-Coro et al., 1999). These upstream signaling mediators activate a cascade of downstream effectors, including ERK1/2 (Ganju et al., 1998) and Akt (Sotsios et al., 1999). Activation of these pathways ultimately drives the chemotactic response or results in transcriptional changes associated with differentiation or survival (summarized in Fig. 40.3) in a cell-specific fashion.

Following receptor activation, downregulation of CXCR4 signaling occurs via serine-threonine phosphorylation of the cytoplasmic tail domain by GPCR kinases and β-arrestin–mediated internalization characteristic of GPCR desensitization (Luttrell and Lefkowitz, 2002). The specific GPCR kinase involved in regulating CXCR4 was initially speculated to be GRK6 based on the neutrophil phenotype in null mice. Bone marrow neutrophils from these animals showed enhanced CXCL12-induced chemotaxis and impaired desensitization of the calcium response in vitro (Vroon et al., 2004). However, GRK3 appears to be more relevant in humans as it is specifically induced by a cytokine (GM-CSF) that downregulates CXCR4 (Wang et al., 2001) and has been shown to be transcriptionally deficient in WHIM syndrome (Balabanian et al., 2008).

The role of the CXCR4 cytoplasmic tail in receptor downregulation and internalization has been extensively characterized by the generation of a series of truncation mutants. Complete or partial truncation of the 47-residue tail domain enhances calcium signaling and abolishes receptor desensitization in response to CXCL12 (Amara et al., 1997; Haribabu et al., 1997). CXCR4 mutants lacking the cytoplasmic tail are refractory to β-arrestin–mediated regulation of G-protein signaling, although regulation can be recovered by the overexpression of β-arrestin 2, potentially via β-arrestin–receptor interactions at an internal receptor loop (Orsini et al., 1999). These defects in signaling desensitization were paralleled by complete or partial impairment of receptor internalization (Amara et al., 1997; Haribabu et al., 1997; Signoret et al., 1997). Mutants with more limited deletions of 23 or 12 residues had intermediate effects, suggesting that multiple residues along the tail domain contributed to internalization efficiency (Signoret et al., 1997). Serine-to-alanine point mutants in the tail domain also impaired ligand-mediated chemotaxis to variable degrees but did not completely abolish internalization (Orsini et al., 1999). The dileucine motif has been identified as an ubiquitinylation site, establishing trafficking to the proteasome as a mechanism for modulation of CXCR4 signaling (Fernandis et al., 2002; Marchese and Benovic, 2001).

CXCR4 internalization can also be regulated in a ligand-independent fashion. Heterologous desensitization occurs in response to phorbol esters (Haribabu et al., 1997; Signoret et al., 1997), cytokines (Nagase et al., 2002; Wang et al., 2001) (G/GM-CSF, IFN-α/γ, IL-4/13), and other chemokines such as CXCL8 (Richardson et al., 2003). Heterologous desensitization of CXCR4 can also occur in the absence of receptor internalization, as described for the cytokines IL-10 (Balabanian et al., 2002) and IL-16 (Van Drenth et al., 2000). This mechanism represents a potential mechanism for modulation of signaling inputs in a cytokine-rich environment such as the lymph node.

CXCR4 FUNCTION IN HEMATOPOIETIC LINEAGES

In mice lacking CXCR4 or CXCL12, fetal liver progenitor cells failed to home to the bone marrow (Ma et al., 1998; Nagasawa et al., 1996a; Zou et al., 1998), highlighting the critical importance of this receptor/ligand pair in driving localization of neutrophils to the appropriate developmental niche. This phenotype was also observed in irradiated mice reconstituted with donor cells derived from *Cxcr4*$^{-/-}$ fetal liver, with diminished numbers of bone marrow neutrophils and elevated numbers of immature neutrophils in the peripheral blood (Ma et al., 1999). In the postnatal period, CXCR4 continues to play a critical role in neutrophil mobilization from and back to the bone marrow (Levesque et al., 2003; Suratt et al., 2004). Ex vivo human peripheral neutrophils express low levels of cell-surface CXCR4, but the concentration of receptors on the cell surface increases after a short period of culture, a process that can be regulated by various cytokines (Nagase et al., 2002). Studies of murine neutrophils suggest that CXCR4 cell-surface expression is downregulated as neutrophils mature, thus suppressing CXCR4/CXCL12 signaling and permitting mobilization from the bone marrow, then upregulated in the periphery to facilitate the homing

of senescent neutrophils to the bone marrow (Martin et al., 2003).

CXCR4 also plays a critical role in B-cell development and trafficking. Mature B cells are absent from *Cxcr4*-null (Ma et al., 1998; Tachibana et al., 1998; Zou et al., 1998) and *Cxcl12*-null (Nagasawa et al., 1996b) mouse embryos. CXCL12/CXCR4 signaling is critical for B-cell development from the earliest stages of differentiation along this lineage (Egawa et al., 2001). As in neutrophils, chemotaxis and calcium signaling undergo a differentiation-dependent downregulation, with response to ligand diminishing in maturing B cells despite continued robust cell-surface receptor expression (Fedyk et al., 1999; Honczarenko et al., 1999; Wehrli et al., 2001).

Following maturation in the bone marrow, B lymphocytes circulate between blood, lymphoid (lymph node, spleen, Peyer's patches), and extralymphoid compartments in a chemokine-directed fashion (Kim and Broxmeyer, 1999). Normal recirculation involves the reacquisition of CXCL12 responsiveness in order to allow the proper trafficking of B cells into and within lymphoid organs. Access to the lymphoid compartment involves transendothelial migration across specialized postcapillary high endothelial venules by a well-coordinated series of adhesive interactions involving L-selectin–mediated rolling and chemokine-mediated firm adhesion (Moser and Loetscher, 2001). CCR7 plays a primary role in this process, but CXCR4 serves an important, though redundant, role (Okada et al., 2002). Of note, L-selectin signaling in lymphocytes induces the cell-surface mobilization of internalized stores of CXCR4, potentiating CXCL12-mediated transmigration across high endothelial venules (Ding et al., 2003).

After migration into lymph node germinal centers and antigen-driven maturation, differentiated memory B cells and

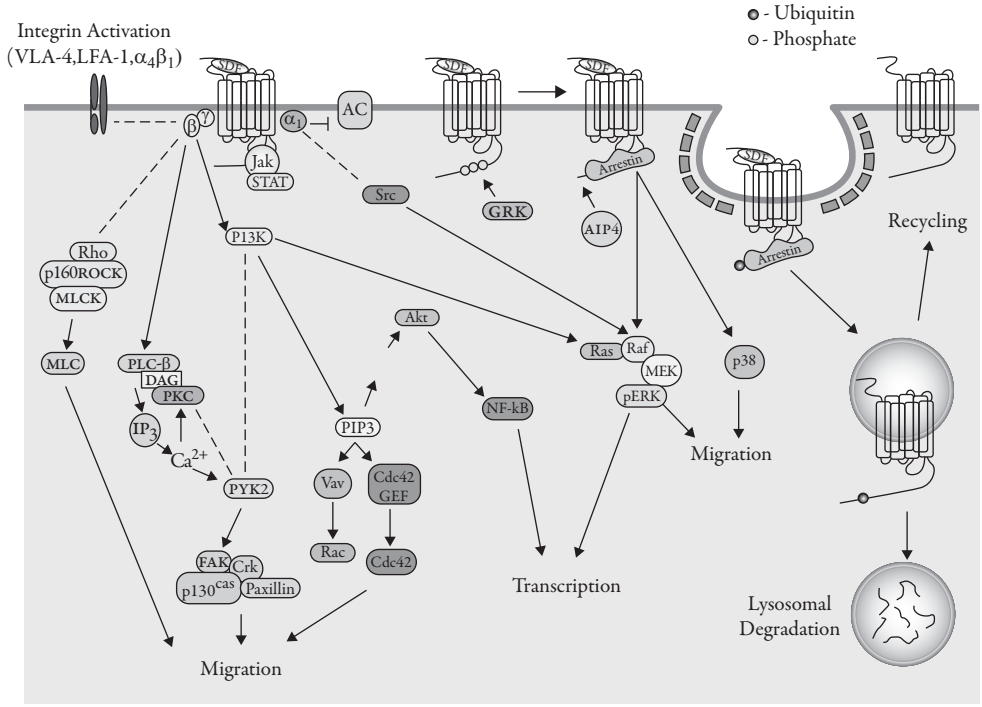

Figure 40.3 *Overview of CXCR4 signaling pathways.* Cartoon of the various signal transduction pathways that have been reported to be activated following receptor ligation with CXCL12. Downregulation by β-arrestin/CXCR4 interaction results in endocytosis of the receptor and intracellular trafficking resulting in recycling to the cell surface or degradation. (Adapted from a review by Busillo and Benovic, 2007.) (See Color Plate).

plasmablasts migrate to medullary cords, exit via the efferent lymph, and ultimately home to bone marrow, epithelia, or inflammatory sites. During the course of maturation, germinal-center B cells become unresponsive to CXCL12 (Bleul et al., 1998; Vicente-Manzanares et al., 1998). Loss of chemotactic responsiveness has been proposed to be important for the regulated migration of plasmablasts from lymph nodes (Wehrli et al., 2001). Mature, antibody-secreting plasma cells regain chemotactic responsiveness to CXCL12 (Hargreaves et al., 2001; Nakayama et al., 2003) and lodge in tissues (splenic red pulp, lymph node medullary cords, bone marrow) that express high levels of CXCL12.

DISEASE PATHOPHYSIOLOGY

Given the narrow spectrum of *CXCR4* mutations identified to date in WHIM syndrome, an attractive model to explain the disease pathophysiology focused on the role of the carboxyl terminal tail domain in receptor downregulation. As anticipated, based on studies of CXCR4 truncations characterized in vitro, disease-associated mutations enhanced intracellular release calcium, actin polymerization, and chemotaxis (Balabanian et al., 2005; Gulino et al., 2004; Hernandez et al., 2003). A receptor internalization defect has been demonstrated in both transfected cell systems and patient-derived cells, confirming the relevance of this mechanism to disease pathogenesis (Balabanian et al., 2005; Gulino et al., 2004; Tassone et al., 2009). This conclusion is supported by the observation that CXCR4 transduced into cultured dermal fibroblasts derived from WHIM syndrome patients lacking *CXCR4* mutations failed to internalize following stimulation, an observation subsequently explained by deficient *GRK3* expression (Balabanian et al., 2005, 2008). The mechanism of this internalization defect has been explored further and the enhanced signaling has been suggested to also involve prolonged β-arrestin 2-dependent signaling (Lagane et al., 2008).

Based on the current evidence, a plausible model explaining the pathophysiology of myelokathexis can be constructed. Recent models proposed to describe the regulation of neutrophil mobilization from the bone marrow stroma suggest that the reciprocally regulated activities of CXCR4 and CXCR2 are the major determinants in trafficking from and to the bone marrow (Martin et al., 2003; Suratt et al., 2004). The data on the effects of the truncating mutations found in WHIM syndrome neutrophils suggest that mutant cells respond inappropriately to stromal CXCL12 with respect to chemotactic response and potentially to adhesiveness (Gulino et al., 2004). The inhibitory effect of CXCR4 signaling on CXCR2 would render the mutant neutrophils unable to respond as robustly to CXCR2 ligands as necessary to drive trafficking out of the bone marrow compartment, effectively sequestering them. Inflammatory mediators such as cytokines or other chemokines that inhibit CXCR4 activity through heterologous desensitization would alleviate this inhibition of CXCR2, allowing egress of mature neutrophils (Fig. 40.4). It is also possible that the signaling abnormalities caused by the mutant receptor also have an effect on neutrophil apoptosis. Accelerated apoptosis compared to control samples has been observed in peripheral and bone marrow neutrophils (Aprikyan et al., 2000; Taniuchi et al., 1999), consistent with such a mechanism. Nonetheless,

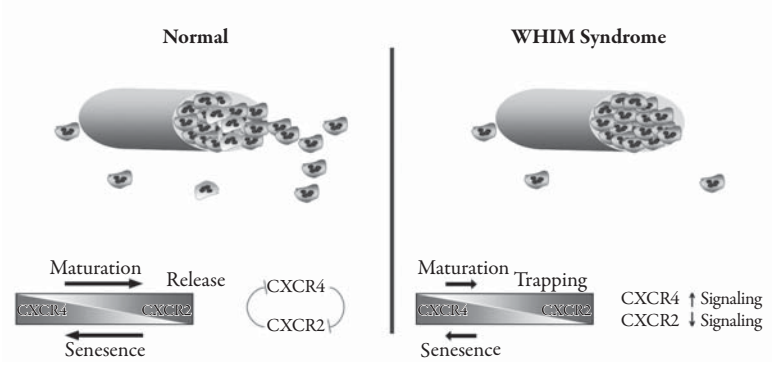

Figure 40.4 *Model for the mechanism leading to the myelokathexis phenotype in WHIM syndrome.* The downregulation of CXCR4 and upregulation of CXCR2 during normal neutrophil maturation is shown at left with the counterregulatory relationship of CXCR4 and CXCR2 diagrammed. In WHIM syndrome, the overactivity of the mutant CXCR4 receptor predominates in the CXCR2/CXCR4 axis, effectively keeping mutant neutrophils sequestered in the bone marrow unless a significant cytokine release, as in the setting of infection, causes heterologous desensitization of CXCR4 and permits CXCR2 signaling to drive chemotaxis to the periphery. (Adapted from Diaz and Gulino, 2005.) (See Color Plate).

the preponderance of evidence currently suggests that the trafficking defect is the principal mechanism explaining the myelokathexis of WHIM syndrome.

The disease pathophysiology for the immunological and HPV-associated aspects of the disorder is less clear. Lymphocytes are not sequestered in the bone marrow of WHIM patients, and while there have been no descriptions of morphological changes suggestive of apoptosis, it is not apparent whether the observed lymphopenia is due to trapping in an as-yet-uncharacterized compartment or due to premature apoptosis. The susceptibility of WHIM syndrome patients to HPV infection is also poorly characterized. Of note, *CXCL12* expression in HPV-infected dermis from WHIM syndrome patients and normal controls was upregulated, raising the possibility that enhanced CXCR4 signaling could represent a host susceptibility factor favorable for HPV persistence (Balabanian et al., 2005).

DIAGNOSIS AND TREATMENT

DIAGNOSIS

Diagnosis of WHIM syndrome in patients with the full spectrum of clinical features is relatively straightforward, but the variability observed in the disorder can lead to overlap with other conditions. Patients with a history of immunodeficiency and warts might be considered for the diagnosis if significant (<1,000/mL) and noncyclical neutropenia can be demonstrated. Features that suggest the presence of myelokathexis and the need for a bone marrow biopsy include reactive leukocytosis with infection and rapid response to granulocyte growth factors within hours. The absence of myelokathexis excludes the diagnosis (Fig. 40.5). A family history consistent with dominant inheritance is suggestive, as is a history of cardiac malformation. The diagnosis is made on clinical grounds if all features are present, but mutation analysis is useful to characterize disease as *CXCR4*wt or *CXCR4*mutant. If only a subset of clinical features is present, the likelihood of detecting a *CXCR4* mutation is significantly lower (Tassone et al., 2009). In patients with confirmed *CXCR4* mutations, neutropenia and lymphopenia, particularly B lymphopenia, appear to be universally present but HPV and hypogammaglobulinemia are quite variable over the lifetime of a patient. A diagnostic algorithm for evaluating potential WHIM syndrome cases is shown in Figure 40.5.

The list of potential phenocopy diseases with hematological and immune deficits similar to those observed in WHIM syndrome (neutropenia, B lymphopenia, variable T-cell dysfunction) is relatively short (Cham et al., 2002): common variable immunodeficiency (CVID), IgA deficiency, reticular dysgenesis, and class-switch recombination defect syndromes. The genetic etiologies have been described for class-switch recombination defects (*CD40* gene, encoding the CD40 protein and *CD40L* gene, encoding CD40 ligand), cartilage-hair hypoplasia (*RMRP*, a structural RNA), and Griscelli syndrome (*MYO5A*, encoding a myosin motor; *RAB27A*, encoding a vesicular transport protein). The spectrum of gene defects that can cause this constellation of hematological findings is diverse, and the pathophysiological basis of the shared hematological phenotype is not readily apparent.

TREATMENT AND PROGNOSIS

To date, treatment regimens described for WHIM syndrome patients have involved the use of neutrophil mobilizing agents (G-CSF or GM-CSF), intravenous immunoglobulin (IVIG), and prophylactic antibiotics individually or in combination. The efficacy of each of these approaches is not possible to assess currently with any confidence. There is a rational basis for employing G-CSF and/or GM-CSF, as the direct stimulation of neutrophil elastase release from myeloid precursors results in cleavage of both CXCR4 and CXCL12, facilitating myeloid-cell release from the bone marrow (Petit et al., 2002; Valenzuela-Fernandez et al., 2002). Both have been used to elevate neutrophil counts in confirmed WHIM syndrome cases (Alapi et al., 2007; Hord et al., 1997; Siedlar et al., 2008; Tassone et al., 2009; Wetzler et al., 1992), but efficacy is not

well established. Similarly, there are available data to suggest that WHIM patients who are having frequent bacterial infections will benefit from treatment with IVIG. Good control of recurrent bacterial infections has been reported with the institution of IVIG therapy (Goddard et al., 1994; Siedlar et al., 2008; Wetzler et al., 1990), but the rarity of the disease has precluded statistically rigorous approaches to testing efficacy. With an understanding of the molecular pathogenesis of the disease, the opportunity exists to capitalize on the development of CXCR4 inhibitor molecules developed for use in the treatment of HIV.

Regardless of which, if any, therapy was employed, the clinical outcomes for most of the patients described to date have been good. However, in light of the growing number of cases in which neoplasia has developed, surveillance for EBV-associated cancers is certainly warranted. Ongoing gynecological surveillance for potential malignant transformation of genital papillomavirus lesions is also essential.

PULMONARY ALVEOLAR PROTEINOSIS

Luigi D. Notarangelo

Pulmonary alveolar proteinosis (PAP) is characterized by accumulation of surfactant in alveolar macrophages, resulting in respiratory insufficiency. Patients with PAP also present with abnormalities of myeloid cells leading to increased susceptibility to infections.

The surfactant is composed of lipids and proteins (surfactant proteins [SP]) and is produced by type II alveolar epithelial cells (AEC-II). Lipids (mostly phospholipids) make up 90 percent of surfactant and form bilayers that reduce surface tension at the air–liquid interface in the alveoli, thus avoiding alveolar collapse. Surfactant also contains hydrophobic proteins (SP-B, SP-C) that contribute to surfactant organization (Weaver and Conkright, 2001), as well as hydrophilic proteins (SP-A, SP-D) with antimicrobial properties (Kingma and Whitsett, 2006). Careful balance of surfactant production, reuptake, recycling, and catabolism by AEC-II and by alveolar macrophages maintains the surfactant pool at relatively stable levels.

Conditions with surfactant metabolism dysfunction in humans include disorders of surfactant production (DSP) and PAP. In the former, the composition of surfactant is affected because of mutations in genes that encode for SP-B, SP-C (Whitsett and Weaver, 2002) or for the ATP-binding cassette subfamily A member 3 (ABCA3) protein, a membrane lipid transporter (Shulenin et al., 2004). As a result of altered composition of surfactant and inability to lower alveolar surface tension, alveolar anatomy is distorted in patients with DSP, leading to respiratory failure. In contrast, surfactant composition is normal and alveolar architecture is largely preserved in patients with PAP, but surfactant accumulates in alveolar macrophages and in alveolar walls, leading to inflammatory changes (Trapnell et al., 2009). A series of observations in humans and mice have shown that defects of granulocyte macrophage-colony stimulating factor (GM-CSF)–mediated signaling play a critical role in the pathophysiology of PAP, regardless of the congenital, autoimmune, or secondary nature of the disorder.

MOLECULAR PATHOPHYSIOLOGY OF PAP

The molecular pathophysiology of PAP was unraveled following the serendipitous discovery that disruption of the *Csf2* gene (encoding for GM-CSF) in mice leads to a lung pathology that is similar to human PAP, with accumulation of foamy alveolar macrophages, periodic acid-Schiff (PAS)–positive material in alveolar walls, and peribronchial lymphocytic infiltrate (Dranoff et al., 1994; Stanley et al., 1994). While the material that accumulates in alveolar macrophages and walls was shown to be surfactant, and its composition to be normal, the accumulation of surfactant was found to be due to reduced clearance by alveolar macrophages; reuptake, recycling, and catabolism by AEC-II are not affected (Dranoff et al., 1994). Similar features were subsequently demonstrated in mice in which the *csf2rb* gene, encoding for the β chain of the GM-CSF receptor (GM-CSFR), had been disrupted (Robb et al., 1995).

Following this discovery, the effect of GM-CSF on the function of alveolar macrophage has been studied extensively. GM-CSF binds to a heterodimeric cell-surface receptor (GM-CSFR) that includes a GM-CSF–binding α chain and a signal-transducing common β chain (β_c) shared by the receptors for interleukin (IL)-3 and IL-5 and known to bind the intracytoplasmic tyrosine kinase JAK2 (Hercus et al., 2009). Upon ligand binding, a dodecahedral complex is formed that consists of four molecules each of GM-CSFRα, β_c, and JAK2 molecules (Hansen et al., 2008). At low GM-CSF

concentrations, signaling through GM-CSFR results in myeloid cell survival and differentiation via activation of NF-κB and induction of bcl-2, whereas higher GM-CSF concentrations induce STAT5 phosphorylation and result in cellular activation and proliferation. This dual effect is mediated by β_c phosphorylation at residues Ser^{585} or Tyr^{577}, respectively (Guthridge et al., 2006). Importantly, the levels of GM-CSF in the lungs regulate expression of the transcription factor PU.1 in alveolar macrophages (Fig. 41.1) and promote adhesion, phagocytosis, expression of various surface receptors (Toll-like receptor [TLR]-2, TLR-4, Fc receptors, α- and β-integrins), secretion of inflammatory cytokines, microbial killing, and catabolism of surfactant (Shibata et al., 2001). These functions were defective in alveolar macrophages obtained from *csf2*$^{-/-}$ mice (Paine et al., 2001; Shibata et al., 2001) but could be rescued by retroviral-mediated expression of PU.1 (Shibata et al., 2001). Furthermore, the PAP pathology observed in *csf2*$^{-/-}$ mice can be rescued by restoring GM-CSF levels in the lungs, but not by its systemic administration (Huffman et al., 1996; Reed et al., 1999), indicating a critical role for pulmonary GM-CSF in alveolar macrophage function and surfactant homeostasis. Moreover, the lung phenotype of *csf2rb*$^{-/-}$ mice can be rescued by transplantation of bone marrow cells from wild-type donors (Nishinakamura et al., 1996) or of β_c-deficient bone marrow cells transduced with a β_c-expressing retroviral vector (Kleff et al., 2008), indicating the critical role of lung macrophages (of hematopoietic origin) rather than AEC-II cells in the pathophysiology of the disease.

GM-CSF–mediated signaling brings together innate and adaptive immune responses. It induces secretion of IL-18 and IL-12 by macrophages. These cytokines stimulate Th1 and NK lymphocytes to produce IFN-γ, thus prompting immune responses against intracellular pathogens (Berclaz et al., 2002). In keeping with this, *csf2*$^{-/-}$ mice are highly susceptible (and show increased mortality) to a variety of pathogens, including *Streptococcus*, *Pseudomonas*, *Listeria*, *Pneumocystis jiroveci*, *M. tuberculosis*, and adenovirus (Ballinger et al., 2006; Carey et al., 2007; Gonzalez-Juarrero et al., 2005; LeVine et al., 1999; Shibata et al., 2001). These infections are not strictly confined to the lungs, indicating that impaired GM-CSF–mediated signaling results in systemic defects of immune responses. Altogether, these data from *csf2*$^{-/-}$ mice clearly indicated that GM-CSF plays a critical role in the regulation of alveolar macrophage differentiation and function and in immune defense. Furthermore, the striking similarities in lung pathology between *csf2*$^{-/-}$ mice and patients with PAP suggested that congenital or acquired abnormalities of GM-CSF–mediated signaling play a role in the pathophysiology of the disease in humans.

PAP: CLASSIFICATION AND MOLECULAR FEATURES

The first case of PAP in humans was reported in 1958 (Rosen et al., 1958), but its pathogenesis remained obscure for several decades until *csf2*$^{-/-}$ mice were generated and characterized. Current classification of human PAP includes autoimmune, congenital, and secondary forms (Trapnell et al., 2009).

In 1999, Kitamura et al. reported neutralizing anti–GM-CSF autoantibodies in the serum of patients with PAP (Kitamura et al., 1999). Autoimmune PAP accounts for 90 percent of all cases of PAP (Inoue et al., 2008), yet its prevalence is low (3 or 4 individuals per million). Usually, clinical manifestations begin in the third or fourth decade of life, and lung

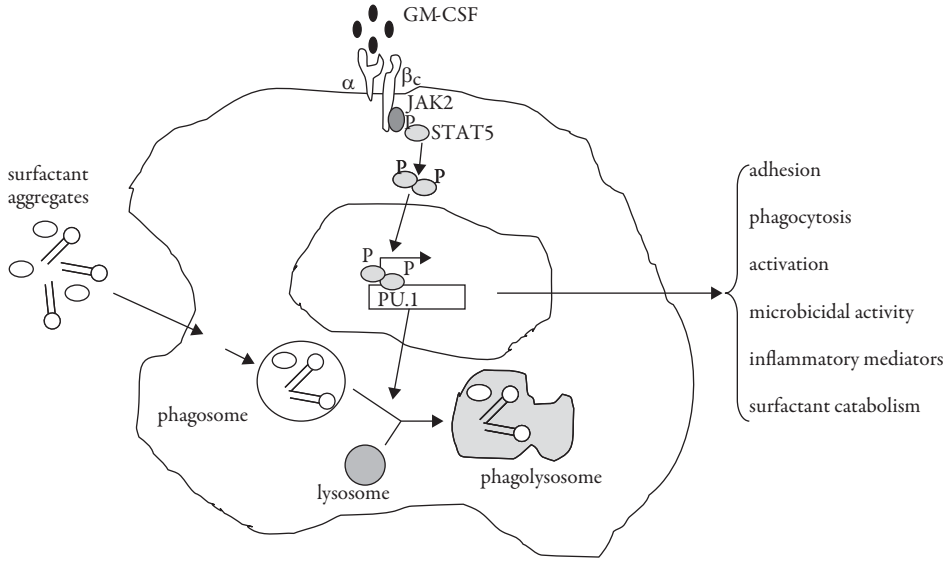

Figure 41.1 *GM-CSF–mediated activation of alveolar macrophages.* GM-CSF binds to its receptor, composed of α and β_c chains, expressed on the surface of alveolar macrophages. This promotes phosphorylation of JAK2 and recruitment and phosphorylation of STAT5. Phosphorylated STAT5 homodimers translocate to the nucleus and drive PU.1 gene transcription. Expression of the PU.1 transcription factor promotes phagocytosis and catabolism of surfactant aggregates within phagolysosomes, as well as cellular adhesion, production of microbicidal molecules, and release of inflammatory mediators.

pathology is characterized by accumulation of PAS-positive material in the alveoli that maintain a normal architecture. Patients with autoimmune PAP are also at high risk of infections, which account for 18 percent of the deaths (Seymour and Presneill, 2002). The antibodies detected in patients with autoimmune PAP bind GM-CSF with high affinity (Uchida et al., 2004). Interestingly, it has recently been shown that GM-CSF autoantibodies are present also in healthy donors (Uchida et al., 2009) and in pharmaceutical immunoglobulin preparations (Svenson et al., 1998). However, the levels of GM-CSF autoantibodies are much higher in patients with autoimmune PAP, leading to the hypothesis that they may play a pathogenic role when their concentration exceeds a certain threshold (Bendtzen et al., 2007), estimated to be more than 10.4 μg/m: (Uchida et al., 2009). Injection of GM-CSF autoantibodies isolated from patients with autoimmune PAP into nonhuman primates can in fact reproduce the features of the disease if autoantibody levels are maintained above 40 μg/mL for several months (Sakagami et al., 2009).

Following the demonstration that disruption of the *csf2* and *csf2rb* genes in mice leads to a PAP phenotype, defects in the same genes were sought in humans with PAP. In 1997, four infants with an established or putative diagnosis of PAP were reported in whom lack of β_c expression was demonstrated on the surface of peripheral leukocytes (Dirksen et al., 1997). Expression of the GM-CSFRα chain was preserved, but binding of GM-CSF and in vitro progenitor clonogenic assays showed altered response to GM-CSF. Homozygosity for a single amino acid substitution (Pro603Thr) was identified in one of the three patients studied, but this was then found to represent a polymorphism (Freeburn et al., 1998). No defects in the *CSF2RB* gene were identified in the remaining patients, leaving the molecular basis of the disease unclear. However, more recently, a homozygous missense mutation in the *CSF2RB* gene, resulting in S271L amino acid substitution, was identified in a female child presenting with pneumonia and progressive dyspnea. The mutation prevented STAT5 phosphorylation in blood leukocytes following stimulation by GM-CSF and IL-3 (Suzuki et al., 2011). While this observation extends to humans previous observations in mice that *csf2rb* mutations may lead to a PAP phenotype, this remains a very rare cause of the disease.

In contrast, two groups have provided conclusive evidence that PAP may be caused by genetic defects of the *CSF2RA* gene, which is located in the pseudoautosomal region of chromosome X, at Xp22.3, and at the tip of the short arm of chromosome Y, at Yp11.32. Susuki et al. (2008) described two sisters aged 6 and 8 years with growth failure, tachypnea, and severe pulmonary restrictive impairment. Chest radiograph and histopathological examination of a lung biopsy were consistent with the diagnosis of PAP. Search for GM-CSF autoantibodies was negative. The concentrations of GM-CSF in the bronchoalveolar lavage (BAL) fluid, and of SP-D in the serum, were markedly elevated. Although expression of both GM-CSFRα and β_c chains at the surface of leukocytes was normal, GM-CSF–induced upregulation of CD11b was impaired and expression of a low-molecular-weight form of GM-CSFRα chain was demonstrated by Western blotting. Genetic analysis revealed that both sisters carried a 1.6 Mb deletion in the pseudoautosomal region 1 of the maternally derived X chromosome and a single nucleotide mutation, leading to Gly174Arg substitution, in the paternally derived *CSF2RA* gene. When co-transfected with β_c into 293 cells, the GM-CSFRα chain mutant failed to internalize GM-CSF added to the culture and resulted in markedly decreased phosphorylation of STAT5 in response to GM-CSF. This defect was partially rescued at higher GM-CSF concentrations (Suzuki et al., 2008). Martinez-Moczygemba et al. described a 4-year-old girl with Turner syndrome and respiratory insufficiency; pathological findings at lung biopsy and on BAL were also consistent with the diagnosis of PAP. Search for GM-CSF autoantibodies was negative, but serum GM-CSF concentration was increased more than 200-fold. A complete lack of GM-CSFRα chain expression on the surface of peripheral blood monocytes was demonstrated, and expression of CD11b was not upregulated in response to GM-CSF. Molecular cytogenetic analysis showed a 46Xi(Xq) karyotype, with truncation of the Xp arm and lack of pseudoautosomal region 1 on the i(Xq) chromosome. The observation that the GM-CSFRα chain transcript could not be demonstrated by RT-PCR prompted a search for mutation on the other allele of the *CSF2RA* gene; a deletion of the genomic segment encompassing exons 5–13 was demonstrated (Martinez-Moczygemba et al., 2008). Altogether, these observations provide the first evidence that biallelic mutations of the *CSF2RA* gene cause congenital PAP in humans. Since then, seven additional children, all girls, have been identified with congenital PAP due to *CSF2RA* mutations (Trapnell et al., 2009). Elevated GM-CSF levels were consistently demonstrated in every patient.

Finally, PAP may also occur in association with various hematological disorders (myelodysplastic syndromes, leukemia, lymphoma, etc.), immunological diseases (severe combined immunodeficiency, IgA deficiency), infections (cytomegalovirus, *M. tuberculosis*, *P. jiroveci*, others), lysinuric protein intolerance, hematopoietic cell transplantation, and exposure to toxic substances and elements (Chung et al., 2009; Seymour and Presneill, 2002; Trapnell, 2003). The pathogenesis of secondary PAP remains poorly defined and may reflect acquired depletion or functional defects of alveolar macrophages.

CLINICAL FEATURES, DIAGNOSIS, AND TREATMENT

The main clinical features of PAP include progressive respiratory failure with hypoxemia and growth arrest. Chest radiographs and computed tomography show diffuse and patchy opacities (Ishii et al., 2009; Trapnell et al., 2003). Open lung biopsies demonstrate accumulation of granular PAS-positive proteinaceous material in the alveoli and in the alveolar walls, foamy macrophages, and inflammatory infiltrates, without disruption of the lung architecture. Foamy macrophages and PAS-positive material are also recovered following BAL. In

addition, patients with PAP suffer from increased susceptibility to pulmonary and extrapulmonary infections. These include both community- and hospital-acquired microorganisms (*S. pneumoniae*, *H. influenzae*, *Klebsiella*, *Pseudomonas*) and opportunistic pathogens (*Nocardia*, *Mycobacteria*). In a review of cases reported in the literature between 1958 and 1997, infections accounted for 18 percent of deaths (Seymour and Presneill, 2002).

Some clinical and laboratory features distinguish congenital PAP from autoimmune and secondary forms. The seven patients with molecularly proven *CSF2RA* mutations were 2 to 11 years old at the time of diagnosis (Trapnell et al., 2009); in contrast, autoimmune PAP typically affects subjects aged 30 to 40 years. Furthermore, no underlying disorders can be identified in patients with congenital PAP. At variance with autoimmune PAP, patients with congenital PAP do not have GM-CSF autoantibodies, and their GM-CSF serum levels are significantly elevated. In addition, levels of SP-D in the serum and of inflammatory chemokines and cytokines (MCP-1, GM-CSF, M-CSF) in BAL fluid are increased in patients with PAP, regardless of the congenital, autoimmune, or secondary nature of the disease (Trapnell et al., 2009).

Whole-lung lavage (i.e., large-volume BAL) is often used as the first line of treatment in patients with PAP and results in significant clinical and radiographic improvement (Michaud et al., 2009). However, approximately 15 percent of the patients (including those with congenital PAP) have a relapsing course and may require multiple rounds of the procedure. The observation that some patients with congenital PAP have residual GM-CSF–mediated signaling suggests that aerosolized delivery of GM-CSF might be therapeutic in these patients (Suzuki et al., 2008). Finally, because of the critical role of alveolar macrophage dysfunction in the pathogenesis of congenital PAP, hematopoietic stem cell transplantation (HSCT) and *CSF2RA* gene transfer might be considered. Indeed, one of the patients with congenital PAP due to *CSF2RA* mutations received HSCT from a matched unrelated donor but died from a severe respiratory infection shortly after transplantation, before immune reconstitution was achieved (Martinez-Moczygemba et al., 2008).

ROLE OF *TMC6* AND *TMC8* GENES AND EVER PROTEINS IN EPIDERMODYSPLASIA VERRUCIFORMIS

Maciej Lazarczyk, Patricia Cassonnet, and Michel Favre

Epidermodysplasia verruciformis (EV; OMIM #226400) is a very rare genodermatosis, initially described by Lewandowsky and Lutz in 1922. The nosological identity of the disease as well as its pathogenesis has long remained unclear (for reviews see Orth, 1987 and 2006). Some authors recognized EV as an abnormality of epidermal differentiation (Mashkilleisson, 1931; Oehlschlaegel et al., 1966; Waisman and Montgomery, 1942), whereas others treated it as a generalized form of skin warts (Hoffmann, 1926; Jablonska and Milewski, 1957; Kogoj, 1926; Sullivan and Ellis, 1939). A viral etiology of EV was proposed for the first time by Lutz in 1946 (Lutz, 1946). However, it was not until the 1960s that the presence of the virus in the skin lesions of EV patients was confirmed by electron microscopy, and the virus has subsequently been identified as a member of a specific group of widespread human papillomaviruses (HPV) (Jablonska et al., 1968; Orth et al., 1979; Ruiter and van Mullem, 1966). Malignant conversion of some verrucous lesions is frequently observed. This led to EV being considered as a model for the study of the role of papillomaviruses in oncogenesis (Jablonska et al., 1972). The first evidence for HPV etiology in human carcinogenesis was obtained in 1980 (Orth et al., 1980). All these findings suggested that EV might constitute in fact a defect of the natural mechanisms protecting humans from this specific group of oncogenic papillomaviruses.

Recently EV has been classified into the group of primary immune deficiencies, as a disease in which the defect would concern keratinocytes (Notarangelo et al., 2004). In this context, EV might be considered as the first described primary immunodeficiency (Orth, 2006), although the range of abnormalities observed in EV patients is broader, clearly not limited to the innate immunity.

CLINICAL COURSE OF EV

The first skin lesions emerge in infancy and the disease is usually diagnosed between the ages of 5 and 10 years. Initially, the lesions appear typically on the face and hands, but they subsequently spread to different regions, including the trunk. The lesions affect only the skin; the mucosal membranes are spared. Macroscopically the lesions in EV are classified as flat warts or macules. These lesions might resemble the ones found in the course of pityriasis versicolor, but they are persistent and can become confluent (Majewski et al., 1997; Orth, 2006). Some of the lesions, especially the ones in the sun-exposed areas, undergo malignant transformation, indicating that UV irradiation plays an important role in carcinoma. However, such a natural evolution of the lesion is slow, and nonmelanoma skin cancers (NMSC) emerge in EV patients typically after more than 20 to 30 years. Initially it has been estimated that only 30 percent of EV patients eventually develop NMSC (Lutzner, 1978), but more recent surveys, in which the EV patients have been observed for a long enough period (>40 years), demonstrate that skin cancers can emerge in virtually all of them (Majewski et al., 1997). Among the NMSC, squamous cell carcinoma (SCC) predominates. In EV, even though malignant, SCC only rarely produces remote metastases, unless the patients are exposed to irradiation (e.g., X-ray, UV light).

SUSCEPTIBILITY TO HPV

The constant and the most important characteristic feature of the phenotype associated with EV is an unusual susceptibility to infection by a specific group of evolutionary-related cutaneous HPV. Viruses that are responsible for the induction of

the skin lesions in EV patients belong to the beta genus (also called EV-HPV), and this group comprises more than 40 genotypes (Chouhy D et al., 2012). Initially it was thought that beta-HPV infections were restricted solely to EV patients. However, it has been subsequently demonstrated that these viruses are widespread, although the genetic material of the virus is detected in the general population only by highly sensitive techniques like nested PCR (Boxman et al., 1999). It implies that a natural anti-HPV barrier exists in humans and normally can eliminate or at least control beta-HPV infections. Conversely, the viral load in skin lesions in EV patients is high, suggesting that the molecular defect in EV apparently disrupts the barrier and consequently somehow promotes the life cycle of beta-HPV and/or prevents viral clearance (Lazarczyk et al., 2009).

Intriguingly, the high susceptibility to HPV in EV is extremely selective. EV patients are not more prone to other viral infections, including even those with closely related alpha-HPV—the group of papillomaviruses that comprises the genotypes causing cervical carcinomas (HPV16, HPV18, etc.). The reason for this puzzling selectivity, as well as the cause of the host restriction of beta-HPV, has long remained obscure, but recent reports have shed some light on this issue (Lazarczyk et al., 2008, 2009).

GENETIC BACKGROUND OF EV

The existence of familial aggregation of EV cases, especially in consanguineous families, very early drew the attention of the scientific community, and already in the 1930s the hereditary nature of EV was being considered. However, it was not until the 1970s that EV cases were more systematically investigated and characterized. The studies by Rajagopalan (Rajagopalan et al., 1972), followed by the observations of Lutzner (Lutzner, 1978), revealed an autosomal recessive type of EV inheritance, and currently this mode of genetic transmission of familial EV is considered as predominant. However, the EV locus and the incriminated genes were not discovered until 30 years later.

Two EV loci have been determined so far, on chromosomes 17 (EV1) and 2 (EV2), demonstrating a nonallelic heterogeneity of the disease (Ramoz et al., 1999, 2000). Subsequently, two adjacent genes in the EV1 locus have been identified (Ramoz et al., 2002). The genes belong to the *TMC* family (transmembrane channel-like), and the gene names are *TMC6* (*EVER1*) or *TMC8* (*EVER2*) (Keresztes et al., 2003). The *TMC* genes have been evolutionary conserved, and numerous *TMC* orthologs have been identified, not only in mammals but also in nonmammalian vertebrates (Keresztes et al., 2003). Mutations identified in EV so far are point substitutions, nucleotide insertions, or deletions (frameshift mutations) that create a premature STOP codon or deletion of exons (Table 42.1). All the EVER mutations are believed to prevent synthesis of full-length, functional protein capable of interacting with cellular partners such as the zinc transporter ZnT-1 (Lazarczyk et al., 2008). It is estimated that a nonsense mutation in *TMC* genes is found in around 70 to 80 percent of patients (Orth, 2006, 2008). The remaining, unequivocally diagnosed EV cases might carry a mutation in an as-yet-unidentified gene in the EV2 locus or in another chromosomal region. No mutation was detected in zinc transporter genes located in the EV2 locus (ZnT-6) or mapped to chromosome 1q32.3 (ZnT-1) (M. Favre, unpublished).

FUNCTION OF EVER PROTEINS

EVER genes are ubiquitously expressed, and they encode two related transmembrane proteins. EVER1 (805 amino acids [a.a.]) and EVER2 (726 a.a.) share ~28 percent of a.a.

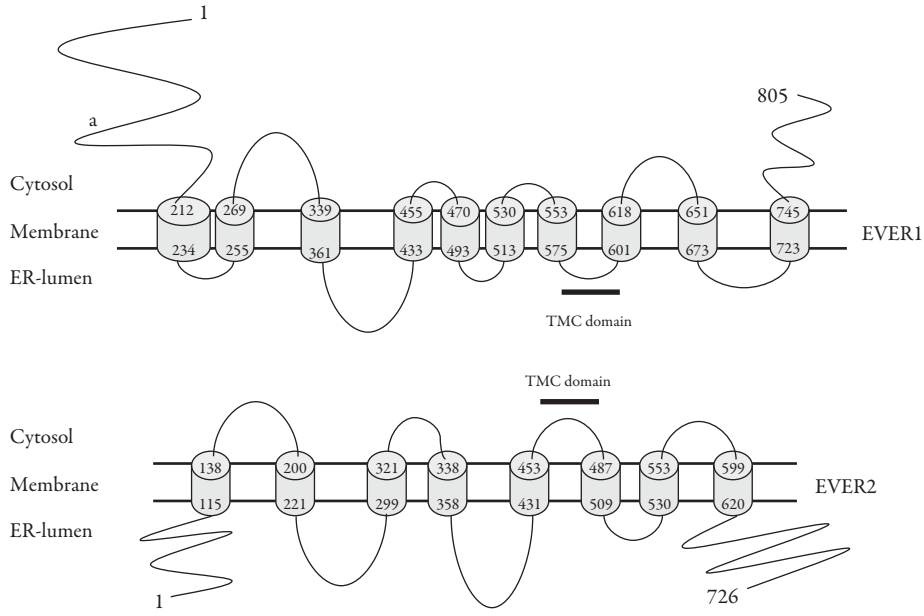

Figure 42.1 Schematic representation of EVER1 and EVER2 proteins. The putative cytosolic and lumenal regions and the conserved TMC domain of EVER1 (805 a.a.) and EVER2 (726 a.a.) are indicated. A.a. positions of the putative 10 (EVER1) and 8 (EVER2) transmembrane domains are shown.

(Ramoz et al., 2002) and are characterized by 10 and 8 putative transmembrane domains, respectively (Fig. 42.1). Both proteins have putative phosphorylation and glycosylation sites. The central part of the EVER proteins constitute the so-called TMC domain, the motif conserved in all the TMC proteins. In human keratinocytes, EVERs are located mainly in endoplasmic reticulum (ER), but also in the Golgi apparatus and nuclear membrane (Lazarczyk et al., 2008; Ramoz et al., 2002). Both EVER1 and EVER2 have been found to interact with zinc transporter 1 (ZnT-1), and the TMC domain of EVERs is necessary and sufficient for this interaction (Lazarczyk et al., 2008, 2009). The EVER complex probably comprises more proteins, as predicted by the yeast two-hybrid screening and bioinformatics analysis (Lazarczyk et al., 2009), but until now only the interaction with ZnT-1 has been unequivocally confirmed.

ZnT-1 was originally described as a plasma membrane zinc effluxer in hamster cells (Palmiter and Findley, 1995). However, in human keratinocytes, ZnT-1 was shown to form a complex with EVER1 and EVER2, which is located inside the cell (Lazarczyk et al., 2008; Lazarczyk and Favre, 2008). This complex does not confer zinc efflux in human keratinocytes but is probably involved in maintaining the low level of free zinc ions and in preventing zinc retention in the nucleus (Lazarczyk et al., 2008). The EVER/ZnT-1 complex is also involved in the regulation of activity of some cellular transcription factors, such as MTF-1 and AP-1. The exact role of the EVER/ZnT-1 complex in the transport or regulation of Zn^{2+} remains unknown, but undoubtedly, EVER1 and EVER2 constitute an element crucial for the complex integrity, as the lack either EVER compromises its activity (Lazarczyk et al., 2008). Recently, EVER2 protein was found to interact with TRADD to promote TNF-α induced apoptosis (Gaud G et al., 2013).

PATHOGENESIS OF EV

Despite the discovery of the EV susceptibility genes (Ramoz et al., 2002), the pathogenesis of the disease remains obscure. Even the cell type primarily affected by the EVER deficiency is uncertain; several possibilities can be considered. First of all, the lack of one of the EVER proteins in keratinocytes, the host cell for HPV, might directly promote the virus life cycle, allowing the virus to establish a persistent infection. On the other hand, EV patients display some immune deviations, in particular in cell-mediated immunity, and it is possible that EVER deficiency in lymphocytes affects their function and consequently the clearance of the HPV infection.

EVER PROTEINS AND THE HPV LIFE CYCLE

Most probably, the EVER/ZnT-1 complex is involved in keratinocytes in regulation of the cellular homeostasis of zinc (Lazarczyk et al., 2008, 2009; Lazarczyk and Favre, 2008). The total zinc in any cell can be classified in one of the two categories: (1) zinc tightly bound to different cellular macromolecules, in particular to metallothioneins, and (2) free zinc—the zinc ions that remain unbound or only loosely bound and are easily accessible (Eide, 2006; Lazarczyk and Favre, 2008). Even though the pool of free zinc remains in the low nanomolar range, the free zinc is metabolically very active and needed for the newly synthesized proteins. It can be assumed that the EVER/ZnT-1 complex is involved in maintaining a low concentration of free Zn^{2+} in the cell (Lazarczyk et al., 2008). Through limiting the accessibility of free zinc ions, the EVER complex could downregulate expression and replication of the virus in at least three different ways. First, many

viruses, including papillomaviruses, comprise zinc-binding proteins that require Zn^{2+} for their activity. In case of HPV, the E6 and E7 oncoproteins comprise two zinc fingers and one zinc finger, respectively (Barbosa et al., 1989). Second, Zn^{2+} affects cell signaling, or it can even serve as a classical second messenger (Yamasaki et al., 2007), and thus zinc ions may stimulate signaling pathways, leading to activation of some cellular transcription factors, including the ones relevant for the virus. Furthermore, by affecting the activity of several cellular transcription factors, zinc can change also the expression of multiple cellular genes and in this way indirectly influence the virus life cycle (for instance, by modifying the differentiation status of the cell, affecting proliferation, etc.). Currently it is unknown which of these tentative and not mutually exclusive mechanisms could explain the anti-HPV potential of the EVER complex. Verification of the role of the intracellular accessibility of free zinc ions for the viral proteins is technically challenging, but the scarcity of free Zn^{2+} in the cell (probably less than 1,000 atoms per cell), especially in the context of a massive synthesis of zinc-binding viral protein, prompts serious consideration of this mechanism. On the other hand, our data might support the last two explanations—that is, the effect of zinc via the influence on the cellular transcription factors and in turn on the cellular and viral gene expression pattern.

Indeed, EVER proteins serve as negative regulators of the activity of the AP-1 transcription factor family in human keratinocytes (Lazarczyk et al., 2008). Zn^{2+} can stimulate AP-1 by activation of Jun N-terminal Kinase (JNK) (Eom et al., 2001), an enzyme that phosphorylates and activates c-Jun and c-Fos. EVER proteins inhibit the transactivation domain of Jun, probably in a JNK-dependent but GSK-3beta-independent manner (Lazarczyk et al., 2008, and unpublished data). It has been demonstrated that c-Jun and c-Fos are essential for the HPV life cycle (Kyo et al., 1997). Therefore, in the EVER-deficient keratinocytes, where AP-1 activity is kept constitutively high (Lazarczyk et al., 2008), the HPV life cycle can be directly facilitated. However, since AP-1 is a transcription factor with pleiotropic activity, it can also affect the expression of multiple cellular genes, including the genes relevant for the virus itself, or those important for the clearance of the infection (for instance, cytokine expression). Indeed, EVER proteins were shown to regulate the expression of some interleukins produced by keratinocytes. Thus, the altered pattern of the cytokine production could contribute to the deregulation of the antiviral immune response and might enable persistent infection.

EVER PROTEINS IN LYMPHOCYTES

The efficient immune response against HPV plays an essential role in the natural history of the papillomavirus infections (clearance vs. persistence of lesions). Notably, even though the majority of women are infected at least once in their life with potentially oncogenic HPV, only in a small proportion of them does this infection lead to clinically apparent disease. Most frequently, the subclinical infections are spontaneously cured in immunocompetent individuals. It is believed that effective antigen presentation corresponding to E6 and E7 proteins and activation of T-cytotoxic lymphocytes are essential for such viral clearance (Tindle, 2002). It has been proposed that EV might constitute a disease in which the innate or adaptive immune response directed toward papillomaviruses is compromised. This might prevent elimination of the beta-HPV and lead to persistent infections. Consequently, a long-lasting exposure to the oncogenic viruses would provoke skin-cancer development in these patients.

Interestingly, the results of genome-wide transcriptome analysis (Su et al., 2004) revealed that the highest *EVER1* and *EVER2* expression takes place not in the skin but in lymphocytes, in particular in T cells (Lazarczyk et al., 2012). Therefore, it is tempting to speculate that the "defect" resulting from EVER deficiency concerns also the immune system. Namely, it has been postulated that the zinc imbalance, primarily reported in EVER-deficient keratinocytes (Lazarczyk et al., 2008), could be imposed by the lack of EVER also in lymphoid cells. Indeed, using a luciferase assay, it has been shown that activity of zinc-inducible transcription factor (MTF-1) is increased in lymphoblastoid lines with a mutation in EVER (Lazarczyk et al., 2009). Since an important role of zinc in maintaining the integrity of the immune system has repeatedly been raised during recent decades (Fraker and King, 2004; Rink and Gabriel, 2001), one can presume that the deregulation of zinc homeostasis might affect the lymphocyte function (Lazarczyk et al., 2012).

In line with these presumptions, multiple immune deviations have been reported in EV patients, although they remain poorly characterized. The response of the T lymphocytes from EV to unspecific mitogens and to HPV-infected keratinocytes is impaired (Cooper et al., 1990; Glinski et al., 1976), whereas the function of the B-cell compartment seems to be preserved (Prawer et al., 1977). Moreover, in the majority of EV patients, an anergy to contact sensitizers (mainly dinitrochlorobenzene) is observed (Glinski et al., 1976), although it is unclear which cellular compartment (dendritic cells, lymphocytes, etc.) contributes to this phenomenon. A distinct issue that remains is whether these immune abnormalities truly contribute to EV pathogenesis or whether they constitute a consequence of a massive, life-long HPV infection in EV patients.

It has been reported that some patients with severe combined immunodeficiency (SCID) develop EV-like lesions a few years after hemopoietic stem-cell (HSC) transplantation. HSC transplantation is a life-saving treatment in SCID patients, but, notably, it remains ineffective toward HPV-induced skin lesions (Laffort et al., 2004). This might disfavor the involvement of the dysfunction of the lymphocyte compartment in EV's pathogenesis, and it emphasizes the role of keratinocytes or NK cells. However, our recent results suggest that the EVER deficiency can have a direct influence on the immune cell function (Lazarczyk et al., 2012). Using the lymphoblastoid lines derived from EV patients or their healthy relatives, we have demonstrated in vitro that the lack of EVER2 correlates with increased MTF-1 transcription factor activity (Fig. 42.2) and TNF-alpha production (Lazarczyk et al., 2009). In accordance with these findings, increased expression of TNF-alpha in EV epidermis had previously been

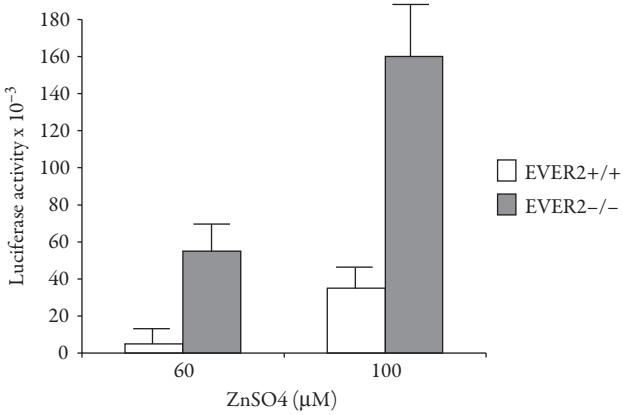

Figure 42.2 Activity of MTF-1 transcription factor is upregulated in mutant EVER2 lymphocytes. Lymphoblastoid cells with wild-type (+/+) or mutant (-/-) *TMC2* gene were transfected with the luciferase reporter gene under the control of the transcription factor MTF-1 in two different $ZnSO_4$ concentrations, as described in Lazarczyk et al., 2008.

reported (Majewski et al., 1991), although the significance of this cytokine in the pathogenesis of EV remains speculative.

SELECTIVITY OF EVER-BASED BARRIER

The reason of the remarkable selectivity of the susceptibility to beta-HPV in EV patients has long been unknown. This selectivity might suggest that the natural EVER-based barrier is highly selective and confers resistance solely to beta-HPV. However, our recent results support an alternative, virus-intrinsic mechanism. One of the important differences between beta-HPV and alpha-HPV is the lack of the E5 open reading frame (ORF) in the beta genotypes. E5 is a small hydrophobic protein with rather moderate transformation potential (Tsai and Chen, 2003), although it does contribute to HPV-mediated carcinogenesis (Maufort et al., 2007). It has been demonstrated that E5 binds to EVER proteins and disrupts the complex (Lazarczyk et al., 2008, 2009). Consequently, E5 exerts an effect strikingly similar to that of the EVER deficiency. Therefore, one can presume that the EVER-based barrier is not truly selective but conversely that some HPVs, different from beta-HPV, have developed a counteracting mechanism that allows them to break or bypass the natural anti-HPV barrier.

A MODEL OF A NATURAL ANTI-HPV BARRIER

Comprehension of EV pathogenesis, even though far from being complete, sheds light on the nature of the host–HPV interactions and gives an insight into the function of the natural mechanisms protecting humans from papillomaviruses. It allowed us to propose a model of the natural anti-HPV barrier (Lazarczyk et al., 2009). According to this model, an essential part of the barrier would be EVER proteins. The exact protein composition of the barrier remains to be established, but the substantial phenotype in EV patients clearly indicates that the presence of the EVER proteins is critical for the integrity of the barrier (Lazarczyk et al., 2008; Ramoz et al., 2002). From a cellular perspective, the anti-HPV barrier would comprise keratinocytes but possibly also the lymphocyte compartment (Lazarczyk et al., 2012). The barrier would be involved in maintaining the low level of free zinc and the low level of AP-1 activity.

In conclusion, deregulation of cellular zinc homeostasis, namely an increase in intracellular free zinc concentration, would constitute an important step in the virus life cycle not solely for EV-HPV but for HPV in general (Lazarczyk et al., 2009), and perhaps also for other viruses (Lazarczyk and Favre, 2008). However, two "strategies" would be employed: E5-mediated inhibition of the EVER complex in the case of alpha-HPV, or EVER/ZnT-1 complex function could be intrinsically compromised as an effect of the lack of one of the EVER proteins. Beta-HPVs, being devoid of E5, are obviously confined to the latter possibility, what imposes a host restriction for this group of papillomaviruses.

WISKOTT-ALDRICH SYNDROME

Hans D. Ochs and Luigi D. Notarangelo

The first description of the Wiskott-Aldrich syndrome (WAS), published in 1937, defined accurately the clinical phenotype: three brothers, but not their sisters, presented shortly after birth with thrombocytopenia, bloody diarrhea, eczema, and recurrent ear infections (Wiskott, 1937). On the basis of this symptomatology, the early onset, and the predominance of male infants, Wiskott differentiated this entity from Morbus Werlhofii, a synonym for idiopathic thrombocytopenia (ITP). Seventeen years later, Aldrich described a large family with multiple affected males, clearly demonstrating X-linked inheritance (Aldrich et al., 1954). In 1957, additional cases were described (Huntley and Dees, 1957), including members of an African American family (Wolff, 1957).

Following these early clinical reports, the immunological abnormalities characteristic of WAS were recognized, including progressive lymphopenia, absence of delayed-type hypersensitivity, and abnormal in vivo antibody production (Blaese et al., 1968; Cooper et al., 1968; Ochs et al., 1980; Sullivan et al., 1994). Most studies implicated a predominant T-cell defect (Gallego et al., 1997; Molina et al., 1993; Sullivan et al., 1994). This idea was reinforced by the discovery that WAS protein (WASp), the protein mutated in this syndrome, plays a crucial role in cytoskeletal remodeling downstream of T-cell receptor (TCR) engagement (Barda-Saad et al., 2005) and contributes to the immune synapse formation between T lymphocytes and antigen-presenting cells (Dupre et al., 2002). However, impaired maturation, decreased motility, reduced migration, and abnormal morphology, including absence of filopodia, have recently been recognized in B cells from WAS patients (Andreu et al., 2007; Park et al., 2005; Westerberg et al., 2005), and a unique role of WASp in marginal-zone B-cell homeostasis and function has been demonstrated (Meyer-Bahlburg et al., 2008; Westerberg et al., 2008). Abnormal natural killer (NK) cell function (Gismondi et al., 2004; Huang et al., 2005; Orange et al., 2002), defective invariant NKT cell (NKT) homeostasis and function (Astrakhan et al., 2009), and impaired T-cell migration and T-cell priming by dendritic cells (Binks et al., 1998; Bouma et al., 2007, 2009; de Noronha et al., 2005) indicate that innate immunity is also affected. In addition to microplatelet thrombocytopenia, characteristic functional and morphological abnormalities of WAS platelets were recognized (Gröttum et al., 1969; Kuramoto et al., 1970; Ochs et al., 1980; Semple et al., 1997). The findings of multiple food allergies, eosinophilia (Huntley and Dees, 1957), and elevated IgE levels suggest an allergic basis for the eczema (Berglund et al., 1968). An increased risk of malignancies, including lymphoma, malignant reticuloendotheliosis, and leukemia, was reported as early as 1961 (Imai et al., 2004; Kildeberg, 1961; Cotelingam et al., 1985; Sullivan et al., 1994; ten Bensel et al., 1966).

Distinguishable from the classic WAS phenotype (MIM 301000) is a milder form designated *hereditary X-linked thrombocytopenia* (XLT, MIM 313900) (Canales and Mauer, 1967; Chiaro et al., 1972; Jin et al., 2004; Notarangelo et al., 1991; Stormorken et al., 1991). In patients with XLT, eczema, if present, is mild; immune functions are less disturbed or normal, autoimmune disorders are rare, and malignancies appear to be less frequent (Albert et al., 2010). The thrombocytopenia may be present intermittently (Notarangelo et al., 2002).

The gene responsible for both WAS and XLT was initially mapped to Xp11.22 (Donner et al., 1988; Kwan et al., 1991). The gene, designated as *WAS*, was subsequently identified by positional cloning (Derry et al., 1994). *WAS* is composed of 12 exons containing 1,823 base pairs and encodes a 502-amino acid protein with a predicted molecular weight of 54 kDa. WASp is constitutively expressed in all hematopoietic stem cell-derived lineages and is located predominantly in

the cytoplasm, with the highest protein density being toward the cell membrane (Rivero-Lezcano et al., 1995; Zhu et al., 1997). WASp belongs to a family of cytoskeleton regulatory proteins that include N-WASp and the Scar/WAVE proteins 1–3 (Oda et al., 2005; Pollitt and Insall, 2009). Several functional domains based on the genomic structure of WASp have been identified, including the N-terminal WASp homology 1 (WH1) domain followed by a basic region (BR), a GTPase-binding domain (GBD), a polyproline-rich region, and a C-terminal Verprolin homology/Central region/Acid region (VCA) domain (Burns et al., 2004; Thrasher and Burns, 2010).

One of the essential roles of WASp is the regulation of actin polymerization by actin-related protein (Arp) 2/3, as illustrated by the finding that WAS macrophages fail to organize the Arp2/3 complex in podosomes (Linder et al., 1999). In this model, WASp is present in two configurations: the active form, in which the C terminus of WASp is free to interact with the Arp2/3 complex, and the inactive form, in which the C terminus forms an autoinhibitory contact with the BR of the GBD (Kim et al., 2000).

The distinct domains of WASp form the basis for its multiple functions, which include self-regulation, cytoplasmic signaling, and, through the interaction with Arp2/3, actin polymerization. The identification of the *WAS* gene has not only provided new insight into the critical role played by this complex molecule in cell movement and cell–cell interaction but also has had an impact on establishing a genotype–phenotype correlation (Albert et al., 2010; Imai et al., 2004; Jin et al., 2004; Lemahieu et al., 1999; Zhu et al., 1997), carrier detection, and prenatal diagnosis. Early diagnosis of WAS is crucial for optimal therapy, which includes antibiotics and intravenous immunoglobulin (IVIG) substitution, and hematopoietic stem cell transplantation and gene therapy to cure this devastating disease.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

INCIDENCE, ONSET OF SYMPTOMS, AND AGE AT DIAGNOSIS

The incidence of the classic WAS phenotype has been estimated to be between 1 and 10 in 1 million individuals (Ryser et al., 1988; Stray-Pedersen et al., 2000). With broader awareness of the classic syndrome and the much milder XLT phenotype, along with the availability of reliable diagnostic tools, the true incidence is expected to be higher.

Early manifestations of WAS and XLT consist of petechiae, bruises, and bloody diarrhea and are often present at birth (Wiskott, 1937). Because of the increased risk of intracranial bleeding during vaginal delivery, birth by cesarean section is an option if the diagnosis is known prenatally. Excessive hemorrhage following circumcision is an early diagnostic clue. Eczema, either mild and localized or severe and generalized, is a consistent early manifestation of classic WAS (Fig. 43.1; Color Plate 43.II). The most characteristic findings at diagnosis, both in classic WAS and in XLT, are thrombocytopenia and small platelets. Infections, including otitis media with drainage of mucoid purulent material, are frequent complaints during the first 6 months of life. In a retrospective study of North American patients with a clinical presentation compatible with WAS/XLT completed before the *WAS* gene was identified, the average age at diagnosis was 21 months, with a range from birth to 25 years (Sullivan et al., 1994). The diagnosis was established earlier in patients with known affected family members (mean age at diagnosis 10 months) than in patients without a family history (24 months). Patients presenting with the XLT phenotype are often considered as having ITP, considerably delaying the actual diagnosis (Bryant and Watts, 2011).

INFECTIONS

Because of the profound cellular, humoral, and innate immune deficiency, infections are common manifestations of classic WAS. Upper and lower respiratory tract infections, often caused by common bacteria, are frequent and include otitis media (reported by 78 percent of WAS patients), sinusitis (24 percent), and pneumonia (45 percent) (Sullivan et al.,

1994). In the same retrospective study, sepsis was observed in 24 percent, meningitis in 7 percent, and "infectious" diarrhea in 13 percent. Severe viral infections do occur, including varicella with systemic complications that may require treatment with acyclovir and high-dose IVIG or varicella-zoster immunoglobulin (VZIG), and recurrent herpes simplex infections (observed in 12 percent). *Pneumocystis carinii (jiroveci)* pneumonia (PCP) (reported to affect 9 percent of WAS patients) is less prevalent than in patients with severe combined immune deficiency (SCID) or X-linked hyper-IgM syndrome (X-HIM) (Sullivan et al., 1994). Fungal infections, caused predominantly by *Candida* species, are relatively rare (10 percent of WAS patients) but may become more extensive during treatment with antibiotics. Patients with the XLT phenotype often lack a history of severe and frequent infections (Albert et al., 2010; de Saint Basile et al., 1996; Imai et al., 2004; Jin et al., 2004; Villa et al., 1995).

DEFECTS OF THE IMMUNE SYSTEM

Adaptive Immunity

The extent of the immune deficiency varies from family to family and depends largely on the mutation and its effect on WASp expression (Imai et al., 2004; Jin et al., 2004; Lutskiy et al., 2005a). Both T- and B-lymphocyte functions are affected. During infancy, the number of circulating lymphocytes may be normal or moderately decreased (Ochs et al., 1980; Park et al., 2004). By 6 years of age, lymphopenia due to loss of T lymphocytes is a common finding in patients with classic WAS (Ochs et al., 1980), and the numbers of B cells in lymph node follicles and T cells in the interfollicular area are reduced (Fig. 43.2; Color Plate 43.I). This may be in part due to accelerated cell death observed in peripheral blood lymphocytes from patients with WAS but not from those with XLT (Rawlings et al., 1999; Rengan et al., 2000). Abnormal T-cell function is suggested by diminished but not absent lymphocyte responses to mitogens (Cooper et al., 1968), depressed proliferative responses to allogenic cells (Ochs et al., 1980) and immobilized anti-CD3 monoclonal antibody (Molina et al., 1993), and complete lack of proliferation in response to periodate (Siminovitch et al., 1995). In a retrospective study of 154 patients, Sullivan et al. (1994) reported depressed proliferative responses to mitogens and allogenic cells in approximately 50 percent of the patients. Skin tests for delayed-type hypersensitivity were abnormal in 90 percent of the patients studied. Partial mixed chimerism due to the engraftment of only donor T lymphocytes seems to have corrected the immune defect, including antibody responses to polysaccharides, which suggests that the abnormal antibody production observed in WAS patients is largely caused by defective T-lymphocyte function (Parkman et al., 1978). The increased incidence of PCP also points to a significant T-cell defect in classic WAS. T cells from was$^{-/-}$ mice fail to spread, cap their TCR, proliferate, and secrete IL-2 in response to TCR cross-linking with anti-CD3 (Snapper et al., 1998).

Serum IgG and IgM levels are usually normal; IgA and IgE are frequently elevated. The fact that serum immunoglobulin

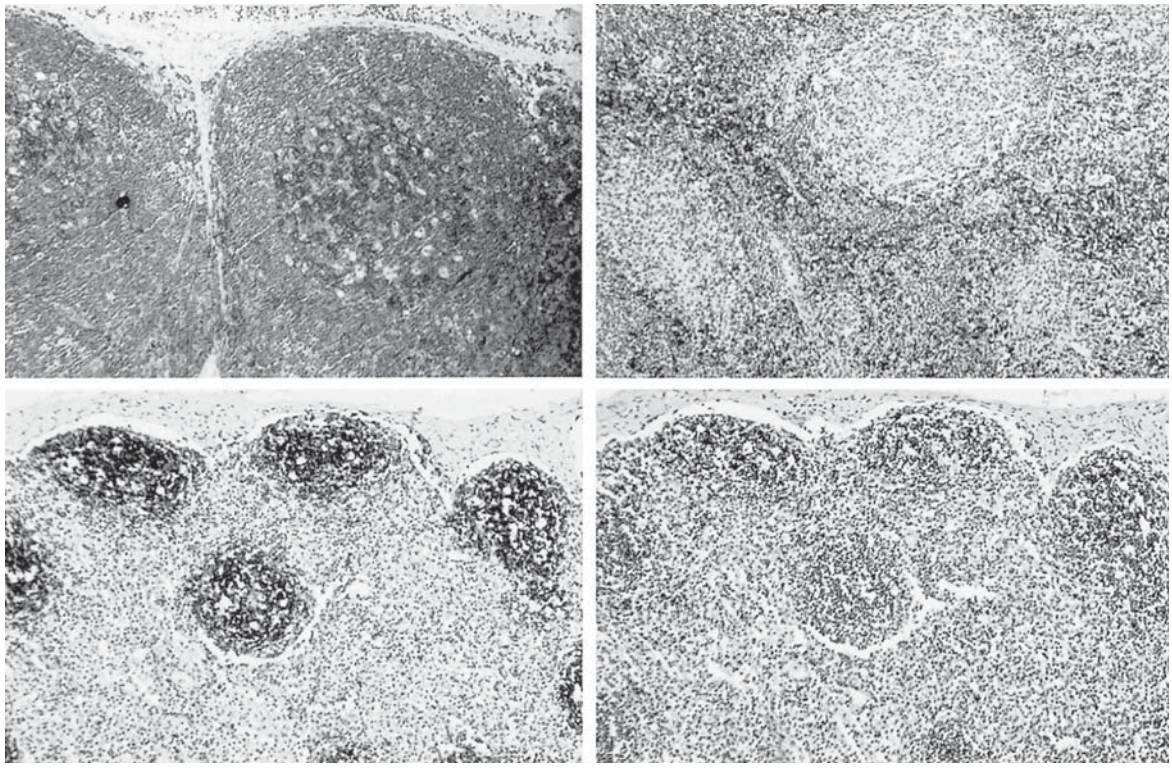

Figure 43.2 Color Plate 43.I Normal lymph node (*top*) and lymph node from a WAS patient (*bottom*). The left panels have been stained for B cells (in red). B cells are present in the poorly formed follicles of the WAS lymph node. The right panels have been stained for T cells (in red). The abundant numbers of T cells in the interfollicular area of the normal lymph node are sparse in the WAS lymph node (Perez-Atayde and Rosen, 1995). (See Color Plate.)

levels are normal or elevated suggests increased production, considering that the catabolism of immunoglobulin and albumin is twice that of normal controls (Blaese et al., 1971). The absolute number of B cells may be normal or moderately depressed (Park et al., 2005). Isohemagglutinin titers are frequently low (Ochs et al., 1980; Sullivan et al., 1994). Antibody responses are normal to some antigens and insufficient to others. A consistent finding is a markedly depressed response to polysaccharide antigens (Cooper et al., 1968; Ochs et al., 1980). This characteristic pattern of antibody deficiency is further illustrated by the observation that antibody responses to staphylococcal proteins are often normal, whereas antibody responses to streptococcal polysaccharides are consistently abnormal in WAS patients (Ayoub et al., 1968). In a multicenter retrospective review, antibody responses to a variety of protein antigens, including diphtheria and tetanus toxoid and to Hib vaccine (conjugated and unconjugated), were reported to be abnormal in more than 50 percent of WAS patients; in contrast, antibody responses to live virus vaccines were normal (Sullivan et al., 1994).

Antibody responses to intravenous immunization with bacteriophage ΦX174 are severely depressed in patients with classic WAS (who often lack WASp in lymphocytes and myeloid cells) and are characterized by absence of amplification and failure to switch from IgM to IgG (Fig. 43.3). These findings suggest abnormal class-switch recombination and lack of somatic hypermutation due to either defective T–B cell interaction or an intrinsic B-cell defect. In contrast, patients with the XLT phenotype mount a more robust response with amplification and isotype switching that may reach values comparable to those of normal individuals.

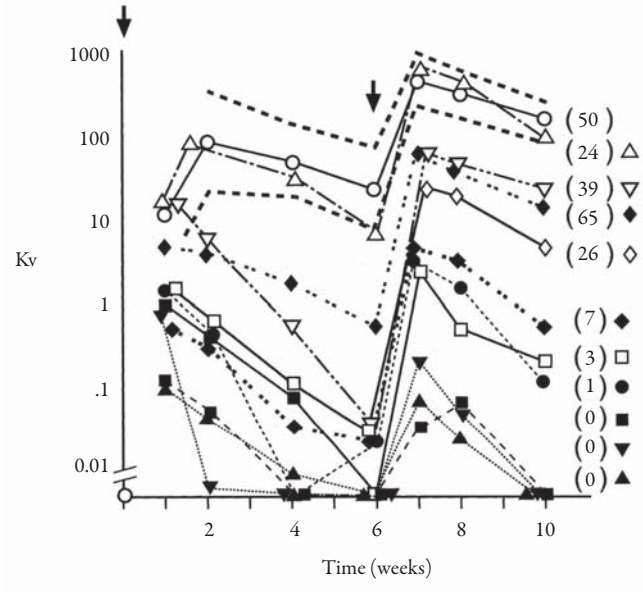

Figure 43.3 Antibody responses to the T-cell–dependent neoantigen, bacteriophage ϕX174 (phage), in patients with WAS/XLT. Phage was injected intravenously twice, 6 weeks apart (primary and secondary immunization), at a dose of 2×10^9 PFU/kg body weight (↓), and the production of phage-specific antibody was determined. Antibody titers were measured by a neutralizing assay expressed as rate of phage inactivation (Kv). The geometric mean antibody titers of normal males, following phage immunization, are indicated (○); ±1 SD is shown by broken lines. Percent IgG (in parentheses) was determined for serum samples obtained 2 weeks after secondary immunization by treatment with 2-mercaptoethanol (2-ME). Patients characterized by ♦, ◆ and ▲, ▼ are two pairs of cousins from two unrelated families with severe classic WAS (scores 4 and 5). The two patients indicated by the symbols ■ and ● are unrelated and also have classic WAS (score 3 and 4). The symbols Δ, ∇, □, ◊ indicate patients with XLT.

More recent studies suggest, however, that B-cell function is equally affected. Epstein-Barr virus (EBV)–transformed B lymphoblasts derived from WAS patients have reduced levels of filamentous (F) actin (Facchetti et al., 1998). B cells from WAS patients with mutations that lead to a complete absence of WASp, compared with normal B cells, have a defect in cell motility in response to CXCL13, and decreased ability to adhere homotypically and form long cytoplasmic protrusions after stimulation with anti-CD40 and interleukin (IL)-4 (Westerberg et al., 2005). By extending these studies to wasp-deficient mice, a reduced and delayed antibody response not only to T-dependent but also to T-independent antigens was consistently observed, supporting an intrinsic functional B-cell defect. It is possible, however, that this B-cell deficiency is secondary to the abnormal migration and impaired homing of B cells, reduced germinal-center formation, and abnormal marginal-zone (naïve) B-cell homeostasis and function observed in *was* knockout mice (Andreu et al., 2007; Meyer-Bahlburg et al., 2008; Park et al., 2005; Westerberg et al., 2005, 2008). Additional experimental evidence is required to determine if the observed B-cell deficiency is at least in part due to defective macrophage/dendritic or T-cell function (Bouma et al., 2007, 2009).

Innate Immunity

The susceptibility of WAS patients to viral infections and to malignancies may be the consequence of cytolytic or cytotoxic dysfunction. In normal NK cells, WASp can easily be detected, together with F-actin, in the immunological synapse. NK cells from patients with classic WAS lack WASp and show a markedly reduced accumulation of F-actin in the immunological synapse. As a direct result, WAS patients have defective cytolytic NK cell function (Orange et al., 2002). These findings were confirmed and expanded in a subsequent study of NK-cell cytotoxicity in both classic WAS and XLT patients (Gismondi et al., 2004). Although the percentages of NK cells were normal or increased, NK-cell cytotoxicity was inhibited in all patients with classic WAS and in most patients carrying mutations associated with the XLT phenotype. This inhibition of NK cell-mediated cytotoxicity, both natural and antibody-mediated, was associated with a reduced ability of WAS/XLT-NK cells to form conjugates with susceptible target cells and to accumulate F-actin on binding. Interestingly, addition of IL-2 corrected the functional defects of NK cells in vitro by affecting their ability to bind to target cells and to accumulate F-actin (Gismondi et al., 2004).

WASp-deficient humans and mice have regulatory T (Treg) cells that fail to suppress effector cells in vitro and that are incapable of controlling autoimmunity in mouse models (Adriani et al., 2007; Humblet-Baron et al., 2007; Maillard

et al., 2007; Marangoni et al., 2009). While WASp does not seem to be required for the thymic generation of natural Treg cells, it appears to play a crucial role in peripheral homeostasis of these cells (Humblet-Baron et al., 2007).

The involvement of the cytoskeleton in cell migration, active phagocytosis, and cell trafficking of myeloid cells, macrophages, dendritic cells, and Langerhans cells makes these cells vulnerable to *WAS* gene mutations. A large number of studies, some performed more than 35 years ago (Altman et al., 1974), have investigated the functionality of WASp-deficient monocytes, macrophages, and dendritic cells. In both WAS and XLT patients and in *was*$^{-/-}$ mice, a substantial defect in cell trafficking, pathogen clearance, and uptake of particulate antigen has been observed. Formation of the actin-rich phagocytic cup, which depends on the presence of WASp (Tsuboi and Meerloo, 2007), and IgG-mediated apoptotic cell phagocytosis are impaired in WASp-deficient macrophages (Leverrier et al., 2001; Lorenzi et al., 2000). The requirement of continuous WASp activity for podosome formation and function (Dovas et al., 2009) explains the complete failure to assemble podosomes in monocytes, macrophages, dendritic cells, and osteoclasts lacking WASp, which results in a severe defect of cell adhesion and motility (Burns et al., 2004; Calle et al., 2004a; Linder et al., 1999). WASp-deficient macrophages have an abnormal, elongated shape, lack a clear lamellipodium front, and show impaired chemotactic responses (Badolato et al., 1998; Calle et al., 2004a). With the use of wasp-deficient mice (Calle et al., 2004b) or an in vitro system (Ma et al., 2008), an extensive inhibition of osteoclast sealing ring formation and bone resorption has been demonstrated. Abnormalities are likely caused by defective filopodia and lamellipodia formation, since filopodia are involved in sensing the immediate microenvironment of the cell. Transfection of full-length *WAS* cDNA into WASp-deficient macrophages restores chemotaxis in response to CSF-1 (Jones et al., 2002). The in vivo homing of dendritic cells to the T-cell zones of secondary lymphoid tissues is impaired kinetically and quantitatively in wasp-deficient mice (Bouma et al., 2007; de Noronha et al., 2005).

The number of circulating neutrophils, the efficiency of neutrophil migration into the tissue, phagocytosis, and bactericidal activity are normal in WAS/XLT. However, in vitro chemotaxis of WAS neutrophils in response to various chemoattractants is insufficient, an abnormality that is most pronounced in the early phase of chemotaxis (Ochs et al., 1980).

PLATELET ABNORMALITIES

The platelet defect, thrombocytopenia and small platelet volume, is a consistent finding in patients with mutations in the *WAS* gene. Platelet counts vary from patient to patient and within affected individuals and may be as low as 5,000/mm^3 or as high as 50,000/mm^3. Higher counts, observed transiently, are often associated with inflammation or bacterial infections (Oda et al., 1998). Two families with intermittent thrombocytopenia associated with unique amino acid substitutions in the *WAS* gene have been described (Notarangelo et al., 2002). In most patients, the mean platelet volume (MPV) is half that of normal control subjects (3.8–5.0 fl vs. 7.1–10.5 fl), resulting in a thrombocrit of approximately 0.01%, compared with a normal range of 0.14% to 0.31% (Ochs et al., 1980). After splenectomy, platelet counts and platelet volume increase but are still less than that of normal controls (Haddad et al., 1999; Litzman et al., 1996). Partial but significant recovery of platelet counts following splenectomy suggests that the development of thrombocytopenia is at least in part due to the uptake and destruction of platelets by macrophages in the spleen or other reticular endothelial organs of patients with WAS or XLT (Baldini, 1972; Gröttum et al., 1969; Murphy et al., 1972). This interpretation is supported by the observation that platelet and macrophages co-localize in spleen sections from WAS patients, a finding strongly suggesting that damaged or antibody-coated platelets are ingested by macrophages in the spleen (Shcherbina et al., 1999). Increased expression of phosphatidylserine (PS) on circulating platelets from WAS patients (Shcherbina et al., 1999) and the presence of opsonizing anti-platelet antibodies in approximately half of wasp-deficient mice (Marathe et al., 2009) have been suggested as possible causes of increased phagocytosis of platelets (Shcherbina et al., 1999). In a recently published retrospective analysis of data collected by the French Registry of patients with WAS/XLT, a specific subset of infants ≤ 2 years of age was identified with an extremely poor prognosis. In addition to autoimmunity, inflammation and malignancies, half of these infants presented with Severe Refractory Thrombocytopenia (SRT), suspected, but not proven, to have anti-platelet autoantibody (Mahlaoui et al., 2013), suggesting that autoimmune thrombocytopenia can be a complication in WAS/XLT, especially in the very young. An alternative explanation for the thrombocytopenia is a decrease in platelet production. This possibility was suggested by the observation that autologous platelet survival in WAS and XLT patients was only reduced to half (5 days ± 1.3 days SD) that of normal (Ochs et al., 1980). A persistent finding was a decrease in platelet turnover, which was approximately 30 percent of the value found in normal subjects, indicating a significant platelet-production defect. Because the marrow megakaryocyte mass is normal or increased in WAS and XLT patients (Haddad et al., 1999; Ochs et al., 1980), it has been suggested that ineffective thrombocytopoiesis is at least in part responsible for the low platelet count. The discrepancy between a normal to increased marrow substrate available for platelet production (megakaryocyte cytoplasmic mass) and the low rate at which platelets actually appear in the circulation (platelet turnover) characterizes the platelet production defect known as ineffective thrombocytopoiesis (Slichter and Harker, 1978). It was hypothesized that this abnormality was caused by a defect in platelet demarcation and platelet release from megakaryocytes, possibly a direct consequence of the interaction of WASp with the cytoskeleton. This mechanism is supported by the observation of Kajiwara et al. (1999), who reported that in semisolid culture assays, bone marrow CD34$^+$ cells from WAS patients failed to form efficiently megakaryocyte colonies and to mature fully into platelet-releasing megakaryocytes. Using a megakaryoblastic cell line (MEG-01), Miki et al. (1997) showed that WASp is indispensable for

actin filament reorganization to microvesicles during megakaryocyte differentiation. In contrast, Haddad et al. (1999), studying megakaryocytes derived in vitro from $CD34^+$ cells, found normal megakaryocyte differentiation and pro-platelet formation in both WAS and XLT patients. Interestingly, the platelets produced in vitro were of normal size, whereas peripheral blood platelets from the same patient exhibited an abnormally small size. Moreover, F-actin distribution was abnormal and filopodium formation deficient in cultured megakaryocytes from WAS patients. In spite of these abnormalities, megakaryocytes from WAS patients migrated normally in response to stroma-derived factor-1α (SDF-1α). At this point, it is unclear if transendothelial migration of megakaryocytes is important for enhanced platelet formation, or if movement of WAS megakaryocytes would be abnormal if other chemotactic active factors were used. The observation that WASp is tyrosine phosphorylated after stimulation of platelets by collagen (Oda et al., 1998) may be relevant to megakaryocyte migration since collagen seems to be involved in the interaction between megakaryocytes and endothelial cells. It is also possible that abnormal interaction between WAS megakaryocytes and endothelial cells through adhesion signals other than SDF-1α might have a direct impact on platelet formation. Although wasp-deficient mice show only moderate thrombocytopenia, significant abnormalities have been demonstrated in platelet production in the bone marrow, suggesting that WASp plays an important role in platelet biogenesis. In particular, megakaryocytes from *was*$^{-/-}$ mice shed platelets ectopically within the bone marrow space and display functional defects in response to fibrillar collagen I (the major matrix component of bone), including impaired migration to SDF-1α, loss of α2β1 integrin-mediated inhibition of pro-platelet formation, and virtual lack of actin-rich podosomes, that are normally induced by interaction between collagen I and its receptors GPVI or α2β1 integrin (Sabri et al., 2006).

Several investigators have reported abnormal structure, function, and metabolism of WAS platelets (Baldini 1972; Kuramoto et al., 1970). Because it is generally difficult to examine the function of platelets from thrombocytopenic patients, the data obtained may merely reflect the reduced size or damage of platelets. Platelet aggregation defects, as determined by abnormal responses to ADP, collagen, and epinephrine, have been reported (Gröttum et al., 1969; Kuramoto et al., 1970). These findings have been interpreted as platelet functional defects, but the severe thrombocytopenia compromises interpretation. One splenectomized XLT patient who had enough platelets for aggregation studies showed normal aggregation (Ochs et al., 1980). Tsuboi et al. have recently discovered that WASp binds to the calcium and integrin-binding (CIB) protein in platelets and that WASp altered by missense mutations affecting exons 1–3 shows lower affinity for CIB than wild-type WASp. This impaired complex formation between mutant WASp and CIB reduces αIIbβ3-mediated cell adhesion and causes defective platelet aggregation, possibly contributing to the hemorrhagic diathesis of WAS/XLT patients (Tsuboi et al., 2006). WASp deficiency in human and murine platelets decreases αIIbβ3-mediated integrin "outside-in" dependent responses initiated by fibrinogen when measured by platelet adherence and spreading (Shcherbina et al., 2010). The fact that the incidence of severe, life-threatening bleeding is relatively small, in spite of platelet numbers being as low as 5,000/mm^3, suggests that WAS/XLT platelets function adequately in vivo. Nevertheless, the pronounced bleeding tendency due to persistent thrombocytopenia is often the first sign of WAS or XLT and may be the only clinically relevant symptom in XLT patients. The presence of petechiae or prolonged bleeding after circumcision in newborns may alert the physician and lead to early diagnosis. In a retrospective study of a large cohort of WAS patients, the clinical manifestation of bleeding was present in 84 percent, consisting of petechiae and/or purpura (78 percent), hematemesis and melena (28 percent), epistaxis (16 percent), and oral bleeding (6 percent). Life-threatening bleeding, including oral, gastrointestinal, and intracranial hemorrhage, occurred in 30 percent of WAS patients, with intracranial hemorrhage being observed in only 2 percent (Sullivan et al., 1994). In a recent retrospective study involving 173 XLT patients (median age 11.5 years), serious bleeding episodes were reported in 13.9 percent, including 18 events of intracranial hemorrhage with five fatalities (Albert et al., 2010).

Carrier females with mutations leading to classic WAS in half of their male offspring have normal platelet numbers, size, function, and survival time. This finding is explained by the nonrandom X chromosome inactivation in T cells, B cells, and platelets (Fearon et al., 1988; Gealy et al., 1980; Greer et al., 1989; Puck et al., 1990). However, carrier females in families with a mild XLT phenotype may have random X chromosome inactivation in hematopoietic cells, with occasional skewing in favor of the X chromosome with the mutation. In these rare situations, carrier females may present with the XLT phenotype, which is often confused with ITP (Bryant and Watts, 2011; Inoue et al., 2002; Lutskiy et al., 2002; Zhu 2002).

ECZEMA AND OTHER ATOPIC MANIFESTATIONS

Eczema is another characteristic finding (Fig. 43.1; Color Plate 43.II) that differentiates WAS from ITP (Wiskott, 1937). The typical skin lesions resemble acute or chronic eczema in nature and distribution. A history of eczema, mild or severe, transient or consistent, was reported by 81 percent of WAS patients (Sullivan et al., 1994). In the most severe cases, eczema is resistant to therapy and may persist into adulthood. Molluscum contagiosum, herpes simplex, or bacterial infections may develop in areas of the skin affected with eczema, often posing a therapeutic challenge. Patients with the XLT phenotype have either mild and transient eczema or none at all (Albert et al., 2010; Imai et al., 2004; Jin et al., 2004). Bacterial antigens appear to play an important role in the persistence of chronic eczema, because the skin lesions of WAS patients often respond promptly to treatment with systemic antibiotics. It has been hypothesized that defective chemotaxis of dendritic and Langerhans cells may play a role in generating T cells responsible for the development of atopic diathesis involving the skin (Thrasher et al., 1998). This hypothesis is further supported by the observation that eczema disappears during

conditioning but before the infusion of donor hematopoietic stem cells has occurred. The eczema tends to be worse in families with atopic diathesis, a finding suggesting that other genes responsible for allergies may have a modifying effect.

Some WAS patients develop allergies to certain foods or drugs, and exposure to these antigens may result in anaphylactic shock.

AUTOIMMUNE MANIFESTATIONS

Autoimmune diseases are frequent, having been reported in 40 percent of a large cohort of WAS patients (Sullivan et al., 1994). The most common autoimmune manifestation observed has been hemolytic anemia, followed by vasculitis involving both small and large vessels (McCluggage et al., 1999; Merlini et al., 2009), renal disease, Henoch-Schönlein–like purpura, and inflammatory bowel disease. Other less frequent autoimmune diseases include neutropenia, dermatomyositis, recurrent angioedema, uveitis, and cerebral vasculitis. Infants with severe refractory thrombocytopenia were recently identified as a subset of a large cohort of WAS/XLT patients with poor prognosis and considered to represent autoimmune thrombocytopenia ((Mahlaoui N., et al., 2013). A comprehensive report from a single center in France of risk factors, clinical features, and outcome of autoimmune complications in WAS further underlines the importance of this problem (Dupuis-Girod et al., 2003). Of 55 WAS patients, 40 had at least one autoimmune or inflammatory complication. Autoimmune hemolytic anemia was detected in 20 patients with onset before the age of 5 years. Arthritis was present in 29 percent, neutropenia in 25 percent, vasculitis including cerebral vasculitis in 29 percent, inflammatory bowel disease in 9 percent, and renal disease in 3 percent. A high serum IgM concentration was a significant risk factor for the development of autoimmune disease or early death. Of 15 patients with high serum IgM levels, 14 developed autoimmune hemolytic anemia. In contrast, low serum IgM concentration (a frequently observed finding in WAS/XLT) was a marker of a favorable prognosis. In a recent study by the European Bone Marrow Transplantation/ESID Working Party, autoimmune diseases were observed in 21 of 97 long-term survivors following hematopoietic stem cell transplantation. Of those with partial (mixed) chimerism, the incidence was 67 percent compared with only 14 percent in those with full chimerism (Ozsahin et al., 2008).

The incidence of autoimmune diseases in XLT patients is substantially less frequent than in classic WAS (Albert et al., 2010; Sullivan et al., 1994). Autoimmune complications were reported by 21 of 173 XLT patients enrolled in a worldwide retrospective study, with autoimmune nephropathy and hemolytic anemia being the most frequent manifestations. IgA nephropathy, with or without Henoch-Schönlein purpura, often causing chronic renal failure requiring dialysis or renal transplantation, was a frequent complication in Japanese patients with the XLT phenotype (Becker-Herman et al., 2011; Albert et al., 2010; Imai et al., 2004).

Several mechanisms may contribute to the pathophysiology of autoimmunity in WAS, including impaired function of regulatory T cells, defective phagocytosis of apoptotic cells, reduced apoptosis of activated lymphocytes, impaired secretion of Fas ligand, and B-cell intrinsic abnormalities (Humblet-Baron et al., 2007; Leverrier et al., 2001; Maillard et al., 2007; Marangoni et al., 2009; Meyer-Bahlburg et al., 2008; Nikolov et al., 2010; Recher et al., 2012).

MALIGNANCIES

Malignancies can occur during childhood but are more frequent in adolescents and young adults with the classic WAS phenotype (Brand and Marinkovich, 1969; Cotelingam et al., 1985; Kildeberg 1961; Sullivan et al., 1994; ten Bensel et al., 1966). In a large North American cohort, malignancies were present in 13 percent (Sullivan et al., 1994), the average age at onset of malignancies being 9.5 years. Considering the increasing life expectancy, it is reasonable to assume that the incidence of malignancies will further increase as (untransplanted) WAS patients get older. The most frequent malignancy reported is lymphoma, usually an EBV-positive B-cell lymphoma, which suggests a direct relationship with a defective immune system. Only 3 of 21 tumors—1 glioma, 1 acoustic neuroma, and 1 testicular carcinoma—were not of lymphoreticular origin (Sullivan et al., 1994). WAS-associated malignancies have a poor prognosis, as illustrated by the fact that only 1 of the 21 patients who developed a malignancy was alive more than 2 years after establishing the diagnosis. Bone marrow transplantation was attempted in five WAS patients with malignancies, but none survived more than 6 months (Sullivan et al., 1994). The incidence of malignancies in patients with the XLT phenotype is unknown but is less than in classic WAS. In a retrospective analysis, 9 of 173 XLT patients (5.2 percent) developed malignancies (Albert et al., 2010). The majority (n = 5) were of lymphoid origin; other malignancies reported included spinalioma, seminoma, pancreatic cancer, and myelodysplastic syndrome. Six of the nine patients had died of malignancies at the time of analysis.

LABORATORY FINDINGS

BLOOD CELL ABNORMALITIES

The finding that WASp is expressed in $CD34^+$ stem cells (Wengler et al., 1995) is compatible with the observation that in WAS all hematopoietic stem cell-derived lineages of nucleated cells are functionally abnormal, including lymphocytes, regulatory T cells, NK and NKT cells, neutrophils, macrophages, dendritic cells, and platelets.

The most consistent laboratory abnormality for both WAS and XLT is thrombocytopenia, associated with small platelet size. The other two findings of the classic triad of thrombocytopenia, immunodeficiency, and eczema are often absent at the initial evaluation, even in those developing a classic WAS phenotype later in life (Sullivan et al., 1994). Laboratory evidence to establish the diagnosis is therefore of prime necessity. Moderately severe lymphopenia is a consistent finding in patients with classic WAS (Ochs et al., 1980) and may be present at an early age (Park et al., 2004).

Abnormal function of T and B lymphocytes, regulatory T cells, and NK cells is generally associated with classic WAS. Absence or a reduced quantity of WASp in lymphocytes of WAS/XLT patients is the best confirmatory test (short of mutation analysis), allowing rapid diagnosis by a simple flow-cytometric technique (Yamada et al., 1999).

Iron-deficiency anemia is common in infants and children with WAS/XLT because of the constant loss of red blood cells. This can be corrected with increased dietary intake of iron. Chronic infection may further impair the production of red blood cells. Autoimmune Coombs-positive hemolytic anemia is a frequent complication (Sullivan et al., 1994) and needs to be recognized early for proper therapy.

The thrombocytopenia and small platelet size are present at birth, are persistent, and as a rule do not respond to prednisone or high-dose IVIG. Platelet counts may vary and are usually between 10,000 and 40,000 platelets/mm^3. During infection or acute autoimmune disease, the number of platelets may temporarily increase, without increasing in size. Thrombocytopenia may be intermittent in patients with characteristic missense mutations (Notarangelo et al., 2002) or absent, as in boys with X-linked neutropenia due to mutations within the Cdc42-binding site (Ancliff et al., 2006; Beel et al., 2009; Burns et al., 2004; Devriendt et al., 2001; Moulding et al., 2007).

OTHER ABNORMALITIES

Patients with WAS respond to infections or to autoimmune diseases with increased sedimentation rates and elevated C-reactive protein (CRP). Vasculitis is a common complication affecting small and large arteries (Ilowite et al., 1986). An unexpected high frequency of aortic aneurysms, four affecting the thoracic and one the abdominal aorta, were observed in a cohort of 38 WAS patients during routine imaging procedures (Pellier et al., 2011). Deposits of IgA-containing immune complexes were found in purpuric skin lesions and in the small bowel of a WAS patient with a Henoch-Schönlein purpura–like vasculitis (H. D. Ochs, unpublished observation). Hemolytic anemia is often due to a warm autoantibody to red blood cell surface antigens that can be demonstrated by direct or indirect Coombs test.

RADIOLOGICAL FINDINGS

X-ray films may reveal chronic lung disease, sinusitis, or mastoiditis. Subperiosteal hemorrhage is seen occasionally. Arteriograms, CT scans, or ultrasounds are useful for the detection of aneurysms (McCluggage et al., 1999; Merlini et al., 2009; Pellier et al., 2011). Brain scans are used if cerebral hemorrhage is expected.

HISTOPATHOLOGY

The lymphoid tissue and thymus are prime targets for pathological changes in patients with *WAS* mutations, although the degree of involvement varies considerably. A gradual loss of cellular elements occurs in the thymus and lymphoid organs (Cooper et al., 1968). The pathological findings in lymph nodes and spleens from WAS patients consistently reveal depletion of small lymphocytes from T-cell areas, prominence of the reticulum cell stroma, the presence of atypical plasma cells with and without plasmacytosis, and extramedullary hematopoiesis (Snover et al., 1981). Progressive depletion of germinal centers is also observed (Fig. 43.2; Color Plate 43.I). In a study of spleens obtained from XLT and WAS patients undergoing splenectomy, a significant depletion of the white pulp was noticed. This depletion was not limited to the T cell-dependent area but also involved the B-cell compartment. Specifically, a remarkable depletion of the marginal zone (MZ) was observed in WAS patients, an abnormality that may be directly responsible for the defective antibody response to polysaccharide and selected protein antigens. There was a strong correlation between morphological abnormalities in the splenic tissue and the clinical severity of the disease (Vermi et al., 1999). Patients with severe disease (scores of 4 and 5) had more severe depletion of the white pulp, including the T-cell area, B-cell area, and MZ thickness, than patients with lower scores (2 or 3). The lymphoid tissues and follicles of the gastrointestinal (GI) tract are usually normal (Cooper et al., 1968), although GI lymphoid depletion may occur (Wolff, 1957).

A variable degree of thymic hypoplasia has been observed. Cooper et al. (1968) described normal thymic architecture, normal corticomedullary differentiation, and intact Hassall's corpuscles despite a small thymus. Wolff (1967) reported two patients with thymic pathology, one with thymic hypoplasia and the other with thymic atrophy. The surface of peripheral blood lymphocytes from WAS patients, when scanned by electron microscopy, is devoid of microvillous projections, compared with normal lymphocytes (Fig. 43.4; Kenney et al., 1986). However, other studies indicate that WASp deficiency allows an intact microvilli organization, strongly suggesting that WASp is dispensable for lymphocyte microvilli formation (Majstoravich et al., 2004). This finding is in keeping with the notion that WASp-mediated Arp2/3 activation results in the formation of a network of short-acting filaments bound in

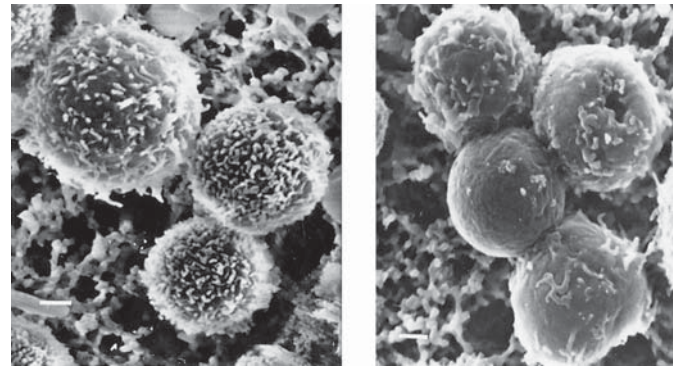

Figure 43.4 Scanning electron micrographs of normal T cells (*left*) and WAS T cells (*right*). The abundant microvilli covering the surface of the normal T cells are absent or sparse on the WAS T cells (from Kenney et al., 1986).

an end-to-side manner, as observed in macrophage and dendritic cell ruffles, whereas microvilli are composed of parallel bundles of side-to-side–linked actin filaments.

MOLECULAR BASIS

Through study of DNA from WAS families with multiple affected members, the *WAS* gene was mapped to the region Xp11.22-Xp11.3 (Kwan et al., 1991) and was then cloned by Derry et al. (1994), who demonstrated mutations in lymphoblastoid cell lines derived from WAS patients.

STRUCTURE OF WAS

The *WAS* gene consists of 12 exons spanning 9 kb of genomic DNA (Fig. 43.5). The 1,821 base pair cDNA generates a protein of 502 amino acids with a predicted molecular weight of 54 kDa. WASp is constitutively expressed in all hematopoietic stem cell-derived lineages and located predominantly in the cytoplasmic compartment, with the highest protein density being along the cell membrane (Rivero-Lezcano et al., 1995; Zhu et al., 1997). WASp is a key member of a family of proteins that link signaling pathways to actin cytoskeleton reorganization by activating Arp2/3-mediated nucleation of branched actin filaments. Several functional domains based on the genomic structure of WASp have been identified (Fig. 43.5), including the N-terminal WASp homology 1 (WH1) domain, a basic region (BR), a GTPase binding domain (GBD)/Cdc42 Rac Interactive Binding (CRIB) motif, a poly-proline region (PPR), a verprolin (V) homology domain, a cofilin (C) homology domain, and a C-terminal acidic (A) region (VCA) (Burns et al., 2004; Miki et al., 1996; Symons et al., 1996; Thrasher, 2002; Thrasher and Burns, 2010).

WASP HOMOLOGY 1 DOMAIN

The WH1 domain (also referred to as EVH1, Ena/VASP homology domain 1) is located close to the N-terminal region of WASp and N-WASp (a broadly expressed homolog of WASp). It includes a pleckstrin homology domain that is considered important for intracellular localization of WASp, through interactions with other proteins or lipids (Lemmon et al., 1996). Some data suggest that phosphatidylinositol 4,5 biphosphate (PIP_2) binds to the WH1 domain of WASp and N-WASp, resulting in PIP_2-dependent actin polymerization (Miki et al., 1996), but other observations indicate that PIP2 binds to the BR domain (Prehoda et al., 2000; Rohatgi et al.,

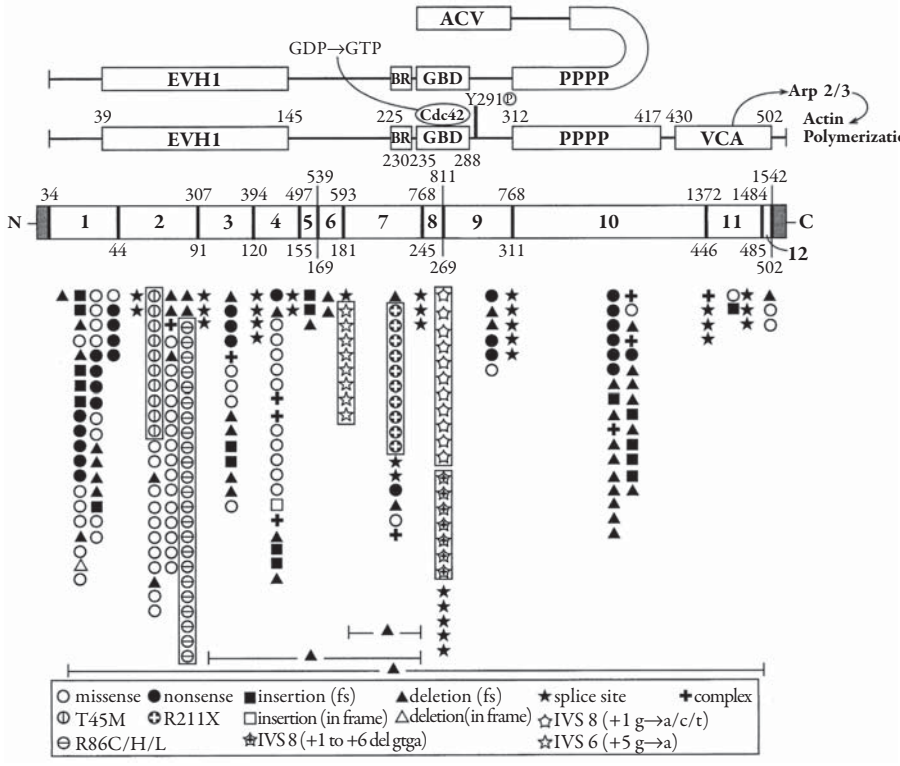

Figure 43.5 Schematic representation of the *WAS* gene, consisting of 12 exons (*center*). The top panels illustrate the major functional WASp domains and autoinhibition of WASp. The VCA domain interacts with a region from residues 242 to 310, which include the C-terminal part of the GBD (Kim et al., 2000). If Cdc42 is activated (GDP → GTP), WASP assumes the active form, allowing the C-terminal VCA domain to freely interact with Arp2/3 to initiate actin polymerization (see text for details). The *WAS* gene mutations identified in WAS families cared for in three centers (Seattle, Brescia, and Tokyo) are visualized according to their location in the exons and the exon–intron junctions. Each symbol represents a single WAS family. Missense mutations are located mostly in exons 1–4; deletions and insertions are distributed throughout the *WAS* gene; and splice-site mutations are found predominantly in introns 6, 8, 9, and 10. Arp2/3, actin-related protein 2/3; Br, basic region; EVH1, Ena/VASP homology 1 domain; GBD, GTPase binding domain; PPPP, proline-rich region; VCA, verpolin/cofilin homology domains/acidic region.

2000). There is evidence that PIP_2 synergizes with Cdc42 to fully activate WASp/N-WASp in vitro (Higgs and Pollard, 2000; Rohatgi et al., 2000).

Furthermore, the WH1 domain of WASp allows interaction with the WASp-interacting protein (WIP) (Ramesh et al., 1997). In resting lymphocytes, WASp/N-WASp constitutively associates with WIP, stabilizing WASp in its inactive conformation (Martinez-Quiles et al., 2001; Sasahara et al., 2002; Volkman et al., 2002). In keeping with this, WIP knockout mice show markedly reduced cellular levels of WASp. This defect can be partially reversed by treatment with calpain or proteasome inhibitors, indicating that WIP acts as a WASp chaperone by protecting it from protease- and proteasome-mediated degradation (Chou et al., 2006; de la Fuente et al., 2007). Missense mutations in the WH1 domain of WASp that impair interaction with WIP result in reduced levels of WASp without affecting its ability to bind Arp2/3 and to induce actin polymerization (Ramesh and Geha, 2009). These mutations in humans are most often associated with XLT (Imai et al., 2003). Following engagement of the T-cell antigen receptor, WIP also binds to the adaptor Crkl, which is part of a multimolecular complex that includes Crkl, WIP, and WASp, and is recruited by ZAP-70 to lipid rafts and the immunological synapse. TCR ligation causes protein kinase Cθ (PKCθ)-dependent WIP phosphorylation and disengagement of WASp from the WIP/WASp complex, thus allowing WASp activation by Cdc42 (Moreau et al., 2000; Sasahara et al., 2002). This leads to actin polymerization and stabilization of actin filaments (Volkman et al., 2002). The importance of WIP for stabilization of WASp was illustrated by a WIP-deficient patient due to a homozygous nonsense mutation in the *WIPF1* gene that resulted in lack of both WIP and WASp in patient leukocytes (vide infra) (Lanzi et al., 2012).

GTPASE-BINDING DOMAIN

The GBD is encoded by exons 7 and 8 of the *WAS* gene (Abdul-Manan et al., 1999; Aspenström et al., 1996; Kolluri et al., 1996; Symons et al., 1996) and allows interaction with Cdc42, a member of the Rho family of GTPases that regulates the formation of filopodia and controls cell polarity and chemotaxis (Hall, 1998). Like other proteins containing a GBD motif, WASp recognizes the GTP-bound but not the GDP-bound form of Cdc42 and binds to Cdc42-GTP with a 500-fold greater affinity than to Cdc42-GDP (Rudolph et al., 1998).

Computer modeling and binding experiments strongly suggest an autoinhibitory contact between the GBD and the carboxy-terminal region of WASp, which can be released by the activated (GTP) form of Cdc42 (Kim et al., 2000). Rho-like GTPases such as Cdc42 and Rac are key elements in the dynamic organization of the actin cytoskeleton (Lamarche et al., 1996). Thus, the GBD may have a direct effect on actin polymerization and an indirect effect on the interaction of the C terminus of WASp with the Arp2/3 actin nucleating complex (Fig. 43.5).

Toca-1 protein (transducer of Cdc42-dependent actin assembly) has been recognized as a crucial intermediate required for Cdc42/N-WASp/Arp2/3 complex-induced actin polymerization (Ho et al., 2004). To mediate Cdc42-induced activation of purified N-WASp by Toca-1, N-WASp must be complexed with WIP, thus demonstrating the importance of the WASp/N-WASp-WIP interaction in the regulation of actin polymerization.

POLY-PROLINE-RICH DOMAIN

A proline-rich region encoded by exon 10 contains the PXXP binding consensus for SH3 binding domains. WASp was shown to interact with SH3 domains of selected signaling molecules, including the cytosolic adaptor prtoeins, Grb2, $p47^{nck}$, Fyn, cFgr, Lck, c-Src, $p47^{phox}$, and proline-serine-threonine phosphatase-interacting protein 1 (PSTPIP1). WASp also interacts with the Tec family cytoplasmic tyrosin kinases, Btk, Tec, PLC-γ1, and Itk. This interaction may influence the localization of WASp and contribute to the conformational changes of WASp by regulating its phosphorylation. These observations suggest that WASp, through its interaction with the SH3 domain of multiple but selected molecules, plays an important role in cytoplasmic signaling of hematopoietic cells (reviewed in Imai et al., 2003). The proline-rich region is also required for the optimal actin polymerization activity of WASp (Castellano et al., 2001; Yarar et al., 2002) and for the recruitment of WASp to the immune synapse formed between T cells and antigen-presenting cells (Badour et al., 2003; Barda-Saad et al., 2005; Cannon et al., 2001).

VERPROLIN/COFILIN/ACIDIC REGION DOMAIN

The VCA domain, located in the C-terminus of WASp, plays a key role in the regulation of actin polymerization (Miki et al., 1996; Notarangelo and Ochs, 2003; Padrick and Rosen, 2010; Snapper and Rosen, 2003). If WASp is activated by GTP-Cdc42, the C-terminal region binds to Arp2 and Arp3 and to five unique polypeptides. WASp dimerization by SH3 domain proteins such as Nck, Grb2, Fyn, and PLC-γ1 has also been shown to increase the affinity of WASp for the Arp2/3 complex (Padrick et al., 2008). The actin monomer that binds to the VCA domain of WASp appears to be added to the Arp2/3 complex, thus promoting nucleation of the new daughter filament (Weaver et al., 2003).

FUNCTION AND REGULATION OF WASP

WASp, with its multifunctional domains, is responsible for key tasks of hematopoietic cells. The progress made over the past 10 years in understanding the biological functions of this complex protein has provided new insight into the pathogenesis and clinical presentation of WAS and XLT. WASp is expressed in $CD34^+$ hematopoietic precursors and in all lineage-committed cells. Carrier females of classic WAS show a nonrandom pattern of X chromosome inactivation in $CD34^+$ precursors and in all subsequent blood cell lineages (Wengler et al., 1995). This observation, along with evidence that hematopoietic stem cell (HSC) migration is defective

in *was*$^{+/-}$ mice (Lacout et al., 2003), suggested that WASp-deficient stem cells fail to transit successfully from the fetal liver to the bone marrow. However, more recent data have shown that the HSC compartment of *was*$^{+/-}$ mice contains an equal proportion of WASp-positive and WASp-negative cells. Progressive selection in favor of WASp-expressing cells is observed during lymphoid differentiation, especially in more mature cells (Meyer-Bahlburg et al., 2008; Westerberg et al., 2010). Furthermore, carrier females of XLT often show a residual proportion of WASp-negative cells, especially in the myeloid compartment. Taken together, these data indicate that WASp plays an important role especially at later stages in hematopoietic and lymphoid differentiation, and that this effect is more prominent in the lymphoid than in the myeloid compartment.

CYTOSKELETON AND ACTIN POLYMERIZATION

WASp is a key member of a family of proteins that link signaling pathways to actin cytoskeleton reorganization by activating Arp2/3-mediated actin polymerization (Takenawa and Suetsugu, 2007). This concept was suggested by Facchetti et al. (1998), who observed that the distribution of F-actin in EBV-transformed B lymphoblastoid cell lines from patients with classic WAS who lacked WASp was markedly reduced or completely absent compared with XLT subjects, who expressed reduced amounts of mutated WASp, and normal controls. In addition, cytoplasmic projections containing F-actin, recognizable as microvilli, were reduced in patients with WAS but not in patients with XLT.

Actin polymerization is initiated by the actin-related proteins (Arp), a group of proteins involved in the regulation of the actin cytoskeleton. WASp interacts directly with two of these proteins, Arp2 and Arp3, which form the Arp2/3 complex, leading to actin nucleation and formation of actin filaments (Carlier et al., 1999).

The binding of WASp to the Arp2/3 complex is mediated by the C-terminal acidic (A) region, which is preceded by the VC homology domain. This process is regulated by conformational changes in N-WASp (Rohatgi et al., 1999) and in WASp (Kim et al., 2000) by allosteric relief of autoinhibition through activation of Cdc42 and PIP_2 and by dimerization of WASp (Padrick et al., 2008). As discussed earlier, WASp is present in two configurations. In the active form, the C terminus of WASp is free to interact with the Arp2/3 complex; in the inactive form, the VCA domains interact with the hydrophobic core of the GBD. This binding is reinforced by the interaction of the acidic region (A) with a BR located N-terminal to the GBD (Kim et al., 2000). To revert to the active form, GTP-bound Cdc42 and PIP_2 cooperatively disrupt this autoinhibitory loop and release the C-terminal region for binding to the Arp2/3 complex (Fig. 43.5).

The importance of this self-inhibitory mechanism is exemplified by the observation that point mutations within the GBD of WASp can cause congenital X-linked neutropenia (XLN); these activating (gain-of-function) mutations will interfere with the autoinhibitory contact of the C terminus of WASp with the GBD, resulting in a permanently "active" configuration of WASp (Ancliff et al., 2006; Beel et al., 2009; Burns et al., 2004; Devriendt et al., 2001; Moulding et al., 2007). This unregulated activation of the actin cytoskeleton promotes hematopoietic cell death by enhanced apoptosis affecting mainly myeloid progenitors (Burns et al., 2004). Furthermore, lymphocytes from a patient with XLN (due to I294T mutation) displayed abnormal microvilli architecture and increased content of F-actin and failed to roll normally on L-selectin ligand under flow (Burns et al., 2010). Activating WASp mutations observed in XLN patients (L27OP; I294T) were studied for their effect on lymphocytes in knock-in mouse models generated by using RAG-2–deficient blastocyst complementation with target ES cells. Both activating WASp mutations led to enhanced actin polymerization, altered cytoskeletal responses, and genomic instability (Westerberg et al., 2010).

INTRACELLULAR SIGNALING

The proline-rich domain of WASp interacts with SH3 domains of selected cytoplasmic proteins, a finding suggesting that WASp is involved in intracellular signaling of hematopoietic cells. Phosphorylation by tyrosine kinases regulates signal transduction by connecting upstream cell-surface receptors to downstream pathways. WASp itself undergoes tyrosine phosphorylation following adherence of platelets to collagen (Oda et al., 1998). Baba et al. (1999) identified WASp as one of the major phosphoproteins associated with Btk. Together with Lyn and Btk, Hck has been shown to effectively mediate phosphorylation of WASp Tyr291 (Scott et al., 2002). Tyr291 is conserved in N-WASp and is positioned adjacent to the Cdc42 binding site. Phosphorylation of Tyr291 stabilizes the active conformation of WASp and exposes the VCA domain, allowing interaction with the Arp2/3 complex and enhancement of cytoskeletal reorganization, which is required for the formation of podosomes and filapodia (Cory et al., 2002). Dephosphorylation of Tyr291 by the tyrosine phosphatase PTP-PEST, by contrast, favors the formation of the autoinhibitory structure of WASp (Cote et al., 2002). To confirm the critical role played by Tyr291 phosphorylation, the homolog residue in mice (Tyr293) was replaced by Phe, thus preventing phosphorylation. Tyr293Phe knock-in mice develop significant immunodeficiency (Blundell et al., 2009). On the other hand, mice carrying the Tyr293Glu mutation (that mimics constitutive phosphorylation, as also observed in XLN patients with Tyr291Glu mutation) show reduced levels of WASp, which can be partially restored in vitro by proteasome inhibitors (Blundell et al., 2009). These data suggest that phosphorylation of Tyr291 may target WASp to proteasome-mediated degradation.

The proline-rich region of WASp allows binding to the SH3 domain of the linker protein, PSTPIP1, and may thus allow interaction with the CD2-associated protein CD2AP and recruitment of WASp to the immunological synapse (Badour et al., 2003).

T-cell antigen receptor engagement is crucial for the cytoplasmic signaling events that lead to cytoskeletal reorganization

through actin polymerization. This process is essential for cellular shape change, cellular movement, and immune synapse formation. Recruitment of WASp to the site of actin polymerization depends on a series of biochemical events that follow TCR engagement. In mature T lymphocytes, activation of the TCR results in the phosphorylation of multiple tyrosine residues of LAT (linker for activation of T cells) and SLP-76, which leads to the migration of Nck and WASp to the cell periphery, where these molecules accumulate at an actin-rich circumferential ring. This process ensures that the actin polymerization machinery is carried to the plasma membrane in the vicinity of the activated TCR. These events have been confirmed by direct visualization of the dynamic complexity of molecular recruitment, molecular interactions, and actin polymerization in single living cells in time and space (Barda-Saad et al., 2005). Impaired intracellular signaling is responsible for defective nuclear translocation of NFAT and reduced secretion of IL-2 upon in vitro activation of WASp-deficient T lymphocytes (Cianferoni et al., 2005).

In the absence of WASp, impaired TCR-mediated activation in response to glycolipid antigens affects also the function of invariant NK T (iNKT) lymphocytes, with reduced secretion of IL-4 and IFN-γ (Astrakhan et al., 2009; Locci et al., 2009).

WAS mutations also affect intracellular signaling and cytolytic activity of NK cells. Various mechanisms account for these defects, including poor immune synapse formation between NK lymphocytes and target cells, impaired signaling through CD16 and the activating receptor NKp46, and defective activation of NK cells following interaction with dendritic cells (Borg et al., 2004; Gismondi et al., 2004; Orange et al., 2002).

Reduced toxicity by CTL lines, established from WAS patients, against tumor B-cell lines may contribute to the development of hematological malignancies that are common in WAS (De Meester et al., 2010). Although WAS CTLs expressed normal levels of lytic molecules, the lytic granules appeared not to fully polarize toward the center of the CTL–tumor target cell contact area, compatible with defective synapse formation.

Finally, WASp participates also in integrin- and B-cell receptor (BCR)–mediated signaling of B lymphocytes, and defective WASp signaling may contribute to impaired retention of the MZ B cells (Meyer-Bahlburg et al., 2008) and to defective B-cell activation.

WASP PLAYS A ROLE IN TRANSCRIPTIONAL REGULATION OF TH1 IMMUNITY

Defective TH1 cytokine production by TH lymphocytes from WAS patients is associated with defective induction of the "TH1 master regulator," T-BET (Trifari et al., 2006). An explanation for this abnormality was recently proposed by Taylor et al., who provided evidence that WASp locates to the nucleus in normal lymphocytes, where it engages many TH-specific immune function genes under TH1-differentiating conditions (Taylor et al., 2010). WASp was found in differentiating TH1 cells at the proximal promoter locus of the *TBX21* gene, which encodes the transcription factor T-BET, as part of two distinct histone-modifying complexes (H3K4 trimethyltransferase and H3K9 trimethylase). This epigenetic molecular mechanism to regulate T-BET expression is severely impaired in TH1 cells from patients with classic WAS who lack WASp. In contrast, XLT patients with missense mutations that allow expression of mutated WASp display TBX21 dynamics that are similar to those in normal TH1 cells

CHEMOTAXIS AND PHAGOCYTOSIS

Podosomes are highly dynamic adhesion structures that are mainly found in monocytes, macrophages, osteoclasts, and dendritic cells (Monypenny et al., 2011). WAS macrophages are completely devoid of podosomes (Linder et al., 1999), resulting in defective adhesion and orientation in a chemotactic gradient (Badolato et al., 1998). Wasp-deficient murine dendritic cells fail to establish a leading edge, show defective attachment and detachment on fibronectin-coated surfaces, and display lack of chemokinesis to the chemokine CCL21 (de Noronha et al., 2005). Consequently, migration of Langerhans cells from the skin to the draining lymph node (Snapper et al., 2005) and accumulation of dendritic cells in the T-cell area of the spleen following immunization are impaired in wasp-deficient mice. Along with abnormal formation of the immunological synapse between dendritic cells and T lymphocytes (Pulecio et al., 2008), the impaired migration of dendritic cells may play a role in defective T-cell priming (Bouma et al., 2007).

Involvement of WASp in IgG-mediated phagocytosis has been demonstrated by the observation that this FcγR-dependent process is impaired in WASp-deficient peripheral blood macrophages (Lorenzi et al., 2000). In normal macrophages, WASp itself is actively recruited to the "actin cup"; in WASp-deficient macrophages, formation of the actin cup and local recruitment of tyrosine-phosphorylated proteins are markedly reduced. These findings suggest that the cytoskeletal structure responsible for phagocytosis is dependent on WASp expression. Clearance of apoptotic cells by macrophages and dendritic cells requires recruitment of WASp to the phagocytic cup. Lack of WASp results in delayed phagocytosis, both in vitro and in vivo (Leverrier et al., 2001). Interestingly, phagocytosis of particulate antigens is impaired also in macrophages from patients with X-linked neutropenia due to constitutive activation of WASp (Ancliff et al., 2006).

Reduced chemotaxis of WASp-deficient neutrophils was reported in WAS patients (Ochs et al., 1980) and in *was*$^{-/-}$ mice, both in vitro and in vivo (Snapper et al., 2005). Deficiency of WASp also leads to abnormal migration of T lymphocytes. *Was*$^{-/-}$ murine T cells respond with reduced migration when exposed to the chemokine CCL19, leading to impaired homing of T cells into the Peyer's patches (Snapper et al., 2005). On the other hand, impaired response of *was*$^{-/-}$ MZ B cells to S1P1 may contribute to the abnormalities of the MZ associated with WASp deficiency (Meyer-Bahlburg et al., 2008; Westerberg et al., 2008). Finally, NK lymphocytes from patients with WAS or with XLT show reduced chemotaxis in response to CXCL12 and CX3CL1, with reduced adherence

to ICAM-1 and VCAM-1 (Stabile et al., 2010). In contrast, T and B lymphocytes from mice with activating wasp mutations show normal chemotactic responses, but impaired adhesion and spreading (Westerberg et al., 2010).

ACCELERATED APOPTOSIS

A correlation between actin cytoskeletal function, mutations of WASp, and programmed cell death has been suggested (Kothakota et al., 1997; Melamed and Gelfand, 1999; Rawlings et al., 1999; Rengan et al., 2000). The morphological changes that occur during apoptosis require actin cytoskeletal remodeling, a process necessary for the execution of programmed cell death. Defective actin polymerization may explain the accelerated in vitro cell death of lymphocytes and the progressive cellular and humoral immunodeficiency observed in individuals with classic WAS.

The precise role of WASp in apoptosis is not clearly defined. The downregulation of a cell survival pathway or, conversely, the upregulation of a cell death pathway in WAS lymphocytes has been considered. Accordingly, reduced Bcl-2 expression (Rawlings et al., 1999) and increased expression of caspase-3 and the cell death receptor CD95 (Fas) (Rengan et al., 2000) by WAS lymphocytes, compared with that in XLT and control lymphocytes, have been reported.

MUTATION ANALYSIS

The cloning and sequencing of the gene responsible for WAS and XLT have provided a powerful tool for confirming the diagnosis in affected males, identifying carrier females, and performing prenatal diagnosis. Techniques are available to screen peripheral blood lymphocytes, NK cells, monocytes, and platelets for the presence or absence of WASp, to estimate the quantity of WASp by Western blot analysis or flow cytometry, and to sequence genomic DNA and/or cDNA for mutations in the *WAS* gene. (The updated nomenclature is provided by the Human Genome Variation Society, www.hgvs.org, and by den Dunnen and Antonarakis, 2001.)

SPECTRUM OF WASP MUTATIONS

Following the discovery of the gene responsible for WAS and XLT (Derry et al., 1994), large series of *WAS* mutation analyses were reported from clinical centers throughout Europe, North America, and Asia (Albert et al., 2010; Gulacsy et al., 2011; Imai et al., 2004; Jin et al., 2004) (see WASPbase at: http://bioinf.uta.fi/WASbase). Figure 43.5 summarizes the results of sequencing studies computed from three centers (Imai et al., 2004; Jin et al., 2004). Participants in these studies included natives of North, Central, and South America, Western and Eastern Europe, the Middle East, Southeast Asia, and Japan. As expected, the incidence and type of mutations are similar in all parts of the globe. In this cohort of 270 families with a total of 312 patients, 158 unique *WAS* mutations where identified. As shown in Table 43.1, the most common mutations observed were missense mutations (n = 93 families), followed by splice-site mutations (n = 59), short deletions (n = 46), and nonsense mutations (n = 39). Insertions, complex mutations, and large deletions made up 12 percent of the mutations identified. Most deletions and insertions result in frameshift and early termination of transcription. In addition, unique missense mutations within the GBD/Cdc42 binding domain have been reported to cause X-linked neutropenia (XLN, MIM300299) with a clinical phenotype very different from classic WAS/XLT. XLN, a rare form of severe congenital neutropenia (Boztug and Klein, 2009), was originally described in a three-generation family with five affected members that had an Leu270Pro mutation in the GBD/Cdc42 binding domain of WASp (Devriendt et al., 2001). Subsequently, additional families with missense mutations in this domain were reported. Affected members of two families with an Ile294Thr mutation, one family with a Ser272Pro, and one with an Ile276Ser mutation had neutropenia and normal platelet counts but reduced numbers of NK cells and abnormal lymphocyte proliferation in response to anti-CD3 stimulation (Ancliff et al., 2006; Beel et al., 2009). It was suggested that these "gain-of-function" mutations result in profound reduction in neutrophil production and/or increased apoptosis, the latter being observed in cultured patient-derived bone marrow progenitors. These findings are consistent with an intrinsic disturbance of normal myeloid differentiation as a cause of the neutropenia (Ancliff et al., 2006; Moulding et al., 2007). Affected patients respond to treatment with G-CSF. However, two patients from the original Leu270Pro XLN kindred treated with G-CSF were recently reported as having developed a myelodysplastic syndrome and acute myelogenous leukemia, respectively, both with somatic mutations in the G-CSF receptor (*CSF3R*) gene and monosomy 7 in the leukemic cells (Beel and Vandenberghe, 2009).

As was observed in smaller series reported earlier and subsequently (Derry et al., 1994; Fillat et al., 2001; Greer et al., 1996; Itoh et al., 2000; Kwan et al., 1995; Lemahieu et al., 1999; Remold-O'Donnell et al., 1997; Schindelhauer et al., 1996; Schwartz et al., 1996; Schwarz 1996;; Villa et al., 1995; Wengler et al., 1995; Zhang et al., 2010; Zhu et al., 1995, 1997), the predominant mutations of WASp are amino acid substitutions, typically located in exons 1–4 (Fig. 43.5, Table 43.1). Only eight missense mutations, one each in exons 6, 9, 10, and 12 and two each in exons 7 and 11, were observed downstream of exon 4. One of those, Pro361Thr in exon 10, is the only missense mutation identified to date affecting a proline in the polyproline region of WASp. In addition, two unrelated families, both with the XLT phenotype, had a point mutation affecting the termination codon of exon 12 (503 X > S), resulting in the absence of WASp (Imai et al., 2004; Jin et al., 2004).

The second most common WASp mutations, splice-site alterations, occurred predominantly in the downstream half (introns 6–11) of the *WAS* gene, as has been reported by others (Lemahieu et al., 1999; Schwarz 1996; Wengler et al., 1995; Zhu et al., 1997). Of 31 unique splice-site mutations, 22 affected a donor site and 9 an acceptor site. Mutations involving variant splice sites resulted in multiple splicing

Table 43.1 DISTRIBUTION OF MUTATIONS IN 270 FAMILIES WITH WAS OR X-LINKED THROMBOCYTOPENIA

MUTATION TYPE	FAMILIES AFFECTED N (%)
Missense	93 (34.5)
Splice	59 (22)
Deletion	46 (17)
Nonsense	39 (14.5)
Insertion	19 (7)
Complex + large deletions	14 (5)
Total	270 (100)

products that often included small amounts of normal *WAS* cDNA. Insertions and short deletions typically involving less than 10 nucleotides resulted in most instances in frameshift and premature stop of translation. Complex mutations were rare, involving double missense mutations, point mutations followed by a deletion, or a combination of deletions and insertions. Four large deletions were observed, resulting in the loss of several exons. In one case, the entire WASp coding region was deleted. Of all deletions and insertions, 58 percent were due to "slippage" caused by the deletion or insertion of an extra nucleotide within a stretch of identical basis (Imai et al., 2004; Jin et al., 2004).

MUTATIONAL HOT SPOTS

In the 270 unrelated families studied (Imai et al., 2004; Jin et al., 2004), six mutational hot spots, defined as occurring in seven or more unrelated families (>2.5 percent), were identified (Table 43.2). Three were point mutations within the coding region; all three involved CpG dinucleotides (C > T or G > A) caused by methylation and deamination of a cytosine to a thymidine in a sense or antisense strand. The other three hot-spot mutations involved splice sites.

The 134 C > T mutation, found in 10 families, results in the substitution of threonine with methionine at position 45; the 256 C > N/257G > N mutations, observed in 23 unrelated families, result in the substitution of arginine at position 86 with either a serine, glycine, cystidine, histidine, or leucine. The 631 C > T mutation, which converts arginine at position 211 to a stop codon, was found in 10 families. The IVS 6 + 5 g > a (c.559+5G>A) mutation, present in eight unrelated families, results in both abnormal and normal splicing products. The IVS 8 + 1 g > n (c.777+1G>N) mutation, identified in 11 families, results in the deletion of exon 8, leading to frameshift and premature stop of translation. The IVS8 + 1 (c.777+1) to +6 del gtga, resulting in the deletion of exon 8, frameshift, and early termination, was found in seven unrelated families. These six mutations account for 25.6 percent of all families included in this study (Imai et al., 2004; Jin et al., 2004). Three of these six mutations (134 C > T, 256 C > N/257 G > N, and IVS 6 + 5 g > a) were consistently found in WASp-positive patients with a mild phenotype (XLT) and low score, whereas the three other mutations (631C > T, IVS 8 + 1g > n, and IVS 8 + 1 to + 6 del gtga) were predominantly WASp negative and had a high score ($p < 0.001$) (Table 43.2).

SPONTANEOUS REVERSION OF MUTATIONS

Somatic mosaicism due to spontaneous reversions of the causative mutations or second-site mutations that restore WASp expression were described as early as 1998 (Ariga et al., 1998, 2001; Boztug et al., 2007, 2008; Davis et al., 2008, 2010; Davis and Candotti, 2009; Du et al., 2006; Humblet-Baron et al., 2007; Lutskiy et al., 2005a, 2008; Stewart et al., 2007; Trifari et al., 2010; Wada et al., 2001, 2003;). In comparison to other primary immunodeficiency diseases, the occurrence of this phenomenon seems to be significantly more frequent in WAS patients. In most instances reversions were noticed in patients with the classic WAS phenotype and affected only mutations that lead to complete absence of the protein. These spontaneously occurring reversions result in leukocyte

Table 43.2 WASP HOT-SPOT MUTATIONS AND CLINICAL PHENOTYPE

MUTATION	AFFECTED FAMILIES (PATIENTS)	% OF TOTAL FAMILIES	PATIENTS WITH SCORES OF 1–2.5*	PATIENTS WITH SCORES OF 3–5
134C > T(T45M)	10 (11†)	3.7	10	1**
256C > N/257G>N (R86N)	23 (25)	8.5	23	2**
IVS6 + 5g > a, fs stop aa 190	8 (14)	3.0	11	3**
665C > T(R211X)	10 (11)	3.7	1	10
IVS8 + 1g > n, fs stop aa 246	11 (14 †)	4.1	5	7
IVS8 + 1 to + 6 del gtga, fs stop aa 246	7 (7)	2.6	1	6
Total	69 (82)	25.6	51	29

*A score between 2 and 3 is listed as a score of 2.5. Scores 1–2.5 are considered XLT; scores 3–5 represent the WAS phenotype.

†One patient with the T45M missense mutation and two patients with the IVS8 + 1g > a splice-site mutation could not be scored because of insufficient clinical data.

**Of the six patients with high scores, four developed autoimmune diseases and one died of lymphoma at age 44 years.

Three of the hot-spot mutations (T45M; R86N; IVS6 + 5g > a) are associated with low scores and three hot-spot mutations (R211X; IVS8 + 1g > n; IVS8 + 1 to + 6 del gtga) are associated with high scores ($p < 0.001$). fs, frameshift.

populations that express WASp at different degrees (Fig. 43.6; Color Plate 43.III). In 2006, an international party (Stewart et al., 2007) collected data demonstrating that approximately 11 percent of 272 WAS patients examined had significant reversions. WASp-expressing revertant peripheral blood lymphocytes were detected in infants as young as 3 months and in adult patients who were in their fourth decade of life (Davis et al., 2008; Stewart et al., 2007; Wada et al., 2003). All patients reported to date were found to have reversions within circulating lymphocytes, predominantly $CD8^+$ subsets (Boztug et al., 2008; Davis et al., 2008; Du et al., 2006; Stewart et al., 2007); in addition, some patients were found to have reversions in $CD4^+$ T cells (Boztug et al., 2008; Davis et al., 2008; Du et al., 2006; Lutskiy et al., 2008), NK cells (Boztug et al., 2008; Du et al., 2006; Lutskiy et al., 2005b), and rarely in B lymphocytes (Boztug et al., 2008; Lutskiy et al., 2008). Neither myeloid cells nor megakaryocytes (platelets) from WAS patients were ever found to have undergone a reversion. Interestingly, $WASp^+$ Tregs were found in vivo to exhibit a marked selective advantage in a classic WAS patient with a spontaneous revertant mutation (Humblet-Baron et al., 2007), strongly suggesting that altered Treg fitness likely explains the autoimmune features in human WAS. The development of significant populations of revertant cells in WAS patients involves at least two steps: (1) a spontaneous reversion of the causative mutation or a second-site mutation in the *WAS* gene sequence that restores expression of WASp and possibly its function and (2) the in vivo selection/enrichment for the revertant cells with partial or full restoration of WASp expression and biological function. The mechanism of this molecular reversion is unknown and may involve errors in DNA polymerase or DNA repair activity, mutation-prone sequences, or exposure to toxic environmental events. The observation that in some patients the reverted cells carried multiple different second-site mutations, resulting in different missense mutations, suggests that certain sequences in the *WAS* gene are specifically susceptible to reversion. One such patient carrying a C995G nonsense mutation (Arg321X) in exon 10 developed reversions that included synonymous and nonsynonymous changes within the nucleotide triplet harboring the original mutation and a variety of nucleotide substitutions and deletions at variable distances from the C995 position that restored WASp expression by splicing out the original mutation (Davis et al., 2008). Interestingly, two brothers with a nonsense mutation in exon 1 (c.C58T; p.Gln20X) were found to have $WASp^+$ cell populations among T and B lymphocytes and NK cells that carried multiple second-site mutations, resulting in different missense mutations with discordant distribution in both siblings (Boztug et al., 2008).

An unsolved question is whether the restored or altered WAS protein is functional. Some patients with reversions are judged to demonstrate clinical improvement with time (Boztug et al., 2008), whereas other investigators note that despite the high proportion of functional revertant T cells, the patients still suffer from severe infections and autoimmune disorders (Trifari et al., 2010). This lack of clinical improvement was observed in patients whose $WASp^+$ revertant T cells exhibited a diversified TCR Vβ distribution and normal responses to TCR stimulation by anti-CD3 (Trifari et al., 2010). Although it is unclear in which precursor cells the reversions originated, these observations suggest that gene therapy by inserting a normal gene into hematopoietic stem cells is likely to result in normalization of T- and NK-cell and possibly B- and Treg-cell function. These results

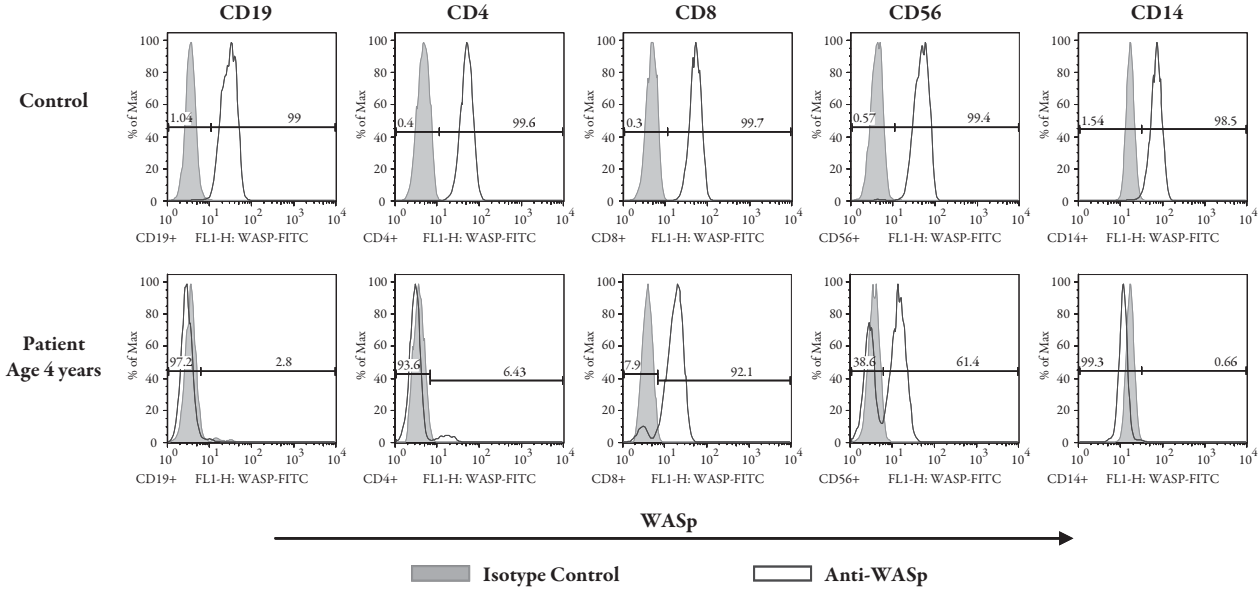

Figure 43.6 A WAS patient with a score of 2 (at 1 year of age), which changed to a score of 5 at age 2 years (due to vasculitis), had a nonsense mutation in exon 8 of the *WAS* gene (W252X) and, when studied at 1 year of age was, as expected, WASp negative. At age 4 years, he was found to have reverted his nonsense mutation to a missense mutation (W252S) that allowed expression of mutated WASp at normal intensity in most $CD8^+$ and $CD56^+$ cell populations and in a small proportion (6.4 percent) of his $CD4^+$ cells, but not in $CD19^+$ and $CD14^+$ lymphocytes, and not in platelets (*top panel* = control, *lower panel* = patient at 4 years of age). (See Color Plate.)

also underline the key role WASp plays in T-cell proliferation and in the in vivo survival and function of both T and NK cells and possibly B cells and Tregs.

GENOTYPE–PHENOTYPE CORRELATION

Mutations affecting the *WAS* gene result in three distinct phenotypes: (1) the classic WAS triad of thrombocytopenia and microplatelets, recurrent infections as a result of immunodeficiency, and eczema (Sullivan et al., 1994; Wiskott 1937), often complicated by autoimmune diseases and malignancies; (2) the milder XLT variant, characterized predominantly by thrombocytopenia and small platelets (Villa et al., 1995; Zhu et al., 1995), which can be intermittent (Notarangelo et al., 2002); and (3) congenital neutropenia without the clinical findings characteristic of WAS or XLT (Ancliff et al., 2006; Beel et al., 2009; Devriendt et al., 2001; Moulding et al., 2007). To clearly distinguish these clinical phenotypes, a scoring system, listed in Table 43.3, has been designed. The most consistent phenotype–genotype correlation was observed when the patients were divided into two categories: WASp positive if the mutated protein was present and of normal size and WASp negative if the protein was absent or truncated (Table 43.4). Patients with mutations that allow the expression of normal-sized mutated protein, often in reduced quantity, developed predominantly the XLT phenotype, whereas those patients whose lymphocytes could not express WASp or expressed only truncated WASp were more likely to have the WAS phenotype ($p < 0.001$) (Imai et al., 2004; Jin et al., 2004). When patients within one of the six hot spots were analyzed, there was a highly significant concurrence of the phenotype within each group (Table 43.2). Progression to a score of 5 due to either autoimmune disease or malignancy was observed in both groups but was far more frequent in WASp-negative patients with an initial score of 3 or 4 (Albert et al., 2010; Jin et al., 2004).

A retrospective analysis of 160 patients entered into the French WAS/XLT Registry identified 26 infants ≤ 2 years of age with a severe phenotype and poor prognosis. Of those 26 patients, half were categorized as severe refractory thrombocytopenia, with platelet counts persistently ≤ 10,000/μl, possibly due to anti-platelet autoantibody (Mahlaoui N., et al., 2013). Conceptually, this subgroup of infants characterized by early onset severe WAS with poor prognosis should be given a score of 5 and should undergo HSCT or gene therapy as soon as possible (Mahlaoui N., et al., 2013).

When the Japanese patients were analyzed separately (Imai et al., 2004), autoimmune diseases were equally frequent in patients with a low symptom score, representing XLT, and in those with a high score, representing WAS; this result was predominantly due to the high incidence of IgA nephropathy in the Japanese XLT patients. There were other exceptions to the rule, as is evident from data shown in Tables 43.2 and 43.4, a clear indication that it may be difficult in individual cases to accurately predict the clinical course based solely on the type of mutations in the *WAS* gene.

It is important to consider the complexity of the disease, the differences in lifestyle and medical care, chance exposure to unusual microorganisms, and the influence of genes that affect allergic predisposition, autoimmunity, and malignancies. Splice-site mutations, especially if affecting variant intronic nucleotide positions, often allow the generation of multiple splicing products, including the generation of normally spliced mRNA and the production of variable quantities of normal WASp. For example, the hot-spot mutation IVS6 + 5 g > a causes the insertion of 38 nucleotides from the proximal end of intron 6, which results in frameshift and early termination of transcription but also in the production

Table 43.3 SCORING SYSTEM* TO DEFINE PHENOTYPES OF *WAS* MUTATIONS

	XLN	IXLT	XLT		WAS (CLASSIC)		
Score	**0**	**<1**	**1**	**2**	**3**	**4**	**5**
Thrombocytopenia	–	–/+	+	+	+	+	+
Small platelets	–	+	+	+	+	+	+
Eczema	–	–	–	(+)	+	+/++	–/++
Immunodeficiency	–/(+)	–	–/(+)	(+)	+	+/++	–/++
Infections	+	–	–	(+)	+	+/++	–/++
Autoimmunity	–	–	–	–	–	–	+
Malignancy	+	–	–	–	–	–	+
Congenital neutropenia neutropenianeutropenia-nutropenia neutropenia	+	–	–	–	–	–	+
Myelodysplasia	+	–	–	–	–	–	–

XLN, X-linked neutropenia; IXLT, intermittent X-linked thrombocytopenia; XLT, X-linked thrombocytopenia.

*Scoring system: –/(+), absent or mild; –/+ intermittent thrombocytopenia; –, absent; (+), mild, transient eczema or mild, infrequent infections, not resulting in sequelae; +, persistent but therapy-responsive eczema or recurrent infections requiring antibiotics and often intravenous immunoglobulin prophylaxis; ++, eczema that is difficult to control or severe, life-threatening infections. Because patients with XLT may develop autoimmune disorders and/or malignancy, although at a lower rate than those with classic WAS, a progression from a score of 1 or 2 to a score of 5 is possible.

*Distribution of mutations observed in $WASp^+$ and $WASp^-$ families is significantly different ($p < 0.001$). †From Imai et al., 2004; Jin et al., 2004; Not all patients were studied for expression of WASp.

of a small amount of normal *WAS* mRNA. Somatic mosaicism due to reversion is another possibility for a more favorable phenotype than that expected from the type of mutation (Boztug et al., 2008; Trifari et al., 2010; Wada et al., 2001). Genes that determine an individual's probability of developing atopic disease, such as allergies and eczema, or genes that control the effectiveness of host defense against infections may modify the WAS/XLT phenotype. Similarly, environmental factors, such as exposure to common or uncommon infectious agents, failure to establish the diagnosis at an early age, or less-than-optimal care, may affect the severity of the clinical presentation. Phenotype scoring before the age of 2 years is unreliable because it often, ironically, suggests a phenotype that is milder than expected from the type of *WAS* mutation identified (Jin et al., 2004).

STRATEGIES FOR DIAGNOSIS

Because of the wide spectrum of clinical findings, the diagnoses of WAS or XLT should be considered in any boy presenting with petechiae, bruises, and congenital or early-onset thrombocytopenia associated with small platelet size (Fig. 43.1, Color Plate 43.II). The presence of transient, mild, or severe eczema supports the diagnosis of XLT or WAS. It is important to note that infections and immunological abnormalities may be absent, mild, or severe, and autoimmune disease may develop more often in WAS than in XLT. Lymphopenia, characteristic for classic WAS, may be present during infancy but will develop invariably during childhood. Abnormal antibody response to bacteriophage ØX17 (Fig. 43.3) seems to be a consistent finding, even in patients with a mild phenotype. Screening for WASp mutations can be successfully performed by flow cytometry (Fig. 43.6; Color Plate 43.III), but patients with a substantial expression of mutated WASp may be missed. In atypical cases, mutation analysis of the *WAS* gene is essential for diagnosis; it may also assist in estimating the severity of the disease (with caution) and in performing carrier detection and prenatal diagnosis. It is vital to differentiate XLT from ITP patients (Bryant and Watts, 2011) because of the vulnerability of XLT patients to splenectomy, the need for different therapeutic approaches, and genetic implications.

FEMALES WITH WAS

Several symptomatic female patients have been identified as being heterozygous for mutations in the *WAS* gene. They presented with either a classic WAS phenotype (Parolini et al., 1998) or an XLT phenotype (Inoue et al., 2002; Lutskiy et al., 2002; Zhu 2002). In each case, the symptomatic females were found to have markedly skewed X-chromosome inactivation in favor of the X chromosome with the *WAS* mutation.

Sporadic cases of females with clinical and laboratory findings compatible with the diagnosis of WAS have been described (Conley et al., 1992; Evans and Holzel, 1970; Lin and Hsu, 1984). Two sisters, born to healthy parents, who presented with recurrent infections, thrombocytopenia, petechiae, and eczema had low serum IgM, normal IgG, and elevated IgA and IgE levels. They had decreased T-lymphocyte subsets and absent isohemagglutinins (Kondoh et al., 1995). Autosomal inheritance was also suspected in a second family with multiple affected female members, displaying clinical and laboratory findings resembling classic WAS (Rocca et al., 1996).

WIP DEFICIENCY—AN AUTOSOMAL RECESSIVE DISORDER WITH A WAS PHENOTYPE

A female infant with typical WAS symptoms and laboratory findings was found to have a mutation in *WIPF1* that encodes WASp-interacting protein (WIP) (Lanzi et al., 2012). The patient presented at 11 days of age with eczema, vesicular and ulcerative lesions of the skin and mucosa, poor weight gain, and thrombocytopenia (but with normal platelet volume). Family history was notable for a female sibling who had vesicular and ulcerative skin lesions and died of sepsis at 4 months of age. The patient's immune deficiency included defective chemotaxis, lack of T-cell proliferation in response to co-culture with anti-CD3, and abnormal NK-cell function. IgE was mildly elevated. Because of failure to thrive and chronic infections, she underwent hematopoietic stem cell transplantation at 4.5 months of age. Analysis of the *WIPF1* gene revealed a homozygous nonsense mutation in exon 6 (Ser434X) located upstream of the region encoding the WASp-binding domain

of WIP. Both parents, who are consanguineous, were heterozygous for this mutation. Both WIP and WASp were absent in the patient's leukocytes. This case illustrates that WAS cannot be diagnosed solely on the basis of lack of WASp expression but may require sequence analysis of *WAS*. WIP deficiency should be suspected in male and female patients with features of WAS in whom WASp is absent but WAS sequence and mRNA levels are normal. The diagnosis of WIP deficiency is confirmed by sequencing *WIPF1*.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

X-inactivation studies in WAS carrier females have shown that the normal X chromosome is preferentially used as the active X chromosome in all hematopoietic lineages, including $CD34^+$ cells (Wengler et al., 1995). Exceptions to this rule are families with milder forms of XLT, in which X chromosome inactivation may be random (Inoue et al., 2002; Lutskiy et al., 2002; Zhu, 2002).

If the *WAS* mutation is known in a given family, carrier females can be identified by mutation analysis. Similarly, prenatal diagnosis of a male fetus at risk for WAS or XLT can be performed by DNA analysis with chorionic villi sampling or cultured amniocytes as the source of genomic DNA (Giliani et al., 1999).

DIFFERENTIAL DIAGNOSIS

Several syndromes presenting with eczema, elevated serum IgE, and susceptibility to infections may resemble WAS/XLT. These include WIP deficiency (Lanzi et al., 2012); Omenn syndrome (see Chapter 13) due to hypomorphic mutations in genes associated with severe combined immunodeficiency (SCID), e.g. *RAG1/2*, *Artemis*, *ADA*, *IL-7R*, *IL-2Rγ*, *RMRP*; immune dysregulation, polyendocrinopathy, X-linked (IPEX, due to mutations in *FOXP3* [see Chapter 32]); Netherton syndrome due to mutations in *SPINK5* (Renner et al., 2009); hyper-IgE syndrome due to STAT3 or DOCK8 mutations (see Chapter 38); and atopic dermatitis.

ITP is a frequent misdiagnosis of patients with XLT. The fact that WAS/XLT platelets are consistently small and ITP platelets are large is useful for differentiating these two conditions. Automated platelet counting, unfortunately, does not pick up very small platelets, and the platelet size difference is less impressive.

The neutropenia associated with *WAS* gene mutations (XLN) is congenital and has to be differentiated from cyclic neutropenia due to *ELA2* mutations, and from severe congenital neutropenia due to *HAX1* mutation (Kostmann disease), *ELA2* mutations, *AP3B1* mutations (Hermansky-Pudlak syndrome) (see Chapter 51), and from WHIM (Warts, Hypogammaglobulinemia, Infections, Myelokathexis) syndrome due to mutations in the *CXCR4* gene (see Chapter 40), and from reticular dysgenesis due to mutations in the gene encoding mitochondrial adenylate kinase 2 (see Chapter 18).

TREATMENT

Progress in nutrition, improved antimicrobial therapy including antiviral and antifungal drugs, and the prophylactic use of IVIG have contributed to the prolonged life expectancy and improved quality of life of WAS patients. Early diagnosis is most important for effective prophylaxis and symptomatic and curative treatment (Albert et al., 2011). If an infection is suspected, careful evaluation for bacterial, viral, or fungal causes followed by appropriate antimicrobial therapy is of crucial importance. Infants with mutations in the *WAS* gene associated with lymphopenia are candidates for PCP prophylaxis. If antibody responses to protein and/or polysaccharide antigens are defective, which is most often the case in patients with the classic WAS phenotype, prophylactic IVIG infusions at intervals of 3 weeks at full therapeutic dose should be initiated. The dose of IVIG may have to be increased during infections, which may aggravate the already accelerated IgG catabolism. Continuous antibiotic therapy should be considered if infections occur despite IVIG therapy.

Killed vaccines can be given, including pneumococcal polysaccharides and protein-conjugated vaccines; the response, however, may be suboptimal and should be determined. Live-virus vaccines are not recommended for patients with the classic WAS phenotype. Varicella-zoster immunoglobulin or high-dose IVIG (which has high antivaricella antibody titers) and acyclovir are indicated following exposure to chickenpox. Antiviral drugs are also successfully used to treat recurrent herpes simplex infections.

Eczema, if severe, requires aggressive therapy including local steroids and, if indicated, short-term systemic use of steroids. Cutaneous infections are common and may necessitate local or systemic antibiotics. Lymphadenopathy is frequently observed and may be the consequence of infected eczema. Tacrolimus ointment (Protopic 0.03 percent) or pimecrolimus cream (Elidel 1 percent) are alternatives to steroid cream in the treatment of WAS-associated eczema. An appropriately restricted diet based on specific food allergies may have to be selected.

Platelet transfusions are reserved for serious bleeding—for example, central nervous system hemorrhages or GI bleeding. Frequent platelet transfusions may induce antibody responses to allogenic/autologous platelets, resulting in nonresponse to platelet transfusions and/or ITP. Blood products are best irradiated and should be cytomegalovirus negative. Aspirin, which interferes with platelet function, is contraindicated.

Splenectomy, sometimes recommended for XLT patients, effectively stops the bleeding tendency by increasing the number of circulating platelets. However, splenectomy increases the risk of potentially fatal septicemia and, if performed, requires lifelong antibiotic prophylaxis (Albert et al., 2010). Data collected at the National Institutes of Health support the clinical experience that splenectomy does not affect the development of autoimmune diseases or malignancies (M. Blaese, personal communication). High-dose IVIG, systemic steroids, or rituximab may be considered for the treatment of autoimmune complications. Long-term immunosuppressive therapy, however, may cause reactivation of viruses or increase the risk of fungal infections.

Because of poor dietary intake and constant loss of red cells, prophylactic treatment with iron is necessary to prevent chronic anemia.

TRANSPLANTATION

Hematopoietic stem cell transplantation, using as source bone marrow, peripheral blood, or cord blood, is the only curative therapy for WAS (Kobayashi et al., 2006; Moratto et al., 2011; Pai et al., 2006; Pai and Notarangelo, 2010). To prevent rejection, a conditioning regimen of busulfan in combination with cyclophosphamide, or fludaribine or antithymocyte globulin with or without irradiation is necessary (Kapoor et al., 1981; Moratto et al., 2011; Ochs et al., 1982; Parkman et al., 1978, Stepensky et al., 2013). Fully matched siblings are preferred donors and result in highly successful stem cell transplantation, even in older patients (Antoine et al., 2003; Filipovich et al., 2001; Moratto et al., 2011). Matched related or unrelated donors have been used in recent years with favorable outcome (Friedrich et al., 2009; Moratto et al., 2011; Pai and Notarangelo 2010). Cord blood stem cells, fully or partially matched, are excellent alternatives for boys with WAS who weigh less than 25 kg and are free of acute infections, if a fully matched bone marrow donor is not available (Bhattacharya et al., 2005; Jaing et al., 2007; Kaneko et al., 2003; Knutsen et al., 2003; Thomson et al., 2000). Haploidentical bone marrow transplants have had disappointing results and are generally not recommended (Antoine et al., 2003; Brochstein et al., 1991; Friedrich et al., 2009; Hong, 1996; Kobayashi et al., 2006; Mahlaoui et al., 2013; Ozsahin et al., 1996; Pai et al., 2006), although reports describing successful engraftment of unmanipulated HLA-haploidentical bone marrow from a parent, resulting in stable chimerism, have been published (Friedrich et al., 2009; Inagaki et al., 2005; Moratto et al., 2011).

Recent reports demonstrate the high rate of success of stem cell transplantation when HLA-identical related (e.g., siblings) or HLA-matched unrelated donors were selected (Friedrich et al., 2009; Moratto et al., 2011). Myeloablative but not "reduced-intensity" conditioning is required to achieve complete donor chimerism. The importance of this postulate is underscored by the recent report of a large European study indicating a strong association of posttransplant autoimmunity with a mixed/split chimerism status, strongly suggesting that residual host lymphocytes can initiate posttransplant autoimmune disease (Ozsahin et al., 2008).

GENE THERAPY

The demonstrated ability of hematopoietic cell transplantation to fully correct the disease has prompted several groups to explore novel therapeutic approaches to WAS based on gene transfer. In initial attempts, primary T and B lymphocytes, herpesvirus saimiri-immortalized cell lines, and dendritic cells derived from WAS patients have been successfully transduced with lentiviral vectors expressing the human *WAS* gene. Following transduction, the cells demonstrated a substantial growth advantage; responded to TCR signaling, including downregulation of CD3 surface expression; formed stable B- and T-cell conjugates; secreted normal amounts of IL-2 upon appropriate stimulation; and showed normal cytoskeletal reorganization (Charrier et al., 2007; Dupre et al., 2004; Martin et al., 2005; Miao, 2004). Furthermore, it has been demonstrated that targeting of human hematopoietic stem cells with a *WAS*-containing retroviral vector reconstitutes the actin cytoskeleton in myeloid progenitor cells that underwent in vitro differentiation (Dewey et al., 2006). These encouraging results have been fully replicated in *was*$^{-/-}$ mice that have been injected with *was*-lentiviral-corrected hematopoietic progenitor cells, with significant multilineage engraftment of gene-corrected cells, normalization of T-cell proliferation and IL-2 production, and improvement of the migratory defects (Astrakhan A. et al., 2012; Blundell et al., 2008; Charrier et al., 2005; Dupre et al., 2006; Marangoni et al., 2009). Experience with *was* gene transfer in mice has provided strong evidence for selective advantage of gene-corrected cells. This is reminiscent of what has been observed in WAS patients who develop somatic reversions that restored WASp expression and function (Boztug et al., 2007, 2008; Davis et al., 2008, 2010; Du et al., 2006; Humblet-Baron et al., 2007; Lutskiy et al., 2005a, 2008; Trifari et al., 2010; Wada et al., 2001). One important question that animal models cannot adequately address is whether gene therapy will correct the platelet defect.

Based on cellular and murine models, a clinical gene therapy protocol using transplantation of autologous hematopoietic stem cells transduced with a GALV pseudotyped MLV-derived retroviral vector was developed in Hannover, Germany. Initially, in 2006, two patients with mutations in the *WAS* gene were enrolled and autologous CD34^{+} hematopoietic stem cells were collected by leukapheresis and transduced with a WASp-expressing retroviral vector. Prior to infusion of the genetically modified hematopoietic progenitor cells, the patients underwent partial ablation with busulfan at a dose of 4 mg/kg of body weight per day on days −3 and −2. Except for transient myelosuppression and partial alopecia, no therapy-associated side effects were observed, and both patients showed expression of WASp in lymphoid and myeloid cells within 3 to 6 months after gene therapy (Boztug et al., 2010). In addition, sustained increases in platelet numbers, as well as in WASp^{+} thrombocytes, were observed. The clinical condition of both patients improved markedly, with resolution of bleeding tendency, eczema, autoimmunity, and predisposition to severe infection. Comprehensive insertion-site analysis showed vector integration that targeted multiple genes controlling growth and immunological responses in a persistently polyclonal hematopoiesis (Boztug et al., 2010). In 2009, this clinical gene therapy trial was expanded by including eight additional WAS patients. Overall, as of January 2012, 9 of 10 patients had evidence of sustained engraftment of WASp^{+} hematopoietic progenitor cells, and WASp expression was detected in 10 to 60 percent of myeloid cells and in most platelets, and had increased in T lymphocytes and NK cells to more than 80 percent 1 year following gene therapy. One patient with insufficient gene-treated cells failed to respond and underwent successful hematopoietic stem cell transplantation. Three patients developed a vector-associated acute T-cell

lymphocytic leukemia, two with integration of the vector in the *LMO2* gene region, and are undergoing chemotherapy. One of the three WAS patients with leukemia subsequently received a hematopoietic transplant (Christopher Klein, personal communication). Lentiviral-mediated transfer of the *WAS* gene (Merten et al., 2011) has recently been initiated in several gene therapy centers to achieve optimal transduction of hematopoietic stem cells and hopefully without vector-associated complications.

ANIMAL MODELS

Mouse models of wasp deficiency have been generated by gene knockout technology (Snapper et al., 1998; Zhang et al., 1999). wasp-deficient mice exhibit poor T-cell proliferation and cytokine secretion in response to TCR activation by cross-linking of CD3 and show mild lymphopenia, which can be normalized by transplantation (Strom et al., 2002). Although *was*$^{-/-}$ mice produce high titers of antinuclear antibodies, their susceptibility to frank autoimmune disease is controversial. In particular, vasculitis and nephritis have not been reported in was knockout mice. Furthermore, while virtually all *was*$^{-/-}$ mice on a Sv129 background develop severe colitis by 6 months of age (Nguyen et al., 2007), this is not observed in other backgrounds. *Was*$^{-/-}$ mice are at high risk of severe complications following challenge with *Streptococcus pneumoniae* (Andreansky et al., 2005), thus recapitulating the susceptibility of WAS patients to encapsulated pathogens. On the other hand, an important limitation of mouse models of WASp deficiency is the mild degree of thrombocytopenia, which does not lead to hemorrhagic manifestations.

Recently, wasp-activating mutations that correspond to those observed in patients with X-linked neutropenia have been introduced in murine embryonic stem cells that have been injected into a Rag2-deficient blastocyst. This has permitted researchers to confirm that constitutively active WASp interferes not only with myeloid development but also with T- and B-cell function, and leads to significant genomic instability (Westerberg et al., 2010). However, full characterization of the effect of these mutations will await development of a knock-in mouse model.

CONCLUSION AND FUTURE DIRECTIONS

The clinical phenotypes associated with mutations in the *WAS* gene are as complex as the function of its product. By studying WAS, XLT, and XLN patients and their specific *WAS* gene mutations, we have learned how a single gene defect can cause unique clinical symptoms. These investigations have provided new insight into the functions of WASp that facilitate not only cell–cell interaction and TCR-initiated cytoplasmic signaling but also cytoskeletal reorganization and actin polymerization, and neutrophil homeostasis. The structure of WASp is responsible for two configurations of the molecule—the active form, in which the C-terminus interacts with Arp2/3 to initiate actin polymerization, and the inactive form, in which the C-terminal forms an autoinhibitory contact with the GBD/Cdc42 binding domain. In the final analysis, WASp is required for efficient thrombocytopoiesis and platelet survival, T-cell activation, T- and B-cell interaction, NK cell function, Treg competitiveness, and effectiveness of the innate immune system. Since mutations of WASp interfere with the homing of hematopoietic stem cells, and thus affect all hematopoietic cell lineages, stem cell transplantation is the treatment of choice for curing this disease. For the same reason, gene therapy is expected to work, and this is one of the challenges to improve life expectancy and quality of life of affected patients.

Using conditional gene deletion to generate mice with selective deficiency of wasp in the B-cell lineage, severe abnormalities in the peripheral B-cell compartment occurred, including reduction of marginal-zone B cells and inability to respond to T-independent antigens. The resulting B-cell dysregulation, characterized by increased serum IgM levels, expansion of germinal-center B cells and plasma cells, and autoantibody production, suggests that wasp-dependent B-cell intrinsic mechanisms contribute to the increased incidence of autoimmunity observed in WAS (Recher et al., 2012).

X-LINKED LYMPHOPROLIFERATIVE DISEASES

Volker Schuster and Sylvain Latour

X-linked lymphoproliferative (XLP) disease is a rare immunodeficiency characterized by a peculiar susceptibility to Epstein-Barr virus (EBV) infection. Mutations in the gene *SH2D1A* coding for SLAM-associated protein (SAP) underlie 80 percent of familial XLP cases. In 2006, the remaining 20 percent of familial XLP cases were shown to harbor mutations in the gene *XIAP* (also termed *BIRC4*), and more recently, a few patients with impaired Mg^{++} flux resulting in impaired T-cell receptor (TCR) signaling caused by mutations in *MAGT1* were identified (Li et al., 2011). By several aspects, XLP can be lumped into the group of familial hemophagocytic lymphohistiocytosis (FHL) (Marsh et al., 2010a; Marsh and Filipovich, 2011) (see Chapter 53).

X-LINKED LYMPHOPROLIFERATIVE DISEASE DUE TO DEFECTS OF SH2D1A (SAP) (XLP-1)

X-linked lymphoproliferative disease type 1 (XLP-1; MIM #308240) is an inherited immunodeficiency involving primarily T, natural killer (NK), and natural killer T (NKT) cells that in most cases is exacerbated following exposure to EBV. In older children and adults, EBV, one of the eight known human herpesviruses, is the causative agent of infectious mononucleosis (Henle and Henle, 1979). This is usually a self-limiting polyclonal lymphoproliferative disease with an excellent prognosis. In immunosuppressed individuals, EBV infection may lead to life-threatening lymphoproliferative disorders and lymphoma (Hanto et al., 1985). Moreover, EBV has been associated with certain malignancies, such as endemic Burkitt's lymphoma, nasopharyngeal carcinoma, certain B- and T-cell lymphomas, and approximately 50 percent of Hodgkin's disease cases (Ott et al., 1992; Weiss et al., 1989; zur Hausen et al., 1970). In 1969 a family was described with two brothers suffering from hypogammaglobulinemia and malignant lymphoma following infectious mononucleosis (Hambleton and Cottom, 1969). This was the first report of XLP-1 in the medical literature. In 1975, Purtilo et al. reported a large family, the Duncan kindred, in which multiple male members had died from fulminant infectious mononucleosis in early life, whereas others developed hypogammaglobulinemia after infectious mononucleosis or extranodal ileocecal malignant lymphoma later in life. The term "lymphoproliferative disease/syndrome" was coined to describe benign or malignant lymphoproliferations; in addition, the term "infiltrates composed of lymphocytes, plasma cells, and histiocytes, some containing erythrocytes" was used to describe the histological features of hemophagocytic lymphohistiocytosis (HLH) or virus-associated hemophagocytic syndrome (VAHS).

This X-chromosomally inherited syndrome with a high vulnerability to EBV infection was originally classified as Duncan disease (in reference to the first-described XLP-1 family). Subsequently, when more families with similar signs and symptoms had been identified, and it became clear that all those studied had a genetic defect localized at Xq25, the condition was named X-linked lymphoproliferative disease (Purtilo et al., 1991b). In 1978, an XLP-1 registry was established for the collection of clinical and laboratory data to facilitate basic research on the pathogenesis of XLP-1 and to develop new diagnostic and therapeutic tools for XLP-1 patients (Hamilton et al., 1980). As of the year 2000, 309 males with one or more XLP-1 phenotype(s) from 89 unrelated families had been registered (Seemayer et al., 1995; Sumegi et al., 2000). The disease has been shown to occur worldwide, with an estimated incidence of 1 to 3 per million males (Purtilo and Grierson, 1991). Primary EBV infection in

XLP-1 males may lead to severe and frequently fatal infectious mononucleosis, lymphoproliferative disorders usually of B-cell origin, dysgammaglobulinemia, and other less frequent manifestations (Seemayer et al., 1995). However, XLP-1 manifestations such as dysgammaglobulinemia or malignant lymphoma may develop in a similar frequency during the life of XLP-1 males who have never been exposed to EBV (Gross et al., 1994, 1995; Strahm et al., 2000; Sumegi et al., 2000), indicating that clinical manifestations of XLP-1 are not EBV-specific and that EBV may only act as a potent trigger of the earliest and most serious clinical manifestation of XLP-1 (i.e., fatal infectious mononucleosis).

In general, XLP-1 has an unfavorable prognosis. However, transplantation of hematopoietic stem cells from a suitable donor may cure this immunodeficiency.

The gene responsible for XLP-1, named *SH2D1A* (SH2 domain-containing gene 1A), was identified in 1998 independently by three groups (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998). The gene encodes a small protein of 128 amino acids named SAP, for SLAM-associated protein, expressed in T lymphocytes and NK cells. SAP has the structure of a signaling adaptor containing a single SH2 domain. Through use of in vitro experiments and SAP-deficient mice, SAP has been shown to be involved in the signal transduction mediated by a family of transmembrane receptors, the signaling lymphocyte activation molecule (SLAM, also termed CD150 in humans) family.

CLINICAL PHENOTYPES AND PATHOLOGICAL MANIFESTATIONS

Prior to EBV infection, most boys carrying the defective XLP-1 gene are clinically healthy. Some of them exhibit subtle immunological abnormalities before EBV infection (see Laboratory Findings, below).

Exposure to EBV may result in three clinical phenotypes in males carrying the defective XLP-1 gene: fulminant and often fatal infectious mononucleosis occurs in more than half, lymphoproliferative disorders including malignant lymphoma develop in approximately one third of affected males, and dysgammaglobulinemia is found in one quarter of the patients (Table 44.1) (Seemayer et al., 1995; Sumegi et al., 2000). Less frequent manifestations are aplastic anemia, vasculitis, and lymphoid granulomatosis (each approximately 3 percent of cases) and bronchiectasis (Arico et al., 2001; Halasa et al., 2003; Schuster and Kreth, 2000; Seemayer et al., 1995; Strahm et al., 2000; Weeks et al., 2006). Several phenotypes (hypogammaglobulinemia, lymphoma, aplastic anemia) may manifest within the same XLP-1 patient over time. Moreover, considerable intra- and interfamilial variations in XLP-1 phenotypes exist.

XLP-1 has an unfavorable prognosis: by 10 years of age more than 70 percent of affected boys are dead; only 2 XLP-1 patients from the registered population of 272 males are older than 40 years of age (Seemayer et al., 1995). Only one man with XLP-1, who is not in the registry, is known to have survived for more than 60 years. He had a nonsense mutation in *SH2D1A* and a history of retropharyngeal lymphosarcoma at age 14 and intestinal lymphoma at 21 years; hypogammaglobulinemia was diagnosed at age 36 years; he died at age 64 from pancreatic cancer (H. D. Ochs, unpublished observation). Survival rates for fulminant infectious mononucleosis, lymphoproliferative disorders, dysgammaglobulinemia, and aplastic anemia are 4 percent, 35 percent, 55 percent, and 50 percent, respectively (Seemayer et al., 1995).

Table 44.1 **COMMON MANIFESTATIONS OF X-LINKED LYMPHOPROLIFERATIVE DISEASE TYPE 1 AND 2**

MANIFESTATIONS	XLP-1 (%)*	XLP-2 (%)*
HLH with EBV$^+$/FIM	45	49
HLH without EBV	7	24
Lymphoma	26	0
Hypo- or dysgammaglobulinemia	38	28
Splenomegaly without HLH	7	88
Hemorrhagic colitis	0	19

*Percentages calculated based on studies of Booth et al., 2011; Doshi et al., 2008; Marsh et al., 2010b; Pachlopnik Schmid et al., 2011; Rigaud et al., 2006; Sumegi et al., 2000; Worthey et al., 2011. Since XLP-1 and XLP-2 males may exhibit more than one phenotype, the sum of percentage values exceeds 100.

FIM, fatal infectious mononucleosis.

FULMINANT INFECTIOUS MONONUCLEOSIS

This is the most serious form of acute infectious mononucleosis, which has all the features of HLH. The median age of onset of illness is 2.5 to 3 years (range, 0.5–40 years) (Mroczek et al., 1987b; Sumegi et al., 2000); the median survival after onset of symptoms is 32 days (Mroczek et al., 1987b; Purtilo and Grierson, 1991). Signs and symptoms of disease are similar although more severe than those of infectious mononucleosis in older children and adults (Markin et al., 1987). Meningoencephalitis is common (Mroczek et al., 1987b; Schuster et al., 1993; Sullivan and Woda, 1989). During the course of fulminant mononucleosis, 89 percent of affected boys develop hepatic dysfunction, 81 percent have anemia, and 93 percent have thrombocytopenia (Mroczek et al., 1987b). Typically, polyclonal EBV-transformed B cells as well as CD4$^+$ and CD8$^+$ T cells (at approximately a 1:1 ratio of B to T cells) invade numerous organs, leading to infiltration and marked destruction of hematopoietic organs, liver, thymus, brain, heart, and other tissues (Markin et al., 1987; Mroczek et al., 1987a, 1987b; Sullivan and Woda, 1989). The extensive destruction of liver and bone marrow often leads to fulminant hepatitis and pancytopenia. In severe hepatitis, an intense periportal infiltration of EBV-positive B cells is typically found, surrounded by T cells, mainly of the CD8 phenotype (Markin et al., 1987). Liver failure with hepatic encephalopathy or hemorrhage involving the central nervous system, the gastrointestinal tract, or the lungs is the most frequent cause of death in these patients (Grierson and Purtilo, 1987).

HLH occurs in 90 percent of boys with fatal mononucleosis (Mroczek et al., 1987b; Seemayer et al., 1995) and is triggered

by EBV-infected cells. It is characterized by the appearance of numerous highly activated histiocytes and macrophages in different compartments (bone marrow, liver, lymph nodes). The development of HLH in bone marrow leading to pancytopenia has been shown to progress in three phases. Initially, moderate pancytopenia and a myeloid hyperplastic marrow develop, followed at 2 to 3 weeks by the appearance of numerous activated histiocytes and macrophages with erythrophagocytosis (Color Plate 44.I). Later, lymphoid infiltration of bone marrow occurs, often associated with necrosis and hemorrhage (Mroczek et al., 1987b). The pathogenesis of HLH in XLP-1 is thought to be linked to functional deficiency of activated NK and cytotoxic T cells that proliferate but do not eliminate EBV-infected cells see section "Function of the SAP Protein". The resulting overwhelming activation of histiocytes and macrophages is the direct result of uncontrolled release of tumor necrosis factor (TNF)-α and other cytokines ("cytokine storm") by activated T cells (Lay et al., 1997; Su et al., 1995).

HYPOGAMMAGLOBULINEMIA AND DYSGAMMAGLOBULINEMIA

This phenotype occurs in approximately 22 to 31 percent of affected males after EBV exposure. Median age at onset is 6 to 9 years (Grierson and Purtilo, 1987; Seemayer et al., 1995; Sumegi et al., 2000). Affected males exhibit varying degrees of hypogammaglobulinemia, and some may have increased serum IgM levels. Histologically, these patients present with extensive necrotic lesions in lymph nodes, thymus, bone marrow, and spleen. Long-term survivors have an inverted ratio of helper/cytotoxic T-cell subpopulations (CD4/CD8) in their peripheral blood (Grierson and Purtilo, 1987; Hügle et al., 2004; Malbran et al., 2004). Patients with hypogammaglobulinemia have a relatively favorable prognosis, particularly if they are treated with monthly intravenous immunoglobulin (IVIG) infusions.

XLP-1 patients with hypogammaglobulinemia resemble patients with common variable immunodeficiency (CVID), which is a heterogeneous disorder characterized by a decrease in all or some immunoglobulin isotypes and an impaired antibody response leading to increased susceptibility to infection (see Chapter 28). Several groups have reported mutations affecting the *SH2D1A* gene in patients with a CVID-like phenotype (Gilmour et al., 2000; Morra et al., 2001c; Nistala et al., 2001).

LYMPHOPROLIFERATIVE DISORDERS

Malignant lymphomas occur in approximately 30 percent of XLP-1 patients, often associated with dysgammaglobulinemia and/or fulminant mononucleosis. The median age of affected males at the time of diagnosis of lymphoma is 4 to 6 years (Grierson and Purtilo, 1987; Harrington et al., 1987; Seemayer et al., 1995; Sumegi et al., 2000). Presenting symptoms are fever, nausea, vomiting, lymphadenopathy, weight loss, and abdominal pain (Harrington et al., 1987).

Most lymphomas studied so far occurred at extranodal sites; in approximately 75 percent the ileocecal region was primarily affected (Harrington et al., 1987). Other common sites of these tumors are the central nervous system, liver, and kidneys. Over 90 percent of malignant lymphomas are of B-cell origin. These can be histologically subclassified as Burkitt's lymphomas (small noncleaved; 53 percent of B-cell lymphomas), immunoblastic lymphomas (18 percent), large noncleaved lymphomas (12 percent), small cleaved or mixed-cell lymphomas (12 percent), and unclassifiable lymphomas (5 percent) (Harrington et al., 1987). Only five cases have been classified as T-cell lymphomas (6 percent of all lymphomas in XLP-1 patients studied to date). Three brothers of one XLP-1 family developed Hodgkin's disease following EBV infection (approximately 3 percent of all lymphomas in XLP-1 patients studied to date), a fourth brother died from malignant non-Hodgkin's lymphoma (Donhuijsen-Ant et al., 1988). Malignant lymphomas with different histological subclassification may occur within the same family (Donhuijsen-Ant et al., 1988; Schuster et al., 1994). In at least four cases of Burkitt's lymphomas, the characteristic 8;14 translocation (Egeler et al., 1992; Strahm et al., 2000; Williams et al., 1993) and in one case the 8;22 translocation (Turner et al., 1992) were demonstrated.

The prevalence of malignant lymphomas in XLP-1 males is higher than in patients with other inherited immunodeficiencies such as the Wiskott-Aldrich syndrome (Chapter 43), and the risk of developing a lymphoma has been estimated to be approximately 200 times greater than that in the general population (Grierson and Purtilo, 1987). In the case of Burkitt's lymphoma, by using a mathematical model simulating lymphomagenesis, the cumulative lymphoma prevalence has been estimated to be 0.002 percent by the chronological age of 18 years in the general population, 0.15 percent by age 6 years for endemic Burkitt's lymphoma, 3 percent by age 10 years for Burkitt's lymphoma in children with AIDS, and 25 percent by age 7 years for Burkitt's lymphoma in boys with XLP-1 (Ellwein and Purtilo, 1992). This markedly increased risk in XLP-1 males, theoretically predicted and later statistically confirmed, may indirectly reflect the enhanced proliferation of EBV-infected B cells, which may be due to impaired immunosurveillance by T lymphocytes and NK cells.

Characteristics that may distinguish malignant lymphomas in XLP-1 patients from other malignant lymphomas include a family history of XLP-1, the early age of clinical manifestation (infectious mononucleosis), the ileocecal localization of the majority of XLP-1–associated lymphomas, and additional XLP-1 phenotypes in the same affected male (such as dysgammaglobulinemia and severe or fulminant infectious mononucleosis). Approximately 30 to 35 percent of XLP-1 patients with malignant lymphoma survive for longer periods (>10 years) (Purtilo and Grierson, 1991; Seemayer et al., 1995).

OTHER RARE XLP-1 PHENOTYPES

A small number of XLP-1 patients (approximately 3 percent of cases) develop isolated bone marrow aplasia (either pancytopenia or pure red cell aplasia) in the absence of any evidence for HLH. A similar percentage of affected patients may develop

necrotizing lymphoid vasculitis or lymphoid granulomatosis of the lung or the central nervous system leading to extensive tissue damage (Loeffel et al., 1985; Dutz et al., 2001; Kanegane et al., 2005; Seemayer et al., 1995). Another rare clinical manifestation of XLP-1 is bronchiectasis, which has been found in association with (Dutz et al., 2001; Hügle et al., 2004; Mehta al., 1999) and without (Strahm et al., 2000) dysgammaglobulinemia. In certain cases, HLH may be the only clinical manifestation in males with XLP-1 (Arico et al., 2001). Recently, a *Helicobacter pylori*-negative, EBV-negative chronic active atrophic pangastritis, with superficial ulcer formation, foveolar hyperplasia, glandular dilatation, and ultimately pseudopyloric intestinal metaplasia was found as a rare clinical phenotype in monozygotic twins with XLP-1 (Rougemont et al., 2008). One XLP-1 patient developed EBV encephalitis, central nervous system lymphoproliferative disease, and lymphoma, as well as diffuse fusiform aneurysmal dilation of intracranial vessels (Weeks et al., 2006). A young adult lacking the typical symptoms of XLP-1 was recently reported to have developed generalized skin manifestations resembling scleroderma with scarring of the subcutaneous tissue at 8 years of age. As the skin pathology progressed, he showed movement limitation of elbows and knees and developed severe mutilation of hands and feet (Mejstríková et al., 2012). Interestingly, a maternal cousin with the same deletion of the entire SH2D1A gene presented as a teenager with a classic XLP-1 phenotype.

CLINICAL MANIFESTATIONS AND IMMUNOLOGICAL FINDINGS IN XLP-1 MALES WITH NO EVIDENCE OF PREVIOUS EBV EXPOSURE

Thirty-eight (symptomatic) males with XLP-1, representing 12.5 percent of 304 registered males with clinical manifestations of XLP-1, had no evidence of prior EBV exposure (Sumegi et al., 2000). The number and percentage may be even higher, since the exact number of asymptomatic XLP-1 males is not known.

Interestingly, EBV-negative XLP-1 patients developed dysgammaglobulinemia and/or malignant lymphoma in a similar percentage to that of the EBV-positive group (Sumegi et al., 2000). In the EBV-negative group, median age at the onset of dysgammaglobulinemia was 4.5 years; for lymphoproliferative disease it was 8 years, which is not statistically different from the EBV-positive group. Infectious mononucleosis, which may be also caused by other herpesviruses such as cytomegalovirus (CMV), human herpes virus type 6 (HHV-6), and HHV-7 or by *Toxoplasma,* was never observed in the EBV-negative group. Survival for the EBV-negative group as a whole was significantly better, but this result is entirely accounted for by the poor survival of fulminant infectious mononucleosis in the EBV-positive group (Sumegi et al., 2000).

Thirty-two EBV-negative males carrying the defective XLP-1 gene as shown by restriction fragment length polymorphism (RFLP) analysis—but not by sequencing—have been further immunologically investigated (Grierson et al., 1991; Gross et al., 1994; Seemayer et al., 1995). Among these, only five males were clinically healthy and had normal serum immunoglobulin levels. The remaining 27 males showed, prior to EBV exposure, one or both of the following XLP-1 phenotypes: 17 subjects had elevated serum IgA or IgM and/or variable deficiency of IgG, IgG1, or IgG3, and 18 males developed lymphoproliferative disease (15 of B-cell origin, three of T-cell origin) without serological and/or genomic evidence of previous EBV infection (22 percent of all lymphomas in XLP-1 studied thus far). Eight of these 27 males (30 percent) had both dysgammaglobulinemia and lymphoma. These phenotypes resemble that of late-onset CVID. The findings strongly suggest that the immunodeficiency in XLP-1 is not strictly EBV-related.

In the few XLP-1 males without evidence of prior EBV infection studied thus far, the number of peripheral T, B, and NK cells; the expression of CD3, CD4, CD8, and CD28; the CD4/CD8 ratio; the proliferative response to phytohemagglutinin (PHA), con-canavalin A (ConA), and pokeweed mitogen (PWM); and NK-cell activity seem to be normal (Gilleece et al., 2000; Strahm et al., 2000; Sullivan and Woda, 1989). In one XLP-1 patient interferon-γ (IFN-γ) secretion by peripheral blood mononuclear cells was shown to be increased (ELISPOT assay) following stimulation with phorbol myristate acetate (PMA) but was decreased after stimulation with anti-CD3 and/or anti-2B4 (Sharifi et al., 2004).

The pattern of dysgammaglobulinemia appears to be due to a partial failure of the patient's B cells to undergo isotype switching from IgM to IgG. Moreover, EBV-seronegative (as well as EBV-seropositive) XLP-1 patients exhibit a deficient switch to IgG antibody production following secondary challenge with bacteriophage ΦX174, a finding that has been used in the past for diagnostic evaluation of males at risk for XLP-1 (Purtilo et al., 1989). However, for various reasons this test possesses only limited diagnostic validity and reliability, and may lead to false-positive and false-negative results (Purtilo, 1991). Therefore, the diagnosis of XLP-1 in EBV-negative asymptomatic males depends on direct mutation analysis of the *SH2D1A* gene. The finding of abnormal immunoglobulin and IgG subclass concentrations (vide supra) in the serum of males at risk for XLP-1 is suggestive but not diagnostic. Because of the high prevalence of EBV in the general population, most males with XLP-1 will be infected with EBV in childhood. About 58 percent of them will develop the most severe XLP-1 phenotype (i.e., fatal infectious mononucleosis).

LABORATORY FINDINGS IN XLP-1 MALES DURING ACUTE EBV INFECTION

During fulminant infectious mononucleosis, a triphasic process develops along a continuum for several weeks within the blood and bone marrow (Purtilo, 1991). Initially (for 1–2 weeks), the leukocyte count is elevated, mostly because of increased numbers of atypical lymphoid cells, most of which are activated T cells. This abnormality is similar to but more extensive than that of immunocompetent children with uncomplicated infectious mononucleosis. At this time the bone marrow is hyperplastic with granulocytic hyperplasia with a left shift of maturation (Mroczek et al., 1987b). Later, severe pancytopenia develops (median leukocyte count,

1.5×10^9/L; median platelet count, 35.5×10^9/L; median hemoglobin level, 8.5 g/dL). The bone marrow shows extensive infiltration by lymphoid cells consisting of activated T cells, immunoblasts, and plasma cells. This is associated with cellular necrosis and HLH (Color Plate 44.I) (Mroczek et al., 1987b). Terminally, the marrow shows massive necrosis with severe cellular depletion and marked histiocytic hemophagocytosis (Purtilo, 1991).

Elevation of serum transaminases, lactic dehydrogenase, and bilirubin, reflecting hepatic involvement, is found in all affected boys with fulminant mononucleosis. Hepatic encephalopathy or severe hemorrhages (central nervous system, gastrointestinal tract, lungs) due to liver failure are the most frequent cause of death in XLP-1 boys with fatal mononucleosis (Grierson and Purtilo, 1987).

The age range of XLP-1 males with fulminant mononucleosis is 5 months to 17 to 40 years (Mroczek et al., 1987b; Sumegi et al., 2000); the median age is 2.5 to 3 years. In most cases there is direct evidence of EBV infection as shown by the presence of heterophile antibodies and/or positive EBV-specific serology and/or the presence of EBV antigens or DNA in lymphoid tissues (positive in 100 percent of cases) (Falk et al., 1990; Mroczek et al., 1987b). Demonstration of EBV genomes in serum by polymerase chain reaction (PCR) is a readily available test to indicate EBV infection (Sumazaki et al., 2001).

IMMUNOLOGICAL STUDIES OF XLP-1 PATIENTS AFTER EBV INFECTION

Subjects with XLP-1 surviving EBV infection exhibit, as a rule, combined T- and B-cell defects. Most XLP-1 patients have normal numbers of peripheral blood B and T cells. The proliferative responses of lymphocytes to B- and T-cell mitogens such as PHA, ConA, and PWM and to anti-IgM antibody were shown to be abnormally low during and after primary EBV infection in four of four XLP-1 patients (Sullivan and Woda, 1989). In contrast, others have found normal lymphocyte proliferation in response to PHA, PWM, EBV, and *Staphylococcus aureus* strain Cowan (SAC) in 9/9 XLP-1 patients (Arkwright et al., 1998; Lindsten et al., 1982). A decreased ratio of $CD4^+$ to $CD8^+$ T cells with a predominance of $CD8^+$ cells has been observed in most XLP-1 patients (Hügle et al., 2004; Lindsten et al., 1982). The in vitro production of immunoglobulins by peripheral blood lymphocytes in response to PWM, EBV, and SAC was markedly decreased compared with healthy controls (Lindsten et al., 1982). Furthermore, in XLP-1 patients with hypogammaglobulinemia, the in vitro synthesis of IgG, IgM, and IgA by B lymphoblastoid cell lines in the presence of autologous T cells was markedly decreased (Lai et al., 1987; Yasud et al., 1991). The degree of this T-cell–mediated "suppression" of Ig synthesis correlated with the decreased serum levels of IgM and IgG in these patients (Yasuda et al., 1991).

XLP-1 patients have a marked reduction in the number of circulating $CD27^+$ memory B cells, which undergo normal somatic hypermutations, but a complete absence of switched memory B cells (Ma et al., 2005, 2006; Malbran et al., 2004). $CD4^+$ cells from XLP-1 patients do not efficiently differentiate in vitro into IL-10–secreting T-helper cells and show reduced expression of inducible costimulator (ICOS) (Ma et al., 2005). These data suggest that in XLP-1 the B-cell defects are mainly extrinsic. More recently, it was reported that XLP-1 patients have increased numbers of functionally immature "transitional" CD24highCD38high B cells, which may further contribute to the humoral immunodeficient state (Cuss et al., 2006).

T cells from XLP-1 patients failed to secrete normal amounts of IFN-γ following stimulation with autologous B lymphoblastoid cell lines or via the SLAM family receptor 2B4 (Sharifi et al., 2004; Yasud et al., 1991). In contrast, in three unrelated XLP-1 patients the frequency of IFN-γ–producing $CD3^+$ T cells (measured intracytoplasmatically by FACS analysis after stimulation of the cells with PMA and ionomycin) was markedly increased (Ehl et al., 2002; Hügle et al., 2004). Furthermore, mononuclear cells from other XLP-1 patients spontaneously produced normal or elevated levels of IFN-γ during EBV infection (Okano et al., 1990; Sullivan, 1983). It is therefore not clear if deficient IFN-γ production in XLP-1 is a primary defect or only secondary to EBV infection. Skin tests with various antigens (purified protein derivative [PPD], tetanus toxoid, *Candida*, and mumps) are frequently negative in XLP-1 patients (Donhuijsen-Ant et al., 1988; Sullivan, 1983). A direct role of SAP in early cell antigen receptor-mediated signaling via CD3 was suggested by defective upregulation of IL-2 and IFN-γ production by herpesvirus saimiri-immortalized $CD4^+$ T cell (Nakamura et al., 2001) and by defective IL-2 production, CD25 expression, and homotypic cell aggregation (Sanzone et al., 2003).

NK cell activity of XLP-1 males was found to be normal before, high at the time of, and low after EBV primary infection, results suggesting that this defect might be acquired during EBV infection (Argov et al., 1986; Okano et al., 1990; Rousset et al., 1986; Sullivan et al., 1980, 1983; Sullivan and Woda, 1989). Recent studies, however, have shown that in XLP-1 patients NK-cell cytotoxicity mediated by the NK-cell activating receptor 2B4 seems to be selectively impaired, whereas NK-cell activation mediated by NKp46, NKp44, NKp30, CD2, or CD16 as well as natural cytotoxicity against K562 cells and major histocompatibility complex (MHC) class I-deficient cells seems not be affected (Benoit et al., 2000; Nakajima et al., 2000; Parolini et al., 2000; Tangye et al., 2000b).

Patients with XLP-1 have a nearly complete absence of CD1d-restricted NKT lymphocytes (Chung et al., 2005; Nichols et al., 2005; Pasquier et al., 2005), which are important for bridging innate and adoptive responses (Bendelac et al., 2007; Latour et al., 2007). Studies in mice showed that in the absence of SAP, the development of NKT cell is blocked early in the thymus at the positive selection step (Griewank et al., 2007; Pasquier et al., 2005). The exact role of NKT cells in the control of EBV infection is not known, but interestingly, a subset of $CD8\alpha\alpha$ NKT cells with cytolytic functions was shown to suppress the proliferation and the expansion of activated $CD8^+$ T cells in vitro. Importantly, expansion of anti-EBV $CD8^+$ T cells was reduced in these conditions (Ho et al., 2004).

EBV-specific T-cell immune function has been studied in only a few XLP-1 patients. Three of eight XLP-1 patients were shown to exhibit EBV-specific memory T-cell activity as measured by an outgrowth inhibition assay (regression assay)

(Harada et al., 1982). In two XLP-1 patients with hypogammaglobulinemia, EBV-specific, HLA-restricted cytotoxicity was demonstrated (Rousset et al., 1986). In recent studies, EBV-specific $CD8^+$ T cells from XLP-1 patients exhibited markedly decreased cytotoxic activity against autologous B-cell lines (Dupre et al., 2005; Hislop et al., 2010; Sharifi et al., 2004). The deficient EBV-specific cytotoxicity could be fully reconstituted by retroviral gene transfer of the *SH2D1A* gene into the T-cell lines. These findings suggest that in XLP-1 patients the lack of SAP may result in severe disruption of cytotoxic T-lymphocyte (CTL) function. XLP-1 patients have normal numbers of EBV-specific $CD8^+$ T cells that are extremely differentiated as defined by loss of CCR7 and CD27, low telomerase activity, and very short telomeres (Plunkett et al., 2005). These observations suggest that excessive proliferation of $CD8^+$ T cells may lead to end-stage differentiation and loss of EBV-specific $CD8^+$ T cells through replicative senescence. Lack of cytotoxic T cells may contribute to the development of EBV-associated B-cell lymphomas.

Interestingly, some of these pathological findings in XLP-1 patients can also be found transitorily and for a short period in patients with uncomplicated acute infectious mononucleosis. T lymphocytes obtained during acute infectious mononucleosis proliferate poorly in response to various mitogens such as PHA, ConA, and PWM as well as to antigens such as tetanus toxoid and *Candida albicans* (Tosato, 1989). Moreover, patients with acute infectious mononucleosis show low or absent delayed-type hypersensitivity reactions when challenged with recall antigens (Tosato, 1989) and respond poorly to the T-cell–dependent neoantigen bacteriophage φX174, both in vivo and in vitro (Junker et al., 1986).

T-cell activation during acute infectious mononucleosis leads to the amplification of $CD8^+$ cytotoxic T cells, of which only a fraction is EBV-specific and HLA-restricted (Callan et al., 1996; Tomkinson et al., 1989). It also leads to the proliferation of $CD8^+$ T cells, which seem to be able to inhibit proliferation and immunoglobulin production by B cells as well as to inhibit nonactivated T cells in a probably virus-nonspecific, HLA-nonrestricted manner (Tosato, 1989; Tosato et al., 1982; Wang et al., 1987). In healthy immunocompetent individuals, both cytotoxic and suppressor functions, displayed by $CD8^+$ T cells during infectious mononucleosis, appear to modulate and finally self-limit the course and severity of EBV infection. As a consequence, aberrant self-destructive killer cell populations and/or suppressor cells are not downregulated or eliminated and may therefore proliferate in an uncontrolled manner, leading to tissue and organ destruction (as found in fatal mononucleosis) and later on to hypogammaglobulinemia and diminished immunosurveillance against EBV-infected B cells, with an enhanced risk of B-cell lymphomas.

EBV–HOST INTERACTION IN X-LINKED LYMPHOPROLIFERATIVE DISEASE

Males with XLP-1 show a range of abnormal antibody responses after primary EBV infection. Antibody titers to the EBV nuclear antigen (EBNA) are decreased or absent, which may indirectly reflect a T-cell immunodeficiency, as this is also seen in other inherited or acquired immunodeficiencies (Okano et al., 1992; Purtilo et al., 1985). Antibodies against the EBV capsid antigen (VCA) are variable in XLP-1 males. In rare instances, XLP-1 patients may not be able to produce any EBV-specific antibodies (anti-VCA-IgM, anti-VCA-IgA, anti-VCA-IgG, or anti-EBNA) despite overwhelming infection with EBV (Dutz et al., 2001; Hayoz et al., 1988; Turner et al., 1992). In these cases the detection of EBV genomes by PCR or the demonstration of EBNA by immunohistochemical staining in lymphoid tissue will document EBV infection in spite of seronegativity. In a large study of patients with sporadic or XLP-1–associated fatal mononucleosis, it was shown that 13 of 15 patients had histological changes that were characteristic for polyclonal proliferation of B cells that expressed, in most cases, all EBV nuclear antigens (EBNA1–6), an expression pattern seen also in lymphoblastoid B-cell lines from healthy controls. In two cases, the B cells were of monoclonal origin and expressed only EBNA1, a pattern also found in Burkitt's lymphoma (Falk et al., 1990).

In one patient with a nonsense mutation in *SH2D1A* (Hügle et al., 2004), EBV DNA and proteins could be detected in most of his peripheral T cells during the acute phase of infectious mononucleosis (Baumgarten et al., 1994). In general, B cells are the primary target of EBV in patients with infectious mononucleosis and other EBV-associated disorders (Kurth et al., 2000). EBV-infected T cells have been found in only one case of fatal acute mononucleosis (Mori et al., 1992) and in patients with severe chronic active EBV (CAEBV) infection (Ohga et al., 2001; Quintanilla-Martinez et al., 2000). Whether XLP-1 is associated with an increased rate of EBV infection of T cells is unknown, but this seems unlikely, since only 6 percent of XLP-1–associated lymphomas are of T-cell origin (90 percent B-cell lymphoma, 4 percent Hodgkin's disease) (Schuster and Kreth, 2000; Seemayer et al., 1995).

Normally, EBV type 1 is found predominantly in immunocompetent subjects after EBV infection. In immunodeficient individuals (HIV infection, organ transplantation), increased infection rates with EBV type 2 have been observed (Sculley et al., 1990). EBV strains isolated from XLP-1 patients have not yet been genotyped systematically. In at least two unrelated XLP-1 patients, EBV type 2 could be identified in lymphoid tissues (Mulley et al., 1992; Vowels et al., 1993). In five XLP-1 patients studied so far, EBV type 1 was found in lymphoma biopsy or peripheral blood (Chaganti et al., 2008; Schuster et al., 1996). It was further shown that in XLP-1 patients the circulating EBV load is concentrated within a small population of nonswitched $CD27^+$ B cells that were IgD^+IgM^+ and lacked IgG or IgA expression (Chaganti et al., 2008).

Patients with XLP-1 are vulnerable only to EBV, whereas the immune response to other herpesviruses, such as CMV, herpes simplex virus (HSV), HHV-6, HHV-7, and HHV-8, does not seem to be impaired.

MOLECULAR BASIS

In 1987 the XLP-1 gene locus was mapped to the long arm of the X chromosome at Xq25 through RFLP analysis with polymorphic DNA markers from Xq24 to Xq26 (Skare et al.,

1987, 1989a, 1989b, 1989c; Sylla et al., 1989). In several families with XLP-1, different partly overlapping deletions in the Xq25 region were identified and further characterized (Coffey et al., 1998, Lamartine et al., 1996; Lanyi et al., 1997; Porta et al., 1997; Sanger et al., 1990; Skare et al., 1993; Wu et al., 1993; Wyandt et al., 1989). In 1998, three groups independently identified the gene defective in XLP-1 by positional cloning (Coffey et al., 1998; Nichols et al., 1998) or through a functional approach (Sayos et al., 1998). The gene (and its encoded protein) was originally designated *SH2D1A* (Coffey et al., 1998), *SAP* (Sayos et al., 1998), or *DSHP* (Nichols et al., 1998). The gene name approved by the Human Gene Nomenclature Committee (HGNC) is *SH2D1A.* The protein encoded by *SH2D1A* is designated as SAP (for SLAM-associated protein). The human, monkey, and mouse *SH2D1A* genes consist of four exons and three introns spanning 25 kb (Coffey et al., 1998; Morra et al., 2001a, 2001d; Wu et al., 2000). The human *SH2D1A* gene encodes a small cytoplasmic protein of 128 amino acid residues consisting of a single SH2 domain, and a 25-amino acid carboxy-terminal tail (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998) (Fig. 44.1a). Two *SH2D1A* mRNA species with a size of 2.5 kb and 0.9 kb are transcribed (Sayos et al., 1998).

The highest level of human *SH2D1A* mRNA expression has been found in the thymus and to a lesser extent in spleen, liver, lymph nodes, and other lymphoid organs, as well as in peripheral blood lymphocytes (Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998). SAP is expressed in all major subsets of human T cells, with activated cells expressing the highest amounts, as well as in $CD56^+CD3^+$ NK cells (Coffey et al., 1998; Nagy et al., 2000, 2002; Nichols et al., 1998; Sayos et al., 1998). *SH2D1A* mRNA and SAP expression has been reported to occur in different B- and T-cell lymphomas and Hodgkin's disease as well as in different T-cell lines, but not in EBV-immortalized B lymphoblastoid cell lines (Kis et al., 2003; Nagy et al., 2000, 2002; Nichols et al., 1998; Sayos et al., 1998). Similarly, in mice SAP expression is predominantly found in T cells and NK cells (Sayos et al., 2000; Wu et al., 2000). In mice and in humans, SAP expression is downregulated in $CD4^+$ and $CD8^+$ T cells upon anti-CD3 stimulation (Wu et al., 2000; D. Howie, unpublished data).

SAP is not unique and shares the same overall gene and protein organization with related molecules named Ewing's sarcoma-activated transcript 2 (EAT-2) and EAT-2-related transducer (ERT; only found in rodent; in humans *ERT* is a pseudogene). This family of molecules is designated as the SAP family of adaptors. EAT-2 is found in NK cells, dendritic cells (DCs), and macrophages, whereas ERT is present only in NK cells (Roncagalli et al., 2005).

FUNCTION OF THE SAP PROTEIN

Based on the single SH2 domain composition (Fig. 44.1a), it was postulated that SAP might be involved in protein phosphorylation-mediated signal transduction events (Fig. 44.2). The first clue supporting this notion was provided by the finding that SAP interacts by the way of its SH2 domain with a tyrosine-based motif in the cytoplasmic domain of the transmembrane receptor SLAM (Sayos et al., 1998). Further experiments, including random peptide library screenings, showed

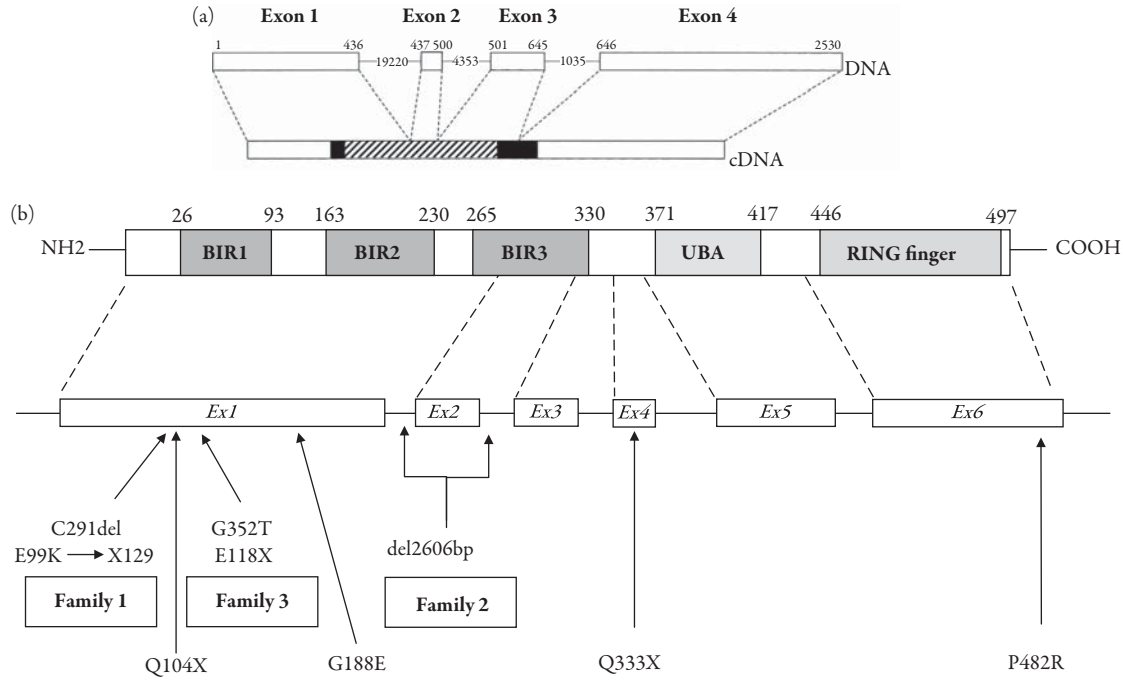

Figure 44.1 Organization of the *SH2D1A* gene (a) and the *XIAP* gene (b). *SH2D1A* gene: black regions: coding sequences; portion with diagonal pattern: SH2 domain (adapted from Coffey et al., 1998). *XIAP* gene: light gray boxes: BIR (baculovirus IAP repeats) domains; dark gray box: ubiqutin binding domain (UBA); RING finger domain or E3 ubiquitin ligase (gray box). Mutations found in XLP-2 patients are indicated in the exon structure of the gene. Three mutations (G188E; deletion Exon 2; P482R) are known to be associated with decreased or normal expression of XIAP. Deletion of Exon 1 to 5 is not shown.

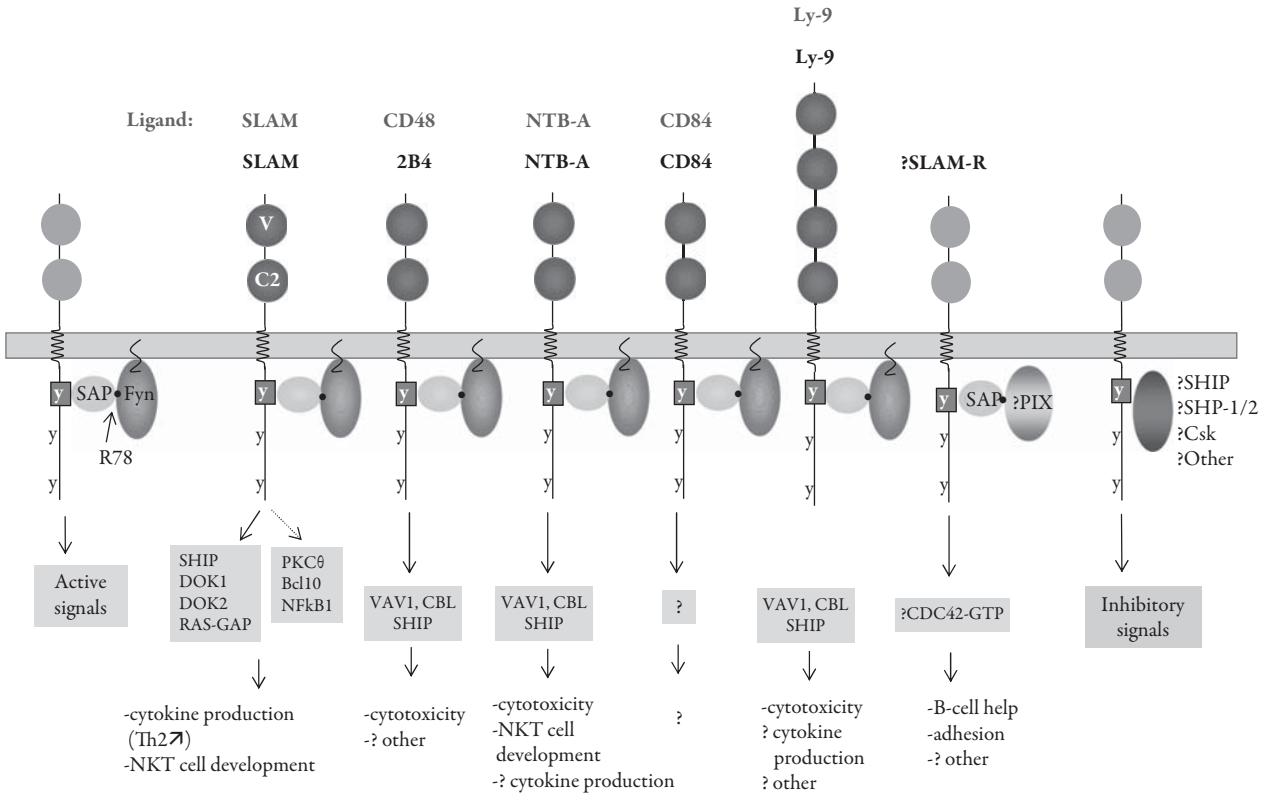

Figure 44.2 A model of regulation of SLAM receptors by SAP (adapted from Schwartzberg et al., 2009, and Veillette et al., 2009). The adaptor molecule SAP is required for mediating active biochemical signals from SLAM family receptors (SLAM-R) by its capacity to recruit and activate the protein tyrosine kinase (PTK) Fyn via its R78 residue that binds to the Fyn SH3 domain. The SLAM receptor family comprises six members: SLAM, 2B4, NTB-A, CD84, Ly-9, and CRACC. With the exception of CRACC, all members contain in their intracytoplasmic domain one or several tyrosine-based motifs that recruit SAP when phosphorylated. All SLAM receptors are self-ligands, with the exception of 2B4, which recognizes CD48. Engagement of SLAM receptors in T and NK cells results in the formation of a transducing module made of SLAM-R, SAP, and Fyn, which promote immune-cell functions such as cytokine production, cytotoxicity, and NKT-cell development.

The T-help to B-cell function (B-cell help), which depends on an adhesion process, is dependent on SAP, but the SLAM receptors that contribute to this function are not known. Moreover, it is not dependent on the PTK Fyn. In this context, it is possible that SAP recruits the exchange factor PIX, which has been shown to bind to SAP via the R78 residue like Fyn. In the absence of SAP, SLAM-R–mediated active signals are shifted toward inhibitory signals. SAP is also a "blocker" molecule that interferes with the intrinsic capacity of SLAM receptors to deliver inhibitory signals by regulating and/or displacing the recruitment of inhibitory molecules such as the 5′ inositol phosphatase (SHIP).

that the SAP and EAT-2 SH2 domains bind with high affinity and specificity to the sequence TIpYxxV/I (where T is threonine, I is isoleucine, Y is tyrosine, and V is valine) (Hwang et al., 2002; Poy et al., 1999). One or more copies are found in the cytoplasmic domain of all SLAM-related receptors, with the exception of CRACC. SLAM-related receptors form the SLAM family, which includes SLAM, 2B4, CD84, NTB-A (Ly-108 in mouse), Ly-9, and CRACC. All members of the SLAM family share a common structural organization, which consists of an extracellular domain with two or four immunoglobulin (Ig)-like domains, a single transmembrane portion, and an intracytoplasmic tail with tyrosine-based motifs. By way of their extracellular domain, SLAM family receptors interact with their ligands via homotypic interactions, with the exception of 2B4, which interacts with the CD48 molecule. These interactions are thought to participate in adhesion processes during cell–cell contact and to trigger intracellular signaling (Cao et al., 2006; Yan et al., 2007).

Because SAP is composed almost entirely of an SH2 domain, it was proposed at first that SAP might function as a natural competitor or blocker of SH2 domain-mediated interactions. The "blocking model" was supported by observations that SAP could prevent binding of SLAM and 2B4 to the SH2 domain-containing protein tyrosine phosphatase SHP-2 in nonimmune cells (Sayos et al., 1998; Tangye et al., 1999). However, the capacity of SLAM receptors to bind SHP-2 in the absence of SAP was not confirmed in several systems including immune cells derived from XLP-1 patients. (Latour et al., 2001; Nakajima et al., 2000; Parolini et al., 2000). Nonetheless, SAP might prevent the binding of SLAM-related receptors with other types of SH2-containing molecules.

An other important clue regarding the mechanism of action of SAP was given by the findings that SAP is absolutely required for SLAM-triggered protein tyrosine phosphorylation in T cells, due to the capacity of SAP to recruit and activate the Src-related protein tyrosine kinase (PTK) FynT (Latour et al., 2001). The ability of SAP to recruit FynT involves a direct interaction between the SAP SH2 domain and the FynT SH3 domain through a second binding surface centered on arginine 78 in the SAP SH2 domain (Chan et al., 2003;

Latour et al., 2003). The SAP–FynT interaction is very specific given that the arginine 78-based motif of SAP does not seem to bind other members of the Src family. Nevertheless, this motif can also associate with another SH3 domain-containing molecule, PAK-interacting exchange factor (PIX) (Gu et al., 2006). Therefore, SAP appears to behave as a true adaptor protein that couples SLAM family receptors to active biochemical signals. Contrary to SAP, EAT-2 lacks the arginine 78-based motif and is unable to bind to the FynT SH3 domain (Latour and Veillette, 2003). In agreement, recent reports indicate that the mechanism of EAT-2 action is distinct from those of SAP (Dong et al., 2009; Roncagalli et al., 2005).

Recent progress indicates that SLAM family receptors play multiple roles in immune responses and that in the absence of SAP dysfunctions of SLAM receptors account for the pathophysiology of XLP-1 (Dong et al., 2009; Rezaei et al., 2011). In T cells, in the presence of SAP, engagement of SLAM triggers a rapid tyrosine phosphorylation signal that results in the recruitment and the activation of FynT by SAP (Latour et al., 2001). This mechanism allows tyrosine phosphorylation of SLAM itself and, as a result, the recruitment of the 5′ inositol phosphatase SHIP-1 via binding of the SHIP SH2 domain to SLAM. This binding induces tyrosine phosphorylation of SHIP-1 and subsequent recruitment of the adaptor molecules Dok1, Dok2, and Shc as well as of the Ras-GTPase-activating protein (Ras-GAP). In murine T cells, the SLAM-SAP-Fyn signaling module selectively inhibits IFN-γ production and enables IL-4 production, hence promoting Th2 responses. In SAP-deficient T cells, IFN-γ production is increased compared with that of normal cells (Howie et al., 2002a; Wu et al., 2001). By contrast, IL-4 production by $CD4^+$ T cells was compromised in SAP- or Fyn-deficient mice as well as in mice expressing the SAP R78A mutant that fails to associate with Fyn (Cannons et al., 2004; Davidson et al., 2004; Wu et al., 2001). In this context, the signaling cascade triggered by the interaction of SLAM with SAP appears also to involve the protein kinaseCθ (PKCθ) and its downstream effectors Bcl-10 and NFκB1 (Cannons et al., 2004).

In NK cells expressing SAP, 2B4 engagement results in a specific protein tyrosine phosphorylation signal that involves 2B4, PLC-γ1, LAT, the exchange factor Vav-1, the ubiquitin ligase c-Cbl, and to a lesser extent SHIP-1 (Bottino et al., 2000; Chen et al., 2004; Watzl et al., 2000). Similar to SLAM signaling, 2B4-mediated protein phosphorylation is strictly dependent on SAP, and on the ability of SAP to recruit FynT. Likewise, the ability of 2B4 engagement to stimulate NK cell-mediated killing requires SAP and Fyn expression, as revealed by the observations that 2B4-mediated cytotoxicity is severely compromised in NK but also in $CD8^+$ T cells derived from XLP-1 patients and in Fyn-deficient mice (Benoit et al., 2000; Bloch-Queyrat et al., 2000; Dupré et al., 2005; Hislop et al., 2010; Nakajima et al., 2000; Parolini et al., 2000; Sharifi et al., 2004; Tangye et al., 2000b).

In the same way, the capacity of NTB-A (Ly108 in mouse) and Ly-9 to transduce active signals also depends on SAP and its aptitude to recruit FynT (Simarro et al., 2004; Zhong et al., 2008). In mouse T cells, stimulation of NTB-A results in the formation of the NTB-A-SAP-FynT signaling module that promotes a specific protein tyrosine phosphorylation signal similar to that triggered by 2B4 (Zhong at al., 2008). In agreement with these findings, NTB-A efficiently promotes cytotoxicity in human NK cells in a SAP-dependent manner as NTB-A–mediated cytotoxicity is impaired in XLP-1 patients similarly to 2B4 (Bottino et al., 2001). When engaged Ly-9 also forms a signaling module with SAP and FynT that mediates a tyrosine phosphorylation signal involving SHIP, Dok2, and the association with the adaptor Grb2 (Martin et al., 2005; Sylvain Latour and Francis Relouzat, unpublished data).

In NKT cells, a signaling module involving at least two SLAM receptors, SLAM and NTB-A, is thought to be important for NFκB activation, which is required for NKT-cell development (Bendelac et al., 2007; Griewank et al., 2007).

Therefore, the capacity of SAP to recruit FynT enables SLAM family receptors to mediate protein tyrosine phosphorylation signals. These signals appear to be essential for the function of SAP in immune cells, given that most of the immune defects caused by the SAP deficiency in T cells, NK cells, and NKT cells are also found in mice lacking Fyn. However, recent findings indicated that some of the functions of SAP may occur through a FynT-independent mechanism affecting T cells leading to humoral immune defects (Cannons et al., 2006; McCausland et al., 2007).

Importantly, early studies of human NK cells from XLP-1 patients revealed that in the absence of SAP, the activating function of 2B4 and NTB-A is shifted toward inhibition of NK-cell–mediated cytotoxicity (Bottino et al., 2001; Parolini et al., 2000) (Fig. 44.3). Similar observations have been reported with $CD8^+$ T cells from SAP-deficient patients. While EBV-transformed lymphoid blast cell lines that did not express SLAM-R were efficiently recognized and killed by autologous SAP-deficient $CD8^+$ T-cell clones, LCLs expressing CD48 and NTB-A were not killed. Importantly, their recognition and their killing were restored by blocking the interactions with 2B4 and NTB-A (Hislop et al., 2010).

Inhibitory function of 2B4 is also observed in NK cells from SAP-deficient mice (Bloch-Queyrat et al., 2000). A recent study shows that this inhibitory pathway is further strengthened in mice lacking the three SAP family adaptors, SAP, EAT-2, and ERT (Dong et al., 2009). In the absence of the three SAP family adaptors, SLAM receptors, including 2B4, NTB-A/Ly108 Ly-9, CD84, and CRACC, become inhibitory receptors in NK cells that repressed other activating receptors like NKG2D. The biochemical mechanism of this inhibition is not clearly understood, but it may be explained by the blocking function of the SAP adaptor family. However, 2B4-mediated inhibition in the absence of SAP family adaptors seems to operate at least in part via SHIP-1 (Dong et al., 2009).

A proapoptotic role for SAP in T cells was also suggested (Snow et al., 2009; Nagy & Klein, 2010). Activation-induced cell death by TCR activation was defective in T cells of XLP-1 patients, although increasing TCR activation strength bypassed the defect. This pathway seems to be dependent on NTB-A. It is possible that this defect participates in the burst of $CD8^+$ T cells in response to EBV infection in XLP-1 patients.

Therefore, SAP appears to have (at least) dual functional roles in SLAM receptor signaling and function by acting both

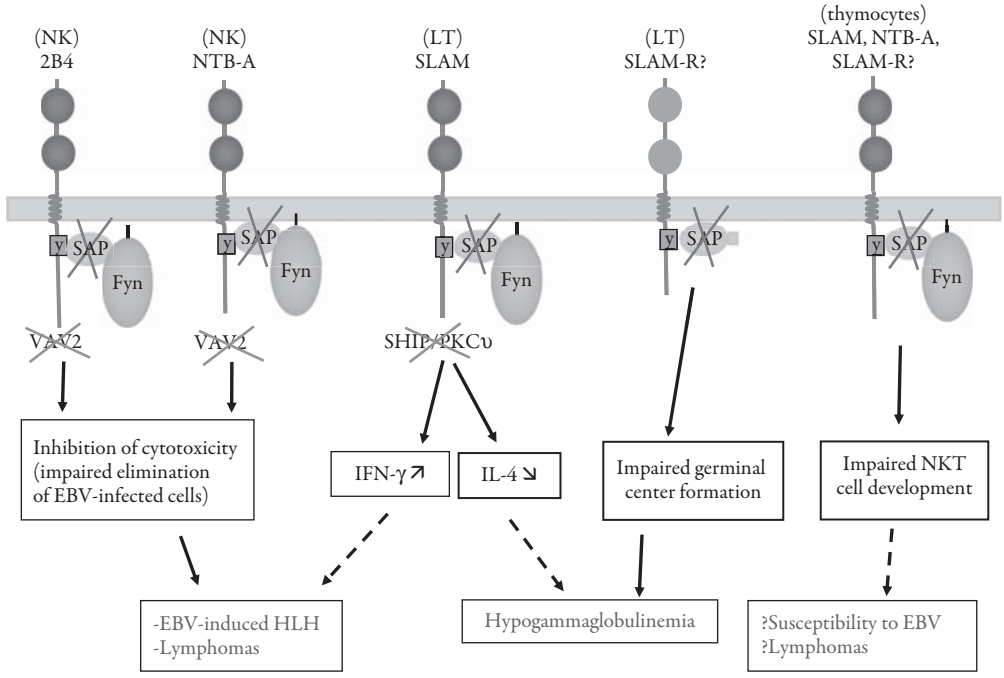

Figure 44.3 A model for defective SLAM receptor functions in the XLP pathophysiology. The loss of SLAM-R functions in the absence of SAP results in immune dysfunction contributing to the different clinical manifestations seen in XLP-1 patients. HLH and lymphoma are caused by dysfunction of SLAM receptors on $CD8^+$ T cells and NK cells that inhibit cell cytotoxicity responses and increase IFN-γ production. Similarly, T-helper follicular defects resulting in defective SLAM receptor function explain the hypogammaglobulinemia phenotype. Finally, it is possible that the lack of NKT cells participates in the high susceptibility to EBV infection, as these cells modulate immunity in a range of immunopathological conditions by their innate-like functions.

as an adaptor for the protein tyrosine kinase FynT and a competitor and/or a regulator of SH2-containing molecules that binds to SLAM receptors (Veillette et al., 2009).

SAP GENE MUTATIONS IN XLP-1 PATIENTS

More than 130 *SH2D1A* gene mutations have been identified in XLP-1 patients, including missense (M1I, M1T, A3S, Y7C, H8D, H8P, G16D, A22P, D26V, G27S, S28R, L31P, R32Q, R32T, D33Y, S34G, S34R, G39V, C42W, C42Y, G49V, T53I, T53R, Y54C, Y54H, R55L, R55P, S57P, E67D, E67G, T68I, I84T, F87S, E88P, D93G, Q99P, P101L, V102G), nonsense (R55X, Q58X, W64X, Y76X, N82FfsX103, I96X, Y100X, V102X, X129RfsX141), splice-site mutations, and micro- and macrodeletions (Alangari et al., 2006; Arico et al., 2001; Benoit et al., 2000; Booth et al., 2011; Brandau et al., 1999; Coffey et al., 1998; Erdös et al., 2005; Gilmour et al., 2000; Halasa et al., 2003; Hare et al., 2006; Honda et al., 2000; Hügle et al., 2004, 2007; Kanegane et al., 2012 ; Lappalainen et al., 2000; Lewis et al., 2001; Malbran et al., 2004; Morra et al., 2001a, 2001c; Nakamura et al., 2001; Nichols et al., 1998, 2005; Nistala et al., 2001; Pachlopnik Schmid J et al., 2011; Palendiar et al., 2011 ; Palendira et al., 2012, Parolini et al., 2000; Pasquier et al., 2005; Sayos et al., 1998; Soresina et al., 2002; Sumazaki et al., 2008; Sumegi et al., 2000; Tabata et al., 2005; Yin et al., 1999a). At present, the R55X mutation has been identified in at least 20 unrelated XLP-1 patients and seems to be the most prevalent mutation causing XLP-1 (Arico et al., 2001; Bottino et al., 2001; Brandau et al., 1999; Coffey et al., 1998; ; Hügle et al., 2004; Lappalainen et al., 2000; Lewis et al., 2001; Morra et al., 2001c; Nakajima et al., 2000; Parolini et al., 2000, 2002; Sumazaki et al., 2001 ; Sumegi et al., 2000). In one patient, no *SH2D1A* gene mutation was found in the coding regions as well as in the 500 bases upstream of the ATG, although SAP expression was undetectable in T-cell blasts derived from the patient (Verhelst et al., 2007). Therefore, it is very likely that mutations in a cis regulatory element distal from the *SH2D1A* gene or in one of its three introns could also predispose for XLP-1.

An *SH2D1A* gene mutation registry (SH2D1Abase) has been established, which is freely accessible through the Internet at http://www.uta.fi/imt/bioinfo/SH2D1Abase/ (Lappalainen et al., 2000). So far, no correlation between *SH2D1A* gene mutations and the clinical phenotype has been found. Identical mutations (e.g., the R55X mutation) may manifest different clinical phenotypes even within the same family (Brandau et al., 1999; Coffey et al., 1998; Lappalainen et al., 2000; Morra et al., 2001a; Sayos et al., 1998; Sumegi et al., 2000). Detectable mutations in the *SH2D1A* gene have been demonstrated in approximately 50 to 80 percent of patients with the XLP-1 phenotype (Brandau et al., 1999; Coffey et al., 1998; Nichols et al., 1998; Sayos et al., 1998; Sumegi et al., 2000).

Most of the missense mutations of SAP result in a marked decrease in protein stability. However, Morra et al. (2001d) identified several mutations (R32Q, C42W, T53I, and T68I) with detectable expression that resulted in structural changes affecting interaction with the SLAM family receptors, SLAM, Ly-9, 2B4, and CD84 in a distinct fashion. Furthermore, most

SAP mutants caused by amino acid substitutions studied thus far (i.e., Y7C, S28R, L31P, R32Q, T53I, Y54C, R55L, E67D, T68I, F87S, G93D, Q99P, P101L, V102G) exhibited significantly reduced binding to the FynT SH3 domain (Li et al., 2003a, 2003b).

SH2D1A gene mutations have not been detected in any of 62 cell lines derived from sporadic Burkitt's lymphoma or in the peripheral blood of male patients with sporadic Burkitt's lymphoma or Hodgkin's disease, thus demonstrating that the *SH2D1A* gene does not play an important role in the development of (sporadic) Burkitt's lymphoma (Parolini et al., 2002; Yin et al., 1999b).

ANIMAL MODELS

The XLP-1 SCID-Hu Mouse Model

Severe combined immunodeficient (SCID) mice engrafted with peripheral blood lymphocytes (PBLs) from XLP-1 patients as well as from healthy seropositive controls readily developed EBV-induced oligo- or polyclonal lymphoproliferative disease regardless of the immunocompetence of the donors (Purtilo et al., 1991a). These lesions expressed all EBV-latent antigens (EBNA1-6, LMP), regardless of whether the SCID mice had been engrafted with PBLs from XLP-1 patients or from healthy controls. Engrafted PBLs of both groups also did not differ in their immunoglobulin production (IgG, IgA, and IgM). These findings suggest that the B cells of XLP-1 patients are functionally normal and exhibit no primary defect.

Graft-versus-host disease (GVHD) developed in 6 of 10 SCID mice engrafted with PBLs from five normal donors (EBV seropositive, n = 2; EBV seronegative, n = 3), but in none of 9 mice engrafted with PBLs from three XLP-1 males (EBV seropositive, n = 2; EBV seronegative, n = 1). These findings may be taken as tentative evidence for a primary T-cell deficiency in XLP-1.

The SAP-Deficient Mouse

Three different SAP-deficient mice have been obtained with a targeted disruption of the first exon of the *sh2d1a* gene (Wu et al., 2001) or with a *sh2d1a* gene mutation coding for SAP T68I (Czar et al., 2001) or with a partial deletion of intron 1 and exon 2 (Yin et al; 2003). To date, SAP-deficient mice have been shown to recapitulate most of the phenotypes found in XLP-1 patients, including enhanced $CD8^+$ and Th1 responses to viral infection, defects in NK-cell cytotoxicity response, hypogammaglobulinemia, decreased switched memory B cells, and lack of NKT cells (Calpe et al., 2008; Schwartzberg et al., 2009; Veillette et al., 2007, 2009). Importantly, several of these defects were found in Fyn-deficient mice, revealing the crucial role of the adaptor function of SAP. Further studies with mice expressing a SAP mutant protein, the SAP R78A with the arginine 78 mutated to alanine, which abolished the binding to the SH3 domain of Fyn, have confirmed the observations made in Fyn-deficient mice. The recent generation of different mice lacking single receptor of the SLAM family has further helped to define the role of each SLAM receptor in SAP-dependent lymphocyte functions. However, it is clear from these studies that there is redundancy, and several members of the SLAM family may cooperate to enable SAP to regulate T- and NK-cell functions.

In early studies, mice deficient in SAP were infected with lymphocytic choriomeningitis virus (LCMV), a virus that elicits strong and well-defined immune responses, or with murine gammaherpesvirus-68 (Wu et al., 2001; Yu et al., 2003). Dramatically increased numbers of virus-specific $CD8^+$ T cells with greater IFN-γ production capacity were found in the spleen and the liver of SAP-deficient animals. Confirming these findings, in vitro studies showed that $CD8^+$ T cells from SAP-deficient animals exhibit enhanced IFN-γ production and proliferation in response to TCR stimulation (Chen et al., 2005; Wu et al., 2001). This increase of $CD8^+$ T-cell numbers and function is apparently caused by decreased activation-induced cell death (Chen et al., 2007). When chronically infected by LCMV, SAP-deficient mice exhibited a severe immunopathology characterized by weight loss, lymphopenia in lymphoid organs, and death (Crotty et al., 2006). These signs resemble those associated with the fulminant infectious mononucleosis found in XLP-1 patients. These observations are reminiscent of findings reported in XLP-1 patients when infected by EBV. Importantly, depletion of $CD8^+$ T cells improved the pathology of SAP-deficient mice, indicating that exacerbated $CD8^+$ T-cell responses play a crucial role and implying that SAP is inhibitor of Th1 responses. These defects are accompanied by defective antibody production to LCMV and gammaherpesvirus-68 (Crotty et al., 2003; Yin et al., 2003).

Several studies have clearly established that SAP-deficient $CD4^+$ T cells produce low amounts of T-helper 2 (Th2) cytokines IL-4 and IL-13 and exhibit decreased ICOS and elevated CD40L expression in response to TCR stimulation (Cannons et al., 2004, 2006; Czar et al., 2001; Davidson et al., 2004; Wu et al., 2001). The role of SAP in Th2 cytokine production is dependent on the SLAM receptor, as SLAM-deficient mice have a similar defect to that found in SAP- and Fyn-deficient mice (Cannons et al., 2004; Davidson et al., 2004). However, partial Th2 cytokine defects were noticed in vitro with Ly108- and Ly9-deficient $CD4^+$ T cells, suggesting that several SLAM receptors cooperate to regulate $CD4^+$ T-cell function (Graham et al., 2006; Howie et al., 2005).

SAP-deficient mice generate only a short-lived IgG antibody response following LCMV infection, whereas the production of LCMV-specific, long-lived plasma cells and memory B cells was nearly absent (Crotty et al., 2003). These findings resemble the inability of XLP-1 patients to mount a sustained anti-EBV humoral immune response. Compromised antibody production is also observed when SAP-deficient mice are infected by the influenza virus and parasites such as *Toxoplasma gondii*, *Schistosoma mansoni*, and *Leishmania major* (Cannons et al., 2006; Chen et al., 2005; Czar et al., 2001; Kamperschroer et al., 2008; Wu et al., 2001) or when mice are immunized with T-cell–dependent protein antigens (Davidson et al., 2004; Hron et al., 2004; Morra et al., 2005). This altered antibody production was associated with defects in B-cell isotype switching, generation of memory B cells and

long-lived plasma cells, as well as a severe block in germinal-center formation (Al Alem et al., 2005; Crotty et al., 2003; Hron et al., 2004; Morra et al., 2005; Veillette et al., 2008).

Implication of T-helper defects in altered humoral immunity in SAP-deficient animal was first demonstrated by adoptive transfer experiments in SAP-deficient mice (Cannons et al., 2006; Crotty et al., 2003; Kamperschroer et al., 2008; Morra et al., 2005). These findings were confirmed by the generation of conditional SAP-deficient mice in which depletion of SAP in T cells leads to a lack in germinal-center formation and a marked decrease in switched memory B cells (Veillette et al., 2008). It was further shown that in the absence of SAP, follicular T-helper cells have a reduced ability to form stable contacts with B cells (Qi et al., 2008). This function of SAP seems to involve at least two SLAM-R, CD84 and Ly-108, which allowed sustained T-cell/B-cell contacts. Thus, abnormal expression of B-cell help molecules by T-helper cells and/or diminished Th2 cytokine production observed in SAP-deficient T cells seems not to account for the humoral defect in SAP-deficient mice as earlier suggested. The role of SAP in humoral responses does not require Fyn, as Fyn-deficient mice have normal antibody production (Cannons et al., 2006; McCausland et al., 2007).

Similar to findings in XLP-1 patients, impaired ability of 2B4 to enhance NK-cell cytotoxicity is present in SAP-deficient or in Fyn-deficient mice (Bloch-Queyrat et al., 2005). Ly-108 and Ly-9 have also the capacity to activate cell cytotoxicity in NK cells in a SAP-dependent manner (Dong et al., 2009). These studies have revealed an essential role of SLAM receptors for NK-cell surveillance of hematopoietic cells.

SAP-deficient mice, similarly to XLP-1 patients, completely lack NKT cells (Chung et al., 2005; Nichols et al., 2005; Pasquier et al., 2005). In SAP-deficient animals, the development of NKT cells is blocked at the positive selection step in the thymus. The phenotype of SAP-deficient mice resembles that of Fyn-deficient mice. However, the role of SAP in NKT-cell ontogeny seems not totally dependent on Fyn, as the development of iNKT cells in mice expressing the R78A SAP is only partially impaired (Nunez-Cruz et al., 2008; Pasquier et al., 2005). Analysis of SLAM- and Ly-108-deficient thymocytes in mixed-chimeras experiments revealed that these two SLAM receptors cooperate to deliver appropriate signals required for NKT-cell development (Griewank et al., 2007).

The understanding of the functions of SAP and the SLAM family receptors has shed light on the pathophysiology of XLP-1. Based on these findings, most of the clinical features of XLP-1 are currently understood to be the result of dysfunctions of the SLAM receptors in the absence of SAP (Fig. 44.3).

X-LINKED LYMPHOPROLIFERATIVE DISEASE TYPE 2 (XLP-2) DUE TO DEFECTS OF XIAP

In 2006, mutations in the gene *XIAP* (X-linked inhibitor of apoptosis) were identified in a cohort of XLP patients without detectable mutations in the *SH2D1A* gene and with normal expression of SAP (Rigaud et al., 2006) (Fig. 44.1b). In these patients, *XIAP* (also known as *BIRC4*) gene defects are responsible for a novel type of X-linked lymphoproliferative syndrome designated as XLP type 2 (XLP-2) (MIM #300635). These findings have been confirmed with the identification of additional patients (Doshi et al., 2008; Filipovich, 2010; Marsh et al., 2010a, 2010b; Pachlopnik Schmid et al., 2011; Worthey et al., 2011; Zhao et al., 2010).

One may also consider that earlier papers reporting XLP before the identification of *SH2D1A* as the first defective gene causing XLP likely included patients with defects in *XIAP*. Clinical similarities and differences in patients with XLP-1 and XLP-2 have recently been summarized based on a retrospective analysis of a cohort of 63 patients whose molecular diagnosis had been confirmed at the Necker Children's Hospital in Paris (Pachlopnik Schmid et al., 2011).

CLINICAL PHENOTYPES AND PATHOLOGICAL MANIFESTATIONS

Similarly to *SH2D1A* deficiency (XLP-1), *XIAP* deficiency (XLP-2) is mainly characterized by a peculiar susceptibility to EBV infection (Pachlopnik Schmid et al., 2011; Rigaud et al., 2006; Zhao et al., 2010) (Table 44.1). However, XLP-1 and XLP-2 can be distinguished by several specific clinical features (Rigaud et al., 2006). The differences and similarities of XLP-1 and XLP-2 have been analyzed recently in more details in two cohorts of 33 and 30 patients with XLP-1 and XLP-2, respectively (Pachlopnik Schmid et al., 201). Survival rates of SAP- and XIAP-deficient patients did not differ, and HLH (XLP-1, 55 percent; XLP-2, 76 percent) and hypogammaglobulinemia (XLP-1, 67 percent; XLP-2, 33 percent) were observed in both groups and apparently did not differ significantly. Infection by EBV was predominantly the common trigger of HLH in both groups (XLP-1, 92 percent; XLP-2, 83 percent). The mean ages at the first HLH occurrence are similar, but HLH with lethal outcome was more frequent in XLP-1. In contrast to XLP-1 patients, 30 percent of whom developed lymphoma, XLP-2 patients do not suffer from lymphomas but have an increased risk to develop chronic hemorrhagic colitis resembling inflammatory bowel disease (IBD) or Crohn's-like disease, a complication observed in 17 percent of XLP-2 patients. Confirming that XIAP may represent a novel IBD gene susceptibility, a recent report identified by whole-exome sequencing a deleterious missense mutation in *XIAP* in a 15-month-old boy with severe Crohn's-like disease (Worthey et al., 2010). One other characteristic feature of XLP-2 is splenomegaly (XLP-1, 7 percent; XLP-2, 87 percent); in several cases this has been the first clinical manifestation of the XLP-2 condition (Doshi et al., 2008; Pachlopnik Schmid et al., 2011; Rigaud et al., 2006; Horn et al, 2011). Splenomegaly is mostly recurrent and associated with cytopenia and fever. Based on histopathology, it very likely represents minimal forms of HLH (Pachlopnik Schmid et al., 2011).

In 2009, a cohort of 10 American patients with XIAP deficiency was reported, and interestingly, EBV infection was not found to be the predominant trigger of HLH (30 percent)

(Marsh et al., 2010b). In one patient, HLH was concomitant with a CMV infection, while in the others HLH occurred without a known viral trigger. Thus, minimal forms of HLH and/or full-blown HLH can occur in XLP-2 patients without a clearly identified pathogen trigger.

So far, no cases of lymphoma have been reported in patients with XIAP deficiency. Although the possibility of developing lymphoma has not been formally excluded in XIAP-deficient patients, this complication seems unlikely because XIAP is an anti-apoptotic molecule, and studies using XIAP inhibitors have provided evidence that XIAP represents a potent target for the treatment of cancer (Schimmer et al., 2006). Although 33 percent of XIAP-deficient patients were found to have hypogammaglobulinemia, this complication, in contrast to XLP-1, seems to be transient, as two patients recovered normal levels of Ig (Pachlopnik Schmid et al., 2011). It is possible that in the absence of XIAP, hypogammaglobulinemia develops as a consequence of the HLH and/or secondary to the immunosuppressive treatments, which might affect transiently B cells. Also, most of the XIAP-deficient patients have normal Ig-isotype-switched memory B cells, unlike SAP-deficient patients (S. Siberil and S. Latour, unpublished observations).

Analysis in two independent cohorts of CVID patients failed to detect mutations in *XIAP*, indicating there is no overlapping phenotype (Salzer et al., 2008; Christelle Lenoir, Sylvain Latour, and Ioannis Theodorou, unpublished data).

MOLECULAR BASIS

The identification of the XLP-2 gene defect was performed by linkage studies and positional cloning. A unique region at Xq25 cosegregating with the disease in three XLP families was first identified and further refined (Rigaud et al., 2006). Notably, both XLP-2 (*XIAP*) and XLP-1 (*SH2D1A*) genes are located in the same gene locus in Xq25, and the two genes are only separated by a physical distance of 2.5 Mb. The human *XIAP* (also named *BIRC4*, for baculoviral IAP repeat [BIR]-containing protein 4) gene consists of six exons spanning 55 kb that encodes for cytoplasmic protein of 497 amino acids (Fig. 44.1b). XIAP belongs to the family of inhibitors of apoptosis proteins (IAPs) and in humans comprises eight members, with IAP-1 and IAP-2 being the closest XIAP-related proteins. XIAP consists of three BIR domains (BIR1, BIR2, and BIR3) that mediate protein–protein interactions, one ubiquitin binding domain (UBA), and a C-terminal RING domain with an ubiquitin protein ligase (E3) activity (Gyrd-Hansen et al., 2008; Vaux et al., 2005).

XIAP is ubiquitously expressed. In hematopoietic cells, the expression of XIAP is comparable in the different cell subpopulations tested, including $CD4^+$ and $CD8^+$ T cells, B cells, macrophages, dendritic cells, NK cells, and NKT cells (Marsh et al., 2010a; Rigaud et al., 2006).

FUNCTION OF THE XIAP PROTEIN

XIAP is a potent physiological inhibitor of caspases 3, 7, and 9 (Eckelman et al., 2006). The substrate-binding clefts of caspases 3 and 7 are directly blocked by the interaction with the BIR2 domain of XIAP. By contrast, inhibition of caspase 9 is mediated by the BIR3 domain that sterically hinders caspase 9 dimerization and its subsequent activation. The anti-apoptotic activity of XIAP is regulated by Smac (also known as DIABLO) and Omi. Following apoptotic stimuli, the protein Smac/DIABLO is released from the mitochondria and binds to the BIR2 and BIR3 domains of XIAP, relieving by this way caspase inhibition. In proliferating T cells, XIAP inhibits caspases 3 and 7 (Paulsen et al., 2008).

In addition to its anti-apoptotic role, XIAP is also involved in multiple signaling pathways, including copper metabolism, activation of the NFκB and MAP kinase pathways, and TGF-β (type 1) receptor and BMP (type 1) receptor signaling (Dubrez-Daloz et al., 2008; Galbán et al., 2010). XIAP induces NFκB and the MAP kinase activation via its BIR1 domain that mediates dimerization and interacts with the adaptor protein TAB1. TAB1 directly activates TAK1, a MAP kinase kinase kinase (MAPKKK), which in turn activates the MAP kinase cascade and the inhibitor of IκB kinase (IKK). However, the RING and the UBA domains of XIAP also contribute to the activation of NFκB. The UBA domain in IAP proteins enables them to bind to Lys 63-linked polyubiquitylated proteins. Lys 63-linked polyubiquitylation is involved in nondegradative signaling processes such as activation of NFκB. A recent report provides evidence that XIAP is also involved in NFκB activation by NOD1 and NOD2 intracellular receptors, members of the NOD-like receptor family (NLR) involved in the sensing of pathogens. XIAP was found to associate via its BIR2 domain to the receptor-interacting protein kinase RIP2, an inducer of NFκB that interacts with NOD1 and NOD2 (Krieg et al., 2009).

LABORATORY FINDINGS AND IMMUNOLOGICAL STUDIES IN XLP-2 PATIENTS

The clinical manifestations of XLP-1 and XLP-2 are similar, suggesting that they share common defects. In $CD8^+$ T cells and NK cells, SAP deficiency results in abnormal function of the SLAM-related receptor 2B4. By contrast, IL-2–activated NK cells from XIAP-deficient patients show intact 2B4-mediated cytotoxicity, and their overall cytotoxicity function is normal when measured against K562 target cells (Marsh et al., 2010b; Rigaud et al., 2006). Cytotoxicity and degranulation of $CD8^+$ T cells was also found to be normal in the absence of XIAP (C. Synaeve and S. Latour, unpublished observation). XIAP-deficient patients can also display low but detectable numbers of iNKT cells (0.005–0.02 percent of total T lymphocytes) in the blood; in contrast, SAP-deficient patients have almost no detectable iNKT cells (<0.005 percent) (Marsh et al., 2009; Rigaud et al., 2006).

In accordance with the anti-apoptotic role of XIAP, T-cell blasts from XIAP-deficient patients exhibit augmented apoptosis in response to cross-linking of CD95 or the Fas-related receptor TRAIL-R (Rigaud et al., 2006). Similarly, activation-induced cell death following anti-CD3 stimulation, which is known to be CD95-dependent, is markedly increased in XIAP-deficient T-cell blasts. The increased apoptosis in response to

CD95 signaling is not restricted to T cells as it is also observed in EBV-transformed B cells. This excess of apoptosis is caused by the lack of XIAP, as reconstitution experiments with wild-type XIAP restored normal levels of apoptosis in T-cell blasts and EBV-transformed B cells from XIAP-deficient patients.

Although XIAP-deficient lymphocytes are more prone to apoptosis in vitro, XLP-2 patients seem not to develop T-, B-lymphopenia, with the exception of iNKT cells. In contrast to conventional T cells, iNKT cells might be noticeably sensitive to activation-induced apoptosis and, consequently, more dependent on XIAP for their survival. However, in vivo XIAP is probably also involved in the survival of other leukocytes, as a nonrandom X-chromosome inactivation within leukocytes of XIAP-mutated female carriers is observed, indicating that cells expressing the wild-type XIAP allele have been preferentially selected (Rigaud et al., 2006). These observations were confirmed at the protein level in a recent study (Marsh et al., 2010a). The analysis of NOD2 responses in cells from a XIAP-deficient patient with chronic colitis has revealed a decreased responsiveness to NOD2 ligands, confirming the role of XIAP in NOD receptor signaling (Worthey et al., 2010).

XIAP GENE MUTATIONS IN XLP-2 PATIENTS

To date, more than 27 mutations in *XIAP* have been identified, including missense (R166I, C203Y, G188E, W173G, C230Y, T470S, P482R, I494N), nonsense (E118X, R222X, R238X, Q171X, S253X, Q333X, R381X, Q104X, G466X), and frameshift mutations (E99KfsX129, D130GfsX140, W217CfsX27, K299fsX307, I339fsX348, N341YfsX7, S347Lfs5X, I397FfsX414, E434AfsX457, P482fsX508) and deletions (Exon 2, Del Exons 1–5, Del Exon 6) (Doshi et al., 2008; Fillipovitch et al., 2010; Horn et al., 2011; Marsh et al., 2010b; Pachlopnik Schmid et al., 2011; Rigaud et al., 2006; Yang et al., 2012; Zhao et al., 2010) (Fig. 44.1b). Several of these mutations allow a decreased or normal expression of full-length or truncated protein (Del Exon 6, G466X, T470S, P482R, G188E, E434AfsX457). It is possible that these mutants behave as hypomorphic mutants with less severe phenotype and/or incomplete penetrance. The mothers of XLP-2 patients were found to be asymptomatic heterozygous carriers.

ANIMAL MODELS

XIAP-Deficient Mice

XIAP-deficient mice have been obtained by deletion of exon 1 of *xiap* or deletion of both exon 1 and 2 of *xiap* (Harlin et al., 2001; Olayioye et al., 2005). XIAP-deficient mice were originally reported with no major phenotypic abnormalities, including the lack of obvious abnormal apoptotic phenotypes in cells of the immune system. However, a few specific defects have been identified. Sympathetic neurons and postmitotic cardiomyocytes from XIAP-deficient mice are more sensitive to cytochrome c-induced cell death. XIAP deficiency also leads to delayed lobuloalveolar development in the mammary gland, even though this aberrant phenotype does not result from altered apoptosis and/or proliferation. More recently, XIAP-deficient mice were reported to be more susceptible to infections with *Chlamydophila pneumoniae* and *Listeria monocytogenes* (Bauler et al., 2008; Prakash et al., 2010). In these conditions, decreased cell survival and abnormal cytokine production by macrophages, presumably via TLR-2 and NOD2 receptors, were observed. Importantly, these mice have normal NKT-cell development and normal B-cell function and humoral responses, unlike SAP-deficient mice (Rigaud et al., 2006; Rumble et al., 2009; S. Siberil and S. Latour, unpublished data). Thus far, it is not clear whether XIAP-deficient mice represent a valid model for XLP-2.

The mechanisms underlying the pathophysiology of XLP-2 are not understood and remain to be elucidated. Until now, the defect in NKT cells has been the only immune abnormality shared by XIAP and SAP deficiency, and it is possible that absence or low numbers of iNKT cells contribute in part to the high susceptibility to EBV infection in XLP (Latour et al., 2007). However, the findings that XIAP is involved in NOD2 function may explain the increased risk of XIAP-deficient patients to develop chronic colitis, as NOD2 is one susceptibility gene for Crohn's disease.

DIAGNOSTIC CONSIDERATIONS (XLP-1 AND XLP-2)

The diagnosis of XLP-1 and XLP-2 is based on clinical, immunological, and molecular findings (Pachlopnik Schmid et al., 2011) (Table 44.2) and can only be confirmed by mutation analysis. Prenatal diagnosis or the evaluation of a heterozygous status in (clinically healthy) women is possible by direct mutation analysis of the *SH2D1A* or *XIAP* gene and/or its RNA (Hügle et al., 2004; Shinozaki et al., 2002), or indirectly (in informative families) by RFLP analysis with X-chromosomal markers flanking both *SH2D1A* and *XIAP* genes proximally and distally (Fig. 44.4) (Mulley et al., 1992; Rigaud et al., 2006; Skare et al., 1992; Schuster et al., 1993, 1994, 1995). Furthermore, SAP or XIAP expression can be easily measured by FACS analysis in $CD3^+$ or $CD8^+$ T cells

Table 44.2 **CRITERIA FOR DIAGNOSIS OF X-LINKED LYMPHOPROLIFERATIVE DISEASE**

Definitive diagnosis of XLP-1 or -2
Male patient with one or more XLP phenotypes plus SAP or XIAP deficiency (i.e., mutations in the *SH2D1A* or *XIAP* gene, absent mRNA and/or absent protein expression of the *SH2D1A* gene or *XIAP* in lymphocytes)*
Probable diagnosis of XLP-1 or -2
One or more XLP phenotypes in a male patient *plus* one or more XLP phenotypes in at least one of his brothers, maternal cousins, uncles, or nephews (*SH2D1A* and *XIAP* gene status not known)
Suggestive diagnosis of XLP-1 or -2
One or more XLP phenotypes in a single male family member (*SH2D1A* and *XIAP* gene status not known)

*Presymptomatic diagnosis of XLP-1 or 2 is also definitive in an (initially) healthy male carrying a *SH2D1A* or *XIAP* gene mutation known to cause XLP-1 or -2.

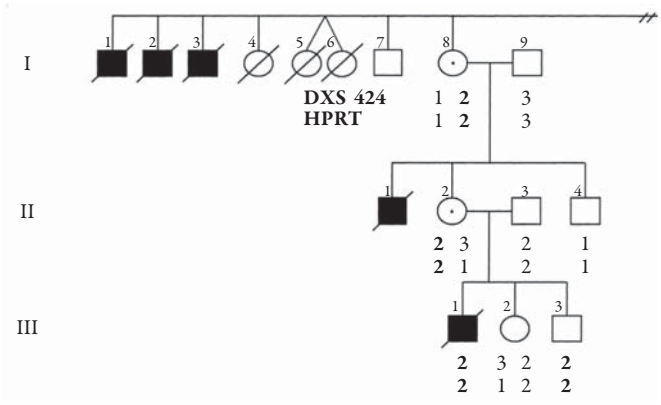

Figure 44.4 Pedigree of a Spanish XLP-1 family with haplotypes of polymorphic markers DXS424 (proximal to *SH2D1A*) and HPRT (distal to *SH2D1A*). Male subjects I-1 to I-3, II-1, and III-1 (black symbols) died of fulminant infectious mononucleosis during early infancy. Haplotype 2-2 co-segregated with XLP-1 (Brandau et al., 1999). In the index patient 3 (III-1), but also in his healthy brother, a nonsense mutation of the *SH2D1A* gene (Y100X) was identified (Brandau et al., 1999). Subjects I-8 and II-2, but not III-2, were shown to be heterozygous carriers for the Y100X mutation.

and NK cells or Western blotting in PBMC or PHA blasts (Marsh et al., 2010a; Rigaud et al., 2006; Shinozaki et al., 2002; Tabata et al., 2005). For SAP deficiency, the carrier status can be easily evaluated by FACS, revealing a bimodal expression of SAP in $CD8^+$ T cells and NK cells. For the carrier status of a XIAP deficiency, determination by FACS is not indicated, as the XIAP wild-type allele is preferentially expressed in hematopoietic cells of the carrier, making detection of a clear bimodal expression of XIAP difficult (Marsh et al., 2010a). Because iNKT cells are nearly absent in XLP-1 patients, the quantification of iNKT cells, together with clinical data and family history, may facilitate the diagnosis of XLP-1. However, for the diagnosis of XLP-2 it might not be relevant, as XLP-2 patients can have normal numbers of iNKT cells (Marsh et al., 2009). To validate missense mutations of XIAP that retain XIAP expression, activation-induced cell death of PHA-T cell blasts upon TCR/CD3 stimulation can be performed. When adequately done in parallel with control cells from healthy donors, it reveals a significant and reproducible excess of apoptosis in T-cell blasts of the patient.

DIFFERENTIAL DIAGNOSIS

While there are some differences in patients with XLP-1 and XLP-2 (Pachlopnik Schmid et al., 2011), the clinical phenotypes of these two syndromes share similarities with other disorders that need to be excluded. These are discussed below. Sporadic fatal infectious mononucleosis occurs in approximately 1 in 3,000 cases of infectious mononucleosis (Purtilo et al., 1992), with a median age of 5.5 years (fatal infectious mononucleosis in XLP-1 occurs at a median age of 2.5 years) and a male/female ratio of approximately 1:1 (Mroczek et al., 1987b). Presenting signs and symptoms are similar to those seen in XLP-1 patients with fatal infectious mononucleosis. Other XLP-1 phenotypes (dysgammaglobulinemia, lymphoma) are absent. In 25 males with sporadic fatal infectious mononucleosis studied to date, no mutations within the *SH2D1A* gene have been found (Sumegi et al., 2000).

Familial hemophagocytic lymphohistiocytosis (FLH) is a group of autosomal-recessive disorders characterized by HLH that resembles HLH/VAHS observed in male XLP-1 and XLP-2 patients (see Chapter 53). Male and female patients with HLH harbor mutations in genes encoding molecules involved in the cytotoxic functions of $CD8^+$ T cells and NK cells. These include mutations in the perforin1, MUNC13–4, MUNC18-2 (STXBP2), syntaxin 11, LYST, and RAB27 genes. Similarly to XLP-1 and XLP-2 patients, affected children may present with fever, splenomegaly, hepatomegaly, pancytopenia, coagulation abnormalities, neurological abnormalities, and high serum concentrations of IFN-γ and TNF-α. In contrast to patients with XLP, the hemophagocytic syndrome in these patients is not particularly associated with EBV infection, and the trigger of HLH is unknown in most of the cases. The onset of the disease is earlier than in XLP-1 and XLP-2, but, importantly, in late-expressing forms of FHL, EBV infection is often one of the triggers of HLH (Katano et al., 2004). Conversely, a few male patients with an HLH-like disease not triggered by EBV have been found to have mutations in the *SH2D1A* gene (Arico et al., 2001; Halasa et al., 2003) or *XIAP* gene (Marsh et al., 2010b; Rigaud et al., 2006).

An autosomal-recessive lymphoproliferative syndrome with hepatosplenomegaly associated with recurrent EBV infections has been recently described in two sisters of a consanguineous Turkish family who exhibited a homozygous missense mutation (R335W) in the gene encoding the IL-2–inducible T-cell kinase (ITK) (Huck et al., 2009). The girls died at age 5 and 10 years, respectively, after developing severe immune dysregulation and therapy-resistant EBV-positive B-cell proliferation identified as EBV-associated Hodgkin's lymphoma. iNKT cells were absent in both patients, a shared feature of XLP-1. However, no signs of HLH have been reported. In 11 further patients with ITK deficiency reported so far additional mutations in the ITK gene were identified: R29H, D500T, F501L, M503X, R265X, Y588X. Clinically these patients presented also with massive EBV+ B cell lymphoproliferation (EBV + LPD, EBV + Hodgkin ′s lymphoma) and hypogammaglobulinemia (Linka et al., 2012; Mansouri et al., 2012; Stepensky et al., 2011).

A similar autosomal-recessively inherited disorder with severe CD4+ lymphopenia and EBV-associated lymphoproliferation was recently identified in three siblings with homozygous Coronin-1A deficiency (Moshous et al., 2013)

EBV-associated lymphoproliferative disorder (EBV+ LPD) with or without HLH, malignant lymphoma or absence of overt clinical phenotype have been recently found also in nine patients lacking functional CD27 (van Monfrans et al., 2011; Salzer et al., 2013).

Chronic active EBV (CAEBV) infection involving mostly T or NK cells is characterized by a persistent severe mononucleosis-like illness (lasting for months or years) with additional unusual clinical features such as hypersensitivity to mosquito bites (43 percent), calcifications in basal ganglia (18 percent),

hydroa vacciniforme (14 percent), hemophagocytic syndrome (21 percent), coronary artery aneurysms (21 percent), and malignant lymphoma (16 percent) (Kimura et al., 2001). Patients with CAEBV have a high EBV load in their peripheral blood ($>10^{2.5}$ copies/μg DNA). In this syndrome, EBV infects predominantly T and/or NK cells (Kasahara et al., 2001; Kimura et al., 2001). In 18 male CAEBV patients studied, no mutations of the *SH2D1A* gene were found (Kimura et al., 2001; Sumazaki et al., 2001). However, one CAEBV patient exhibited a mutated perforin gene (Katano et al., 2004).

Common variable immunodeficiency (CVID) should also be considered in the differential diagnosis (see Chapter 27). The characteristic feature of this rather heterogeneous group of patients is a decrease in all or at least two major immunoglobulin isotypes and an impaired antibody response. In the majority of CVID patients B cells are present in normal numbers. However, these cells are unable to differentiate into antibody-producing plasma cells, possibly due to a primary T-cell abnormality. In a small subset of CVID patients, mutations in the *ICOS* (Grimbacher et al., 2003) or *TACI* genes (Castigli et al., 2005; Salzer et al., 2005) have been identified. In general, CVID occurs in a sporadic manner. Other than the antibody deficiency, there is little similarity to XLP-1. However, a subset of male XLP-1 patients may present with a CVID-like disease (Gilmour et al., 2000; Morra et al., 2001c; Nistala et al., 2001; Soresina et al., 2002).

LABORATORY FINDINGS IN XLP-1 FEMALE CARRIERS

None of the female carriers of the XLP-1 gene studied thus far developed any of the XLP-1 phenotypes. Subtle immunological abnormalities such as hypogammaglobulinemia and elevated IgA and/or IgM levels have been found in a few carrier females (Grierson and Purtilo, 1987; Morra et al., 2001c; Sakamoto et al., 1982). Forty-five of 56 female carriers (80 percent) have been shown to exhibit an abnormal serological response to EBV infection (Grierson and Purtilo, 1987). No data are available for female carriers of the XLP-2 gene.

However, EBV serology alone is not a reliable diagnostic finding in the predictive evaluation of female carriers, since transiently elevated serum antibodies against VCA and EA of the IgM, IgG, or IgA class are also found in normal subjects with a recent primary EBV infection. Carrier females of XLP-1 have a random X-chromosome inactivation pattern in their B and T cells (Conley et al., 1990; Nichols et al., 2005). However, the X-chromosome inactivation pattern in NKT cells of female XLP-1 carriers is skewed (Nichols et al., 2005). In carrier females of XLP-2, the X-chromosome inactivation is skewed in all hemopoietic cells tested, including T, B cells and myeloid cells in which the wild-type allele is preferentially expressed (Marsh et al., 2010a; Rigaud et al., 2006).

At present, direct mutation analysis of the *SH2D1A* or *XIAP* (Birc4) gene or indirect genotype analysis (in informative families) is the only reliable means to determine if a female at risk is a carrier for XLP-1 or XLP-2.

X-LINKED LYMPHOPROLIFERATIVE DISEASE TYPE (XLP-3) DUE TO DEFECTS IN *MAGT1*

In 2011, two unrelated families with a total of three affected males presenting with "idiopathic" CD4 lymphopenia and chronic EBV infection were found to have mutations in the magnesium transported gene, *MAGT1* (OMIM300715). The syndrome, X-linked immunodeficiency with magnesium defect, EBV infection, and neoplasia, has been named XMEN (Li et al., 2011). The patient of family 1 with a nonsense mutation in exon 3 of *MAGT1* (which has 10 exons) died at 45 years of age from chronic EBV-associated lymphoma. The second family had two affected brothers who suffered from recurrent infections, including chronic EBV infection. Both had inverted CD4:CD8 ratios, impaired thymic output of $CD4^+$ T cells, defective TCR-mediated activation in response to anti-CD3, but normal B-cell stimulation via the B-cell receptor or Toll-like receptor. While in normal T cells antigen receptor stimulation results in a rapid transient Mg^{2+} influx, MAGT1-deficient T cells fail to manifest a Mg^{2+} influx, leading to impaired responses to antigen receptor engagement, including defective activation of phospholipase Cγ1 and markedly impaired $C\alpha^{2+}$ influx in T but not B cells. Thus, *MAGT1* deficiency is the third X-linked condition associated with chronic EBV infection and lymphoma. However, in contrast to XLP-1 and XLP-2, affected males have normal numbers of NKT cells and HLH has not been reported.

TREATMENT AND PROGNOSIS

XLP-1 PATIENTS

Prophylactic Treatment of Males at Risk Prior to EBV Infection

There is evidence that maternal EBV-neutralizing antibodies may protect newborn infants, including XLP males, from primary EBV infection for 4 to 6 months (Biggar et al., 1978; Mroczek et al., 1987b). Regular intravenous infusions with immunoglobulins rich in EBV-neutralizing antibodies were therefore started in males at risk to prevent or lessen the effects of EBV infection. However, some boys succumbed to fulminant mononucleosis despite this therapy (Okano et al., 1990, 1991; Seemayer et al., 1995). In any case, all EBV-negative XLP-1 males with hypogammaglobulinemia should receive regular immunoglobulin substitutions (intravenously or subcutaneously) to prevent severe bacterial or viral infections.

Currently, the only means of preventing EBV- and non–EBV-related complications in later life is early transplantation of allogeneic hematopoietic stem cells (HSCT) (Arkwright et al., 1998; Booth et al., 2011; Gross et al., 1996; Hoffmann et al., 1998; Lankester et al., 2005; Pracher et al., 1994; Trottestam et al., 2009; Vowels et al., 1993; Williams et al., 1993; Ziegner et al., 2001). The age of the patient at the time of transplantation appears to be critical. Of eight XLP-1 patients who underwent stem cell transplantation, four boys less than 15 years of age were alive and well for more than 2 years after transplantation, whereas all four boys older

than 15 years of age at the time of transplantation died within 90 days of complications (Gross et al., 1996; Seemayer et al., 1995). Transplantation should be undertaken at the youngest possible age in all patients with HLH because of the poor outcome. Survival of patients with HLH undergoing HSCT is 50 percent but falls to 18.8 percent in untransplanted patients with HLH (Booth et al., 2011).

Gene therapy may become an option in the future. In the murine XLP-1 model it as already been shown that SH2D1A gene transfer into hematopoietic stem cells can correct the multiple immune defects seen in XLP-1 (Rivat et al., 2013).

TREATMENT OF XLP MALES DURING OR AFTER EBV INFECTION

During fulminant mononucleosis, the outcome of treatment with high-dose immunoglobulin, antiviral drugs such as acyclovir, immunosuppressive agents, and IFN-γ has been disappointing (Okano et al., 1990, 1991). Etoposide (VP-16), which has been effective in the treatment of lymphoma, leukemia, and hemophagocytic syndromes, has been shown to induce remissions in some XLP-1 males with fulminant mononucleosis, HLH, or aplastic crisis (Migliorati et al., 1994; Okano and Gross, 1996; Seemayer et al., 1995). One such patient showed rapid improvement of his clinical symptoms of fulminant mononucleosis for a short period after treatment with etoposide. Subsequently, after relapse and clinical deterioration, the boy underwent successful stem cell transplantation following conditioning with etoposide, busulfan, and cyclophosphamide (Pracher et al., 1994). In view of the unfavorable prognosis, a controlled clinical trial with etoposide, with or without stem cell transplantation, in patients with acute exacerbations of XLP-1 is warranted.

One XLP-1 patient with life-threatening EBV-associated HLH reported so far was finally successfully treated by initial intravenous immunoglobulin (IVIG) and high-dose corticosteroids followed by the institution of the HLH-2004 treatment protocol, which includes etoposide, dexamethasone, cyclosporin A, and intrathecal therapy with methotrexate and prednisolone. To reduce the EBV load in B cells, the patient additionally received anti-CD20 monoclonal antibody (rituximab) on day 1. For attenuating the EBV-induced hyperinflammatory state ("cytokine storm"), the patient received the tumor necrosis factor alpha (TNF-α) blocker etanercept (25 mg intravenously) on days 2 and 7 (Mischler et al., 2007).

Males with XLP-1 who develop hypogammaglobulinemia in response to EBV infection require regular intravenous (monthly) or subcutaneous (weekly) immunoglobulin replacement (Nistala et al., 2001) to prevent recurrent bacterial and viral infections. Despite immunoglobulin replacement therapy, other XLP-1 phenotypes such as aplastic anemia or lymphoma may develop in subsequent years (Purtilo, 1991).

XLP-1 patients suffering from malignant lymphomas may enter remissions of short duration after undergoing standard chemotherapy protocols (Seemayer et al., 1995). However, relapses are frequent and other XLP-1 phenotypes may develop. XLP-1 patients with active EBV infection and lymphoproliferative complications may be successfully treated with rituximab in combination with prednisone, acyclovir, and IVIG infusions (Malbran et al., 2004; Milone et al., 2006). Eventually, this procedure may also be useful in the treatment of B-cell lymphoma in XLP-1 patients.

XLP-2 PATIENTS

The therapeutic and prophylactic experiences in XLP-2 patients are still limited due to the low numbers of affected subjects studied and reported so far (Filipovich, 2010; Marsh et al., 2010b; Rigaud et al., 2006). However, XLP-2 patients should be treated like XLP-1 patients according to the HLH-2004 (or a similar) treatment protocol. Treatment with rituximab may be also successful. The indication for stem cell transplantation in XLP-2 is controversial. A multicenter international study of 19 XLP-2 patients with confirmed XIAP deficiency undergoing HSCT revealed poor outcomes. Of seven patients receiving myeloablative busulfan-containing conditioning, only one patient (14 percent) survived; most deaths were caused by transplant-related toxicity. Of the 11 patients receiving reduced-intensity conditioning, 6 (55 percent) are surviving at a median of 570 days following transplantation (Marsh et al., 2013). In contrast, by combining a minimal-intensity immunoablative conditioning regimen with a high stem-cell and T-cell dose graft, XIAP deficiency with uncontrolled HLH has been cured in a 2 year old boy (Worth et al, 2013). Interestingly, one patient with a chronic colitis/IBD was successfully transplanted; at the time of the report, the symptoms of his bowel disease had completely resolved (Worthey et al., 2010). Like XLP-1, XLP-2 patients with hypogammaglobulinemia should be given weekly (subcutaneously) or monthly (intravenously) immunoglobulin infusions.

DIGEORGE SYNDROME: A CHROMOSOME 22q11.2 DELETION SYNDROME

Deborah A. Driscoll and Kathleen E. Sullivan

The association of thymic aplasia with congenital hypoparathyroidism was initially noted by Lobdell in 1959 but wasn't recognized as a syndrome until 1965, when Dr. Angelo DiGeorge described a group of infants with congenital absence of the thymus and parathyroid glands (DiGeorge, 1965). Subsequently, facial dysmorphia and cardiac defects, specifically conotruncal malformations, were included in the spectrum of DiGeorge syndrome (DGS) (Conley et al., 1979). DGS (MIM 188400) is a heterogeneous disorder. However, cytogenetic and molecular studies have shown that deletion of chromosomal region 22q11.2 is the leading cause of DGS. In rare instances, DGS is seen in association with other chromosomal rearrangements, with exposure to teratogens such as retinoic acid, and with maternal diabetes (Lammer and Opitz, 1986; Wilson et al., 1993b).

DGS is a developmental disorder that occurs as a result of abnormal cephalic neural crest cell migration, differentiation, or signaling in the third and fourth pharyngeal arches during the fourth week of embryonic development. Kirby et al. (1983) demonstrated that removal of the premigratory cardiac neural crest cells in the chick embryo results in cardiac outflow tract anomalies similar to those seen in DGS. The cardiac neural crest cells have also been shown to be important in supporting the development of the glandular derivatives of the pharyngeal arches (Kirby and Bockman, 1984). The aortic arch anomalies have been duplicated in transgenic mice with haploinsufficiency due to a deletion of a region of mouse chromosome 16 (Df1) that is homologous to human chromosome 22q11 and contains the *Tbx1* gene encoding a transcription factor with "T-box" DNA-binding domain (Lindsay et al., 2001; Merscher et al., 2001). Jerome and Papaioannou (2001) produced a mouse knockout with a null mutation of *Tbx1*. The heterozygotes have cardiovascular anomalies seen in DGS, whereas the homozygotes are nonviable but display a DGS phenotype as embryos. In fact, the dose of T-box 1 transcription factor during embryonic development is critical for the phenotypic manifestations (Liao et al., 2004).

The gene *TBX1* is the primary gene responsible for DGS, although other genes in the region may contribute to the phenotypic variability. Confirming the importance of the human gene *TBX1* in human DGS, a few patients with classical features of DGS have now been identified with point mutations in *TBX1*. Mutations were also identified in patients with less classical manifestations (Yagi et al., 2003). A further consideration is that gene expression in the gene-rich DGS region of 22q11.2 may be influenced by a long-range regulatory element (Botta et al., 2001).

DGS was initially considered a rare sporadic disorder; however, recent studies suggest that the 22q11 deletion, seen in approximately 90 percent of DGS patients, may occur as frequently as once in 4,000 to 6,000 live births, affecting both sexes equally. Furthermore, acknowledgment of the phenotypic overlap with other genetic disorders that share the 22q11.2 deletion, such as velo-cardio-facial syndrome (VCFS, MIM 192430) and conotruncal anomaly face syndrome (CTAFS), has led to further expansion of the phenotype and a better understanding of the immune, endocrine, cognitive, neurological, and psychiatric problems arising in DGS patients. While most early studies evaluated patients with the classic features of DGS, recent studies have attempted to ascertain all patients with the deletion to better define the clinical spectrum. The immunodeficiency is comparable in all patients with the deletion regardless of the other clinical manifestations (Sullivan et al., 1998). Therefore, we will discuss all patients who carry the deletion under the nomenclature of DGS. It is important to remember that the nomenclature is still evolving, with the term *chromosome 22q11.2 deletion syndrome* being appropriately applied to patients in whom the deletion has been

Table 45.1 DIAGNOSTIC CRITERIA FOR DGS

DIAGNOSTIC CATEGORY	DESCRIPTION
Definitive	<500 CD3 T cells/mm^3 and two of the three following characteristics: Conotruncal cardiac defect Hypocalcemia requiring therapy for >3 weeks Deletion of chromosome 22q11.2
Probable	<1,500 CD3 T cells/mm^3 and deletion of chromosome 22q11.2
Possible	<1,500 CD3 T cells/mm^3 and at least one of the following: Cardiac defect Hypocalcemia requiring therapy for >3 weeks Dysmorphic facies or palatal anomaly

SOURCE: From the European Society for Immunodeficiencies.

confirmed. DGS is still used for both patients with 22q11.2 deletion and patients with the classical clinical triad of cardiac defects, immunodeficiency, and hypocalcemia but without a demonstrable deletion. Approximately 10 percent of patients with DGS will not have the standard chromosome 22q11.2 deletion; thus, the deletion is not absolutely required for the diagnosis of DGS. One scheme for categorizing patients with DGS is given in Table 45.1. The most accurate labels are the genetic descriptions, when applicable (i.e., chromosome 22q11.2 deletion syndrome) and the syndromic descriptor when the etiology is not known.

CLINICAL FEATURES

DGS has classically been characterized as a triad of clinical features: congenital cardiac defects, immune deficiencies secondary to aplasia or hypoplasia of the thymus, and hypocalcemia due to small or absent parathyroid glands. We now recognize that the phenotypic features seen in patients with DGS are much more variable and extensive than previously recognized (Botto et al., 2003; McDonald-McGinn et al., 1999; Ryan et al., 1997; Vantrappen et al., 1999; Table 45.2). The acknowledgment of similarities and phenotypic overlap with other disorders, including VCFS and CTAFS, as well as the association of all of these disorders with genetic defects in 22q11 has led to an expanded phenotype that includes palatal and speech abnormalities and cognitive, neurological, behavioral, and psychiatric difficulties.

IMMUNE DEFICIENCY

Most DGS patients have a mild to moderate immunodeficiency characterized by impaired production and function of T cells, with occasional secondary abnormalities in B-cell function (Barrett et al., 1981; Bastian et al., 1989; Junker and Driscoll, 1995; Mayumi et al., 1989; Schubert and Moss, 1992). The most obvious abnormality is the impaired production of T cells. T-cell counts are typically in the range of

Table 45.2 CLINICAL FEATURES OF THE 22Q11 DELETION SYNDROME

Fregnent
Conotruncal cardiac defects (49–83%)
Immune deficiency (80%)
Hypocalcemia (17–60%)
Palatal abnormalities (69–100%)
Cleft palate (9–11%)
Submucous cleft palate (5–16%)
Velopharyngeal insufficiency (27–32%)
Feeding and swallowing difficulties (30%)
Dysmorphic facies
Prominent nasal root
Narrow nasal alae with bulbous nasal tip

Neuropsychiatric disorders

500 to 1,500 cells/mm^3 for the first months of life (Bastian et al., 1989; Junker and Driscoll, 1995). This defect in T-cell production is due to an anatomical thymus gland deficiency. Studies have demonstrated that most patients have either a very small anterior mediastinal thymus or small rests of thymic tissue scattered throughout the neck and submandibular areas (Bale and Sotelo-Avila, 1993; Lischner and Huff, 1975). This tissue consists of normal thymic components and is apparently sufficient to support normal T-cell maturation. Although decreased numbers of mature T cells are produced, the orderly sequence of maturation appears to be preserved.

The spectrum of immunodeficiency is broad. While the typical patient demonstrates impaired T-cell production in the first months of life, some DGS patients have normal or near-normal T-cell production, whereas a minority has almost

no detectable T-cell production. In general, the T-cell deficit improves during the first year of life, and 35 percent of DGS patients produce normal numbers of total T cells by the end of the first year of life (Jawad et al., 2001). There is some suggestion that DGS patients with a normal-appearing thymus are unlikely to have substantial persistent immunodeficiency (Bastian et al., 1989). In contrast, complete anatomical absence of a thymus does not preclude the ultimate development of normal immunological function.

Although all T-cell subsets are reduced, CD8 T cells are diminished the most. In early infancy the average CD8 count is approximately 300/mm^3 and the average CD4 count is approximately 850/mm^3 (Bastian et al., 1989; Junker and Driscoll, 1995). In an effort to understand whether peripheral blood T cells in patients with DGS develop aberrantly as a result of insufficient thymic epithelium, patient cells have been stained with markers specific for different stages of thymic maturation (Muller et al., 1989; Reinherz et al., 1981; Sirianni et al., 1983a, 1983b). On the basis of these studies, it appears that T cells use the usual developmental pathways; however, DGS patients are simply not able to produce as many T cells during the first months of life. It is not known why CD8 T cells are more profoundly affected than CD4 T cells.

T-cell function is usually grossly normal as measured by responses to T-cell mitogens (Barrett et al., 1981; Bastian et al., 1989; Junker and Driscoll, 1995; Muller et al., 1989). However, a small minority of patients have markedly diminished T-cell responses. In the past, this distinction has led to confusing nomenclature. Patients with minimal T-cell mitogen responses were said to have complete DGS and patients with normal or near-normal T-cell mitogen responses were said to have partial DGS. In fact, there is a spectrum of severity for all of the phenotypic features of this disorder. Some of the patients with markedly impaired T-cell function will not improve with time and will require either a bone marrow transplant or thymus transplant, whereas others will improve, although improvement becomes less likely after the first few months.

The consequences of T-cell deficiency in DGS patients are an increased susceptibility to infections, particularly viral infections, and an increased risk of autoimmune disease. Specifically, parainfluenza, adenovirus, and rotavirus have been shown to cause severe morbidity in DGS patients (Beard et al., 1980; Gilger et al., 1992; Tuvia et al., 1988; Wood et al., 1988). Most viral illnesses are more prolonged in DGS patients with compromised T-cell function. It is not known if decreased T-cell numbers are an independent risk factor for prolonged viral diseases in the absence of T-cell dysfunction. Two studies demonstrated that DGS patients have an impaired T-cell repertoire, suggesting that markedly diminished T-cell numbers do contribute to infectious morbidity (Pierdominici et al., 2000; Piliero et al., 2004). DGS patients with severely diminished T cells are also at risk from the same opportunistic infections as patients with severe combined immunodeficiency (SCID).

Juvenile rheumatoid arthritis, immune-mediated thrombocytopenia (ITP), and autoimmune hemolytic anemia occur with increased incidence in patients with DGS (Duke et al., 2000; Jawad et al., 2001; Pinchas-Hamiel et al., 1994). In addition, individual cases of autoimmune thyroiditis have been described, suggesting that there is a generalized increased frequency of autoimmune disease in DGS patients (Ham Pong et al., 1985). The delayed formation and maturation of T-cell regulatory functions might allow for the development and proliferation of autoreactive T cells (Sullivan et al., 2002).

The natural killer (NK) cell compartment often represents a large fraction of the total peripheral blood lymphocytes. In some cases, this reflects genuine expansion of this cell lineage. NK-cell function has been examined in DGS patients and found to correlate poorly with NK-cell number or T-cell studies (Muller et al., 1989).

In contrast to the quantitative deficiency of T cells, the B-cell compartment is typically normal or expanded. The B cells often represent a larger fraction of the total lymphocyte pool than in normal infants, and the absolute numbers of B cells may be expanded as well. Markedly increased B-cell numbers may correlate with poorer T-cell function (Jawad et al., 2001; Muller et al., 1989). This is thought to be due to aberrant regulation of B cells by the deficient T cells. There is evidence that there is defective T-cell suppression of B-cell immunoglobulin production in infants with DGS (Durandy et al., 1986), and it is not uncommon for infants with DGS to have hypergammaglobulinemia (Muller et al., 1988). On the other hand, hypogammaglobulinemia, IgA deficiency, and delayed acquisition of appropriate antitetanus and antidiphtheria antibody titers have been described in DGS patients (Junker and Driscoll, 1995; Mayumi et al., 1989; Smith et al., 1998). This is also thought to result from the relative deficiency of appropriate T-cell help for immunoglobulin production. A DGS kindred with persistently impaired T-cell production, normal T-cell function, and defective ability to form some antipolysaccharide antibodies has been described. The occurrence of similar humoral dysfunction in the same kindred suggests that modifier genes may play a significant role in the ultimate level of humoral function. In general, however, it is not possible to predict the level of immunological function of an affected child on the basis of previously diagnosed siblings or parents. Recognition that T-cell dysfunction could alter immunoglobulin production prompted a study of immunoglobulin diversity in DGS patients. The immunoglobulin repertoire was normal in a patient with severe T-cell deficits as well as in a patient with mild T-cell compromise. However, somatic mutation was found to be markedly deficient in the patient with significant T-cell dysfunction compared to the more mildly affected patient and normal controls (Haire et al., 1993).

OTHER FEATURES

Congenital Abnormalities

The most common cardiovascular malformations include interrupted aortic arch type B (14–15 percent), truncus arteriosus (7–9 percent), and tetralogy of Fallot (17–22 percent). Although neonatal hypocalcemia is not uncommon in DGS, recent studies suggest that patients are at risk for a spectrum

Figure 45.1 Frontal and side views of a 4-month-old boy with DGS and a 22q11.2 deletion. Note the prominent ears, bulbous nasal tip, mild micrognathia, and sloping forehead.

of parathyroid gland abnormalities including latent hypoparathyroidism, which may evolve to hypocalcemic hypoparathyroidism during adolescence or early adulthood (Cuneo et al., 1997). One study demonstrated that chromosome 22q11.2 deletions were seen in 10 of 14 neonates with hypocalcemia (Adachi et al., 1998).

Newborns and infants with DGS may have dysmorphic facial features such as widely spaced eyes (hypertelorism); low-set, prominent ears; and micrognathia. Later in childhood, adolescence, and adulthood their facial features evolve (Fig. 45.1). The characteristic facial features include a long face; a prominent nose with a bulbous nasal tip and narrow alar base; almond-shaped or narrow palpebral fissures; malar flattening; recessed chin; and malformed, prominent ears (Shprintzen et al., 1981). In addition, a spectrum of palatal abnormalities may be seen in DGS, such as cleft palate, submucous cleft palate, velopharyngeal insufficiency (VPI), bifid uvula, and cleft lip with or without cleft palate. Feeding difficulties and gastroesophageal reflux are common and can require tube feeding or a gastrostomy tube (Eicher et al., 2000). Renal anomalies such as single kidney, multicystic dysplastic kidney, horseshoe kidney, and duplicated collecting system occur in approximately one third of DGS patients. Hearing loss in one or both ears is not uncommon. Other features seen less frequently include microcephaly, short stature, hypospadias, ocular abnormalities, inguinal and umbilical hernias, hematological abnormalities, and skeletal anomalies (McDonald-McGinn et al., 1999; Ryan et al., 1997).

Neurocognitive, Behavioral, and Psychiatric Abnormalities

Structural malformations of the central nervous system such as neural tube defects, a small cerebellar vermis or posterior fossa, and polymicrogyria have been described, but it is unclear if these changes correlate with the developmental, cognitive or behavioral abnormalities observed in DGS patients (Nickel et al., 1994; Mitnick et al., 1994).

Prospective evaluations of children with DGS have enabled us to understand the range of cognitive and neuropsychological problems they are at risk to develop. In children of preschool age, developmental delay, motor delays, mild hypotonia, and language and speech delays, especially for expressive language, are common. Behavioral problems observed include attention-deficit/hyperactivity disorder (ADHD), inhibition, and shyness (Gerdes et al., 1999; Goldring-Kushner et al., 1985; Swillen et al., 1997). Psychoeducational and neurodevelopmental studies of children with the 22q11 deletion demonstrated full-scale IQ scores in the normal to moderately retarded range, with the majority falling in the borderline range (IQ 70–84). In early childhood, nonverbal learning difficulties are not uncommon, but there were no significant differences by adolescence. Math skills are in general lower than reading and spelling (Anthshel et al., 2010; Moss et al., 1999). Language difficulties persisted in approximately 50 percent of the children of school age (Solot et al., 2000). Adults demonstrate deficiencies in social judgment, motor skills, verbal learning, and executive function (Chow et al., 2006).

Recent studies also suggest an increased frequency of behavioral and psychiatric disorders. In children, ADHD, specific phobias, and anxiety are common (Anthshel et al., 2010; Niklasson et al., 2009), and autism spectrum disorders have been reported (Vorstmann et al., 2006). Psychiatric disorders, including generalized anxiety disorder and schizophrenia, have been diagnosed in about 60 percent of adults with the 22q11 deletion. The risk of developing schizophrenia or schizoaffective disorder is about 20 times the population risk (Fung et al., 2010). Prospective studies will provide greater insight into the risk factors for psychiatric disorders and may identify genetic variants in the region, which may be predictive (Philip and Bassett, 2011).

OTHER DISORDERS ASSOCIATED WITH THE 22Q1 1 DELETION

In addition to the overlap between DGS and VCFS, there are striking similarities between patients with DGS and those with CTAFS, a disorder predominantly described among the Japanese. CTAFS is characterized by conotruncal cardiac defects in association with a characteristic facial appearance. The facial features include ocular hypertelorism, lateral displacement of the inner canthi, flat nasal bridge, small mouth, narrow palpebral fissures, bloated eyelids, and malformed ears (Kinouchi et al., 1976). Some patients have a history of neonatal tetany, absent or hypoplastic thymus, and partial depression of T-cell–mediated immune responses. The finding of 22q11 deletions in CTAFS patients confirmed an earlier suggestion that CTAFS, VCFS, and DGS are the same entity (Burn et al., 1993; Matsuoka et al., 1994).

Recent cytogenetic and molecular studies of patients diagnosed with Opitz/GBBB syndrome suggest that there are two distinct genetic etiologies: chromosome 22q11 and a second on the X chromosome (McDonald-McGinn et al., 1995; Robin et al., 1995a). Opitz/GBBB syndrome (MIM 145410) is characterized by hypospadias, laryngotracheal anomalies, and hypertelorism (Opitz et al., 1965). Patients may have other features, including cleft lip and palate, cardiac defects, umbilical and inguinal hernias, cryptorchidism, imperforate anus, and facial dysmorphia such as telecanthus, prominent nasal bridge, or depressed nasal root with anteverted nares.

DiGeorge syndrome features have been observed in several other disorders, including CHARGE association (coloboma, heart defects, atresia of the choanae, retarded growth, genital hypoplasia, ear anomalies), Cayler cardiofacial syndrome, Kallman syndrome, and Noonan syndrome (Bawle et al., 1998; Lammer and Opitz, 1986; Robin et al., 1995b; Wilson et al., 1993a). However, the 22q11 deletion has not been found to be causally related to these disorders in a significant number of cases.

PHENOTYPIC VARIABILITY OF DGS

The variability in DGS arises from two issues. Patients with DGS can have diverse etiologies, such as diabetic mothers, the 22q11 deletion, or other genetic causes. In addition, patients who carry a common deletion with identical endpoints can have very diverse clinical features.

There is a wide range of phenotypic variability associated with the 22q11 deletion. While some individuals present with classic findings of DGS, others have relatively subtle features such as minor dysmorphic facial features or mild cognitive impairment. Prospective studies of newborns and children with conotruncal defects that were initially believed to be isolated indicate that those patients who have the 22q11 deletion often eventually manifest other features of the syndrome, such as mild facial dysmorphism, velopharyngeal insufficiency, and learning difficulties (McDonald-McGinn et al., 1997). Such studies suggest that all deletion-positive patients should receive comprehensive medical evaluations and follow-up as well as neuropsychological and educational assessments (Bassett et al., 2011; Oskarsdottir et al., 2005).

CYTOGENETIC AND MOLECULAR STUDIES

Cytogenetic studies of patients with DGS provided the initial evidence linking chromosome 22 to DGS (reviewed in Greenberg et al., 1988). Early reports of DGS patients with unbalanced translocations resulting in the loss of 22pter to q11 and two patients with interstitial deletions of 22q11 suggested that this region of chromosome 22 was important in the etiology of DGS. Molecular studies demonstrated that apparently cytogenetically normal DGS patients had submicroscopic deletions within 22q11 and defined the DiGeorge critical region (DGCR) (Driscoll et al., 1992a).

The presence of features common to DGS in patients diagnosed with VCFS prompted investigators to study VCFS patients for evidence of a 22q11 deletion (Fig. 45.2).

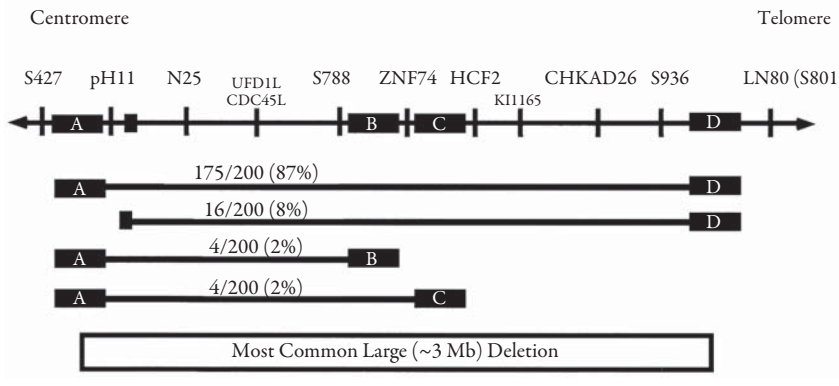

Figure 45.2 DiGeorge chromosomal region illustrating the size and location of the 22q11. 2 deletions in 200 patients. Deletion size and boundaries (A–D) were determined by fluorescence in situ hybridization (FISH), using as probes cosmids containing the genes and markers listed on the map of 22q11.2. The duplicated blocks of sequence or low copy repeats, designated A, B, C, D, coincide with observed deletion endpoints in patients. The extent and frequency of the four recurrent deletions are shown as lines below the map. Eighty-seven percent of DGS patients have a 3 Mb deletion extending from A to D. (Modified figure courtesy of B. S. Emanuel.)

Cytogenetic studies using high-resolution banding techniques detected interstitial deletions (del 22q11.21–q11.23) in 20 percent of VCFS patients (Driscoll et al., 1992b). Molecular studies with chromosome 22 probes previously shown to be deleted in patients with DGS demonstrated that the majority of individuals with VCFS have similar deletions of 22q11 (Driscoll et al., 1992b, 1993; Kelley et al., 1993). These studies coincided with the increasing utilization of fluorescence in situ hybridization (FISH) for the detection of microdeletions and subtle translocations. FISH of metaphase chromosomes by use of DNA probes from the DGCR led to a dramatic increase in the detection of 22q11 deletions in patients with features of DGS, VCFS, CTAFS, and conotruncal cardiac malformations (Color Plates 45.I and 45.II). The majority of DGS patients have a 3 Mb deletion. More recently, newer technology such as PCR-based multiplex ligation dependent probe amplification (MLPA) and array comparative genomic hybridization (CGH) have been used to detect smaller deletions nested within the 3 Mb deletion and atypical distal deletions in about 10 percent of patients with features of DGS and VCFS (Ben-Shachar et al., 2008; Busse et al., 2011; Jalali et al., 2008).

MECHANISM OF THE 22Q11 DELETION

Significant progress has been made in our understanding of the mechanism of the 22q11.2 deletion. Numerous DGS-associated translocations within the commonly deleted region and identification of unstable DNA sequences near the recurrent constitutional t(11; 22) translocation breakpoints suggest that 22q11.2 is an unstable region (Kurahashi et al., 2000). The region contains low copy number repeats (LCRs), which lead to nonallelic homologous recombination due to a misalignment during meiosis that results in deletions and duplications (Saitta et al., 2004; Shaikh et al., 2000, 2001). Analysis of the sequence of these LCRs indicates that they are large, highly homologous, and complex.

GENE IDENTIFICATION

At least 40 genes have been identified within the 3 Mb commonly deleted region of 22q11.2. This entire gene-rich region of chromosome 22 has been sequenced and is now available in the public domain (Dunham et al., 1999). Animal and human studies suggest that *TBX1*, a T-box transcription factor, is the responsible gene; however, there are several genes in the commonly deleted region that may contribute to the variable phenotypic features in DGS. They are described in this section.

The human *TBX1* gene was identified in the commonly deleted region and is deleted in the majority of DGS patients (Chieffo et al., 1997). *TBX1* is a member of a conserved family of genes that share a "T-box" DNA-binding domain and function as transcription factors involved in the regulation of developmental processes. Animal models strongly suggest a dominant role for TBX1 protein in the DGS phenotype (see "Animal Models") and have provided insight into the genetic pathway for DGS. It appears that Tbx1 is part of a regulatory pathway including non-chromosome 22 genes encoding Six1, Eya1, and Fgf8 that controls morphogenesis of the mammalian heart and face (Guo et al., 2011). The demonstration of point mutations in TBX1 leading to the full phenotype of DGS argues strongly for this being the major contributor to the phenotype (Yagi et al., 2003).

Several additional genes described in the common DGS deleted region may also contribute to the phenotype, given their expression patterns and potential role in cardiac and neural crest cell migration and differentiation. In 1995, *DGCR2/LAN/IDD*, a gene expressed in a variety of human adult and fetal tissues, was identified by several investigators (Budarf et al., 1995a; Demczuk et al., 1995; Wadey et al., 1995). This gene encodes a potential adhesion receptor that might mediate specific adhesive interactions between cells resulting in abnormal migration or interaction of the neural crest cells with the branchial arches.

The novel gene *DGCR6* is located in the proximal DGCR and shares homology with the *Drosophilia melanogaster* gonadal protein (gdl) and laminin g-1 (*LAMC1*) chain (Demczuk et al., 1996). Although *DGCR6* is present in all adult tissues except placenta, it appears to be most abundant in heart and skeletal muscle. Because of its homology with laminin, which, through its interactions with a receptor, plays a role in cell attachment, migration, and tissue organization during embryonic development, it is possible that *DGCR6* may play a role in neural crest cell migration. A goosecoid-like homeobox gene, *GSCL* or *GSC2*, has also been identified within the DGS region (Funke et al., 1997; Gottlieb et al., 1997). *GSCL* is expressed during early human development in the derivatives of the cephalic neural crest cells.

Catechol-*O*-methyltransferase encoded by the gene *COMT*, also within the commonly deleted region (Grossman et al., 1992), is important in the metabolism of catecholamines such as noradrenaline, adrenaline, and dopamine. A polymorphism has been identified, *COMT* 158^{met}, that results in decreased enzyme activity, and several studies have looked for an association with cognitive function and psychiatric disorders, with contradictory results (reviewed in Philip and Bassett, 2011). Another gene in the region, *PRODH*, encoding proline dehydrogenase, catalyzes the conversion of proline to pyrroline-5-carboxylate and has been implicated in the etiology of schizophrenia and schizoaffective disorders, but the role in patients with DGS remains to be determined (Philip and Bassett, 2011; Prasad et al., 2008).

Glycoprotein Ibβ, encoded by the gene *GP1BB* in 22q11.2, is a component of the major platelet receptor for von Willebrand factor (Budarf et al., 1995b). Defects in this receptor result in a rare autosomal recessive bleeding disorder, Bernard-Soulier syndrome (BSS), which is characterized by excessive bleeding, thrombocytopenia, and very large platelets. A single patient with features of BSS and VCFS with a 22q11 deletion has been described (Budarf et al., 1995b). Haploinsufficiency for this region of chromosome 22 unmasked a mutation in the promotor region of the remaining *GP1BB* allele, resulting in manifestations of BSS (Ludlow et al., 1996). Haplosufficiency

for *GPIBB* is likely to be responsible for the mild thrombocytopenia seen commonly in patients with deletions of 22q11.2 (Lawrence et al., 2003).

ANIMAL MODELS

The creation of mouse models has enhanced our understanding of the molecular basis of DGS. Initially, maps and sequence of the region of mouse chromosome 16 that is homologous to the DGS chromosomal region on 22q11 were constructed (Lund et al., 1999; Puech et al., 1997; Sutherland et al., 1998). Targeted mutations of single genes and deletions of the homologous region of 16 have been developed to elucidate the role of individual genes or sets of genes in DGS. Most of the initial attempts failed to recapitulate the DGS phenotype. Eventually, using Cre-loxP chromosome engineering, Lindsay et al. (1999) created a mouse with cardiac defects similar to those seen in DGS. The mice had a 1.2 Mb deletion, designated *Df1*, of chromosome 16 containing at least 20 genes that are most often deleted in DGS patients. Most of the mice heterozygotes for this deletion were viable; 18 to 26 percent had abnormalities of the fourth aortic arch arteries but no other manifestations of DGS. Subsequently, through chromosome engineering and P1 artificial chromosome transgenesis, these investigators identified *Tbx1* as the gene in the *Df1* mouse responsible for the cardiac defects (Lindsay et al., 2001). A second group also used the Cre-loxP strategy to generate a slightly larger 1.5 Mb deletion in mouse chromosome 16 that results in conotruncal cardiac anomalies (interrupted aortic arch type B, vascular ring, right aortic arch) and absent parathyroid glands (Mersher et al., 2001). They also used a rescue transgenesis technique and concluded that *Tbx1* was the critical gene for cardiac defects in mice with both deletions. In addition to the cardiac defects, the transgenic mice had a smaller-than-normal thymus, occasionally with small ectopic thymic lobules, along with a reduced number of CD4 and CD8 cells; however, the parathyroids were normal. Similar to humans, the cardiac defects in heterozygous *Df1* mice are not fully penetrant. This mouse model has provided insight into the pathogenesis of the cardiac defects and the basis for reduced penetrance. The aortic arch defects appear to correlate with a delay and occasional failure of the differentiation of vascular smooth muscle from neural crest cell mesenchyme. Migration of the neural crest into the fourth arch and initial formation of the fourth pharyngeal arch arteries proceeds normally in the *Df1* mice, but the affected vessels are impaired in their growth and do not acquire smooth muscle (Lindsay and Baldini, 2001). Many of the heterozygous *Df1* embryos were capable of overcoming this vascular defect and developed normally. These studies suggest that, contrary to previous beliefs, the cardiac defects in DGS are secondary to delayed growth and responsiveness to developmental signals for remodeling of the vasculature. This finding illustrates how the animal model has altered our understanding of DGS as a developmental disorder.

At the same time, Jerome and Papaioannou (2001) reported on the production of a null mutation in mouse *Tbx1*. The heterozygotes were viable, but in 19 to 45 percent of them, depending on the parental strain of mouse, the fourth aortic arches were absent or reduced in thickness. There were no differences in the weight of the thymus, absolute number of thymocytes, or cell-surface markers CD3, CD4, and CD8 in *Tbx1* heterozygote versus wild-type mice; however, the *Tbx1* homozygous mutants were nonviable. Embryos that were recovered displayed a range of phenotypic findings similar to DGS, including short neck, abnormal facial structure, low-set or abnormally folded ears, single cardiac outflow tract, right aortic arch or a double aortic arch, absent thymus, and absent parathyroids. Other investigators have confirmed the cardiac defects in *Tbx1* mutants (Lindsay et al., 2001; Merscher et al., 2001). In the mouse, a *Tbx1* mutation is sufficient to produce a DGS phenotype. The anomalies in the *Tbx1* knockout mouse model correlate with the expression pattern of *Tbx1* in the embryonic mouse head mesenchyme, pharyngeal arches and pouches, and the otic vesicle. This study provides further evidence that in humans the *TBX1* gene is a key gene in DGS (Jerome and Papaioannou, 2001).

The *Ckrol* mouse mutant developed by Guris et al. (2001) suggests that other genes may contribute to the classical features of DGS. *Crkol* is highly expressed in the branchial arches during mouse embryogenesis and maps to mouse chromosome 16 outside the *Df1* deletion. Homozygous mice with a null mutation in *Crkol* have cardiac defects, including double-outlet right ventricle and ventriculoseptal defect with an overriding aorta due to abnormal alignment of the outflow tract. Approximately 40 percent of the mutant embryos also had an abnormal thymus, parathyroid, and thyroid glands, and mild skeletal anomalies of the head. The similarities to DGS suggest that this gene may contribute to the development of at least some of the clinical features.

CLINICAL AND LABORATORY DIAGNOSIS

DGS patients with the 22q11 deletion are ascertained through a variety of medical specialty clinics on the basis of presenting features. Recognition of the 22q11 deletion syndrome is important so that the medical community and schools can meet these patients' diverse needs. Furthermore, identification of a 22q11 deletion enables the clinician to provide the affected patient and his or her family with a more accurate assessment of their recurrence risk. Although deletions of 22q11 may be detected in 20 to 25 percent of DGS patients by means of high-resolution cytogenetic analysis, FISH of metaphase chromosomes or array CGH is more efficient (Desmaze et al., 1993; Driscoll et al., 1993; Wilson et al., 1992). Many commercial and hospital-based laboratories are using FISH with the probes from the DGCR for the clinical and prenatal detection of the 22q11 deletion (Color Plate 33.I). However, array CGH is recommended when a diagnosis of DGS is suspected and FISH fails to identify a 22q11 deletion (Busse et al., 2011). Gene sequencing of *TBX1* may be considered in patients strongly suspected of having DGS in whom FISH and array CGH is normal.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

The majority of the 22q11 deletions are sporadic events, occurring only in the affected individual. The incidence of familial cases of DGS is approximately 10 percent (McDonald-McGinn et al., 2001). Hence, it is important to closely examine the parents of an affected child for subtle features, such as mild facial dysmorphia, hypernasal speech, and history of poor school performance, that are suggestive of a 22q11 deletion. Deletion testing of the parents is recommended. A parent or proband with a 22q11 deletion has a 50 percent chance of transmitting the deletion-bearing chromosome to his or her offspring. Parents with a 22q11 deletion benefit from preconception and antenatal genetic counseling to review their risk of having affected offspring and to discuss their reproductive options, including prenatal testing and preimplantation genetic diagnosis (Driscoll, 2001; Iwarsson et al., 1998).

Antenatal detection of the 22q11 deletion by FISH has been successfully performed on cultured amniocytes and chorionic villi obtained from at-risk pregnancies (Driscoll, 2001; Driscoll et al., 1993). Pregnancies considered at high risk include those of deletion-positive parents or parents with mosaicism for the 22q11 deletion, and those in which ultrasound or echocardiography demonstrates a fetal conotruncal cardiac malformation. Although the recurrence risk for normal parents with a previous affected child is low, parents often request prenatal testing for the deletion to exclude the small possibility of germline mosaicism. Although testing for the deletion is highly accurate, it is impossible to predict the phenotype. The size and extent of the deletion have not shown correlation with the penetrance and severity of features of DGS (Lindsay et al., 1995). There is significant intrafamilial variability, and the parental phenotype is not a reliable predictor of outcome for the fetus (McDonald-McGinn et al., 2001). Fetal imaging techniques such as ultrasonography and fetal echocardiography are recommended to evaluate the fetus for the presence of a cleft palate, renal anomaly, or cardiac defect. Subtle congenital anomalies such as a submucous cleft palate and dysmorphic features cannot be appreciated by ultrasonography (Driscoll, 2001).

At the present time, it remains difficult to counsel families with children with DGS unless an etiology has been identified. For now, fetal sonography and echocardiography are the only available prenatal tests that are helpful when evaluating at-risk pregnancies that are not causally related to an abnormality of 22q11 or other recognizable chromosomal abnormality.

MANAGEMENT AND TREATMENT OF THE IMMUNODEFICIENCY

The clinical management of infants and children with 22q11 deletion syndrome depends on their degree of immunocompromise. Most infants with the classic features of DGS are diagnosed in the first weeks of life through their characteristic cardiac anomalies and hypocalcemia, whereas older children may not be recognized until they develop speech and/or learning problems. As soon as the diagnosis of the 22q11.2 deletion syndrome or DGS is established, the individual should have an initial immunological evaluation. It is important to specifically evaluate immunological function regardless of the severity of the other phenotypic features (Sullivan et al., 1998). Depending on the age of the child and the level of concern, this could include T- and B-cell subset analyses, T-cell mitogen and antigen responses, immunoglobulin production, and tests of specific antibody formation.

Newborns should be evaluated for T-cell production and function by analyzing lymphocyte subsets at a minimum. Very young infants with markedly diminished T-cell numbers and function may be followed for a period of time to determine whether the immunodeficiency persists (Sullivan et al., 1999). During this time, they are at risk for opportunistic infections and should receive prophylaxis for *Pneumocystis jiroveci* pneumonia (PCP), reverse isolation, irradiated blood products, and careful monitoring. They should not receive live viral immunizations. Persistence of a SCID-like phenotype requires either a bone marrow or thymus transplant (Markert et al., 1999, 2003) to restore immunological function (Goldsobel et al., 1987; Markert et al., 2007). Because both interventions carry significant risk and the immunodeficiency of DGS is developmentally expressed, it seems wise to delay intervention for 1 to 2 months when possible.

Most infants with 22q11 deletion will have a mild immunodeficiency with an excellent long-term prognosis. T-cell production is usually moderately impaired and T-cell mitogen responses are often normal or near normal. Strategies such as PCP prophylaxis and use of killed vaccines for the patient and family contacts may be considered for infants with very low T-cell counts. Most infants will develop normal or near-normal T-cell counts over time. However, the first year of life represents a vulnerable time during which they require careful monitoring. Although there are limited data to support specific management strategies, a reasonable approach to minimize risk to the affected infant is to withhold live viral vaccines until T-cell function is normal and the child has demonstrated an ability to form functional antibodies. Using the criteria of a CD8 count of at least 250/mm^3 and normal antibody responses to diphtheria and tetanus, we and others have not observed any serious side effects with OPV (oral polio vaccine), MMR (measles, mumps, and rubella vaccine), or varicella vaccine administration (Moylett et al., 2004; Perez et al., 2003). The recent widespread use of inactivated poliovirus vaccine (IPV) has limited early infant exposure to live viral vaccines. To date there have not been serious adverse events with the live rotavirus vaccine in patients with 22q11 deletion syndrome, though vaccine strain diarrhea has been reported in infants with SCID. PCP prophylaxis is required only for patients with extremely low T-cell counts. Sequential follow-up studies are important because the pace of immunological recovery is very unpredictable. Furthermore, there are no laboratory studies or phenotypic markers that predict ultimate immunological outcome. A typical strategy would be to measure lymphocyte subsets and mitogen responses at the time of diagnosis. The T-cell proliferative responses track very well with the T-cell counts; therefore, for many infants the measurement of T-cell counts is sufficient. If the mitogen responses are normal and the T-cell

Table 45.3 SUGGESTED IMMUNOLOGICAL EVALUATIONS OF NEWBORNS AND INFANTS WITH DGS

IMMUNOLOGIC EVALUATIONS	TIME OF DIAGNOSIS	AGE 4 MONTHS	AGE 8 MONTHS	AGE 12 MONTHS
Lymphocyte subsets	X	X	X	X*
Mitogen responses	X*			
Antigen responses				X*
Humoral function				X*

*Requires periodic re-evaluation if abnormal.

production is mildly to moderately impaired, the lymphocyte subsets should be repeated every 4 to 12 months until they have normalized or stabilized (Table 45.3). At 8 to 12 months of age, an analysis of humoral function should be performed. This can be quite helpful for determining the risk/benefit analysis for live viral vaccines. After a year of age, mitogen and antigen responses should be followed sequentially if abnormal on the first evaluation. More severely affected infants require more careful follow-up, while less severely affected infants may require somewhat less frequent follow-up.

Patients with all the elements of DGS at birth typically have a significant immune deficiency by definition. Early management of DGS patients often revolves around their cardiac anomaly, and it may be difficult to adequately assess the patient's immunological function. Blood transfusions and hemodynamic instability may require that the evaluation be limited or delayed. It is prudent to consider the patient as severely immunodeficient until such time as appropriate studies can be done. Because several cases of graft-versus-host disease due to blood transfusions have been recorded in DGS, and because early infancy is the most vulnerable time for DGS infants, only irradiated and cytomegalovirus (CMV)-negative blood products should be given (Brouard et al., 1985; Muller et al., 1989; Washington et al., 1993, 1994; Wintergerst et al., 1989).

In older children with DGS or 22q11 deletion syndrome, it is possible to examine immunological function thoroughly at the first evaluation. Patients with normal or near-normal T-cell production, normal T-cell mitogen and antigen responses, and a demonstrated ability to form functional antibody do not require special treatment or restrictions. Some patients have persistent mild T-cell abnormalities. These patients require individualized management, depending on the degree of T-cell compromise and the extent to which they develop significant infections. These patients also require follow-up studies because the immunological changes can be unpredictable. Most immunological improvement occurs in the first year of life, but additional T-cell function and improved T-cell production can occur later. Furthermore, thymic involution occurs as they get older, and they can have a decline in peripheral blood T-cell counts (Piliero et al., 2004).

Despite laboratory evidence of normal immunological function, many patients have recurrent upper respiratory infections due to abnormal palatal anatomy. These patients benefit from the same surgical interventions as other children, and prophylactic antibiotics as adjunct therapy may be considered. Allergies occur more frequently in 22q11 deletion syndrome than in the general population, and this too can contribute to the recurrent infections (Staple et al., 2005).

Since the majority of DGS patients will ultimately have normal or near-normal immunological function, most research efforts have been directed at improved management of the severely affected infants. Bone marrow transplantation (non-T-depleted) from an HLA-matched sibling donor has been efficacious (Borzy et al., 1989; Goldsobel et al., 1987). It may provide sufficient numbers of mature T cells to allow adequate T-cell function even in the absence of thymic tissue. Early therapeutic efforts were directed at replacing the missing thymic tissue and used fetal thymic grafts (Thong et al., 1978; Touranine, 1979). Although a minority of these grafts succeeded, the limitations imposed by the use of fetal tissue have compromised their practical application. Recently, success has been reported using discarded postnatal thymic tissue obtained during cardiac surgery grafts (Markert et al., 1995, 1999, 2003, 2004, 2007). Four months after placement of a thymic graft, mature functional host T cells were identified in peripheral blood. Antigen-specific T-cell responses developed and B-cell function normalized. This management strategy appears to offer many advantages over fetal thymus or bone marrow transplantation for severely affected DGS patients, although involution of the thymic graft may be a long-term issue.

A specific management issue for patients with DGS and no naïve T cells is the development of an Omenn-like picture (Markert et al., 2004). This is due to escape clones of T cells infiltrating skin and other organs and is just as dangerous as Omenn syndrome associated with SCID. The patients require strong immune suppression prior to definitive therapy. More important than the complex management issues that arise is the diagnostic conundrum. These patients have normal or even high T-cell counts in the peripheral blood. This can cause diagnostic confusion. A close examination of the phenotype of the T cells will reveal that they are all of a memory phenotype (CD45RO). This relatively subtle finding can be a very important diagnostic clue.

FUTURE CHALLENGES

DGS is characterized by a wide range of congenital malformations, facial dysmorphia, endocrine and immune disorders,

cognitive impairment, and neurological and psychiatric abnormalities. Cytogenetic and molecular studies have contributed greatly to our understanding of the genetic basis of this disorder. These studies have shown that deletions of chromosomal region 22q11 are the leading cause of DGS. More recently, *TBX1* was identified as a major contributor to the phenotype. Other genes within or outside the critical region may mold the phenotypic manifestations. The broad availability of genome-wide studies of single nucleotide polymorphisms may allow risk stratification of patients to be more proactive in management.

Prospective studies of DGS patients with 22q11 deletions continue to further delineate the range and severity of the medical, cognitive, and neuropsychological problems for which these patients are at risk. The wide range of phenotypic variability remains poorly understood. Neither the size of the deletion nor the parental origin, a factor in some genetic syndromes because of differences in chromosomal imprinting, appears to explain the penetrance or severity of the phenotype. Murine studies suggest that genetic background is an important influence on the phenotype. Therefore, we hypothesize that the severity and phenotypic variability in DGS may be due to modifier genes. Genetic studies of potential modifying genes in both humans and animal models may further our understanding of this complex disorder and eventually lead to more accurate prediction of the outcome and need for specific therapeutics and intervention. In the meantime, we urge clinicians to pursue comprehensive evaluations by a team of medical professionals in genetics, cardiology, immunology, endocrinology, plastic surgery, speech and hearing, and developmental pediatrics who have the expertise in caring for individuals with DGS.

INTRODUCTION TO DISORDERS ASSOCIATED WITH DNA REPAIR AND METHYLATION DEFECTS

Mark O'Driscoll and Penny A. Jeggo

Our genetic material represents a thread of double helical DNA composed of around 3×10^9 base pairs. To compress this material into the small dimensions of a cell, the DNA is highly compacted by sophisticated and defined mechanisms, which collectively represent the higher-order chromatin structure. However, during the process of development, cells undergo defined DNA transactions that necessitate transient or limited relaxation of the compacted DNA structure. The development of the immune response is one such process. Our cellular DNA is also subjected to constant damage, which can arise from both endogenously generated and exogenous DNA-damaging agents. Proteins, particularly histones, which coat the DNA, provide one mechanism to afford protection from such damaging agents, but it is far from an efficient barrier, and DNA damage still ensues. The cell's major strategy for protection lies in an array of DNA damage-response mechanisms that repair damaged DNA or activate processes that optimize the opportunity for repair. Failing all that, cells have processes that eliminate damaged cells from the cycling population. However, the operation and optimal functionality of these damage-response mechanisms often necessitates the decondensation or relaxation of DNA from its compacted state. It is, therefore, not unsurprising that there is an interesting *ménage à trois* between the development of the immune response, the DNA damage response, and processes that regulate higher-order chromatin structure.

The major aim of the DNA damage-response mechanisms and, indeed, a role for higher-order chromatin structure is to help maintain genomic stability, since genomic instability can lead to cell death or, as significantly, enhance steps in the etiology of carcinogenesis. The development of the cognate immune response has the opposite aim—the generation of genetic diversity to create a repertoire of distinct T and B cells that are able to recognize the vast numbers of antigens to which we are constantly exposed. To achieve this, cells have subverted the DNA damage-response mechanism to help generate genetic diversity rather than maintain stability (Fig. 46.1). In these processes, defined lesions and/or breaks are created in DNA during immune development, which are then rejoined or repaired in a manner creating DNA sequence changes—quite the opposite endpoint that aims to be achieved by the damage-response mechanisms.

In this chapter, we will overview the damage-response mechanisms of relevance to immune development, consider how they have been supplanted to create diversity during immune development, and consider recent advances in our understanding of the impact of chromatin structure on both the response to DNA damage and immune development. Finally, we will consider how the DNA damage-response processes and chromatin structure affect other aspects of development, which is relevant to considering the basis underlying the additional clinical features that are characteristic of this class of immunocompromised patients and serve as useful differential diagnostic indicators.

DNA DAMAGE RESPONSES RELEVANT TO DEVELOPMENT OF THE IMMUNE RESPONSE

RANGE OF DNA LESIONS ENCOUNTERED BY A CELL

Reactive oxygen species (ROS) are a major contributor to DNA damage and by introducing purine and pyrimidine base and/or deoxyribose sugar damage can lead to both DNA single-strand breaks (SSBs) and DNA double-strand breaks (DSBs). Base modifications, such as methylation, can be

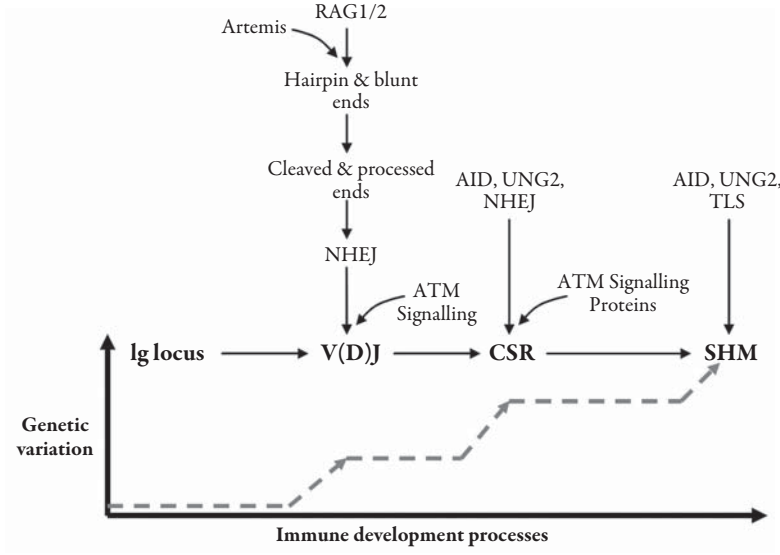

Figure 46.1 *How the immune response exploits DNA damage-response processes.* DNA damage-response processes are used by somatic cells to maintain genomic stability. During development of the immune response, these processes are subverted to generate genetic diversity. This figure highlights the stages of immune development that utilize DNA damage-response proteins. RAG1/2, recombination activating gene proteins 1 and 2; NHEJ, DNA nonhomologous end-joining; AID, activation-induced cytidine deaminase; UNG2, uracil-N-glycosylase 2; TLS, translesion synthesis.

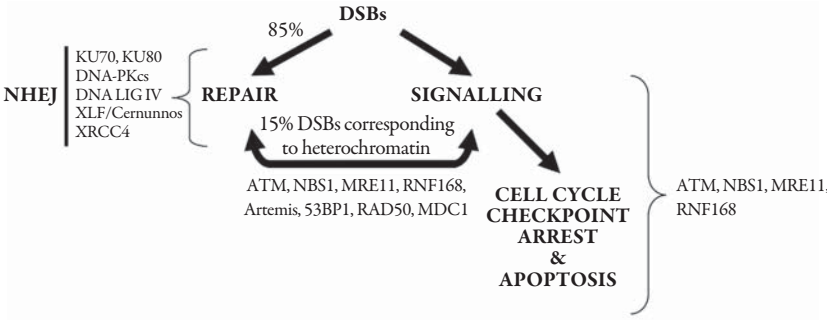
induced by DNA alkylating agents present in our environment (e.g., methyl chloride) but can also arise in a programmed manner as a consequence of epigenetic gene programming during development. DNA bases can also undergo chemical changes such as spontaneous deamination and depurination. SSBs and DSBs can be introduced into DNA by topoisomerase I and II to relieve torsional stresses built up in the DNA double helix following transcription and replication, although these remain hidden, for the most part, as protein bridged lesions. DSBs are the most critical lethal lesion for a cell and can arise directly from DNA-damaging agents, most importantly from exposure to radiation, or via the processing of other lesions. As will be discussed in more detail below, the lesions of most significance in the context of immune development are DSBs, SSBs, and deamination events.

RESPONSES TO DNA DSBS

Despite the fact that a DNA DSB is a potentially devastating lesion, the programmed introduction of DSBs is a critical step during the development of the immune response, being a prerequisite for both V(D)J recombination and class-switch recombination (CSR) (Gellert, 2002; Mahaney et al., 2009; Manis et al., 2002). Since the inability to appropriately respond to DSBs enhances genomic instability, it is not surprising that certain genomic instability disorders display immunodeficiency (see Fig. 46.2 for an overview). To help set the stage for understanding the basis of this overlap, we provide below an overview of the DNA damage response (DDR) to DSBs.

The DDR encompasses pathways of DNA repair and damage-recognition signal transduction pathways. The DNA repair pathways are lesion or lesion-type specific, while the signal transduction pathways recognize one of two broad classes of lesions, a DNA DSB or a single-stranded region of DNA (Shiloh, 2001). DNA nonhomologous end-joining (NHEJ) represents the major DSB repair pathway, with homologous recombination (HR) repairing one-ended DSBs that arise at stalled replication forks as well as a subset of the DSBs that arise in G2 phase (Wyman et al., 2006). The kinase ataxia telangiectasia mutated protein (ATM) lies at the apex of the signal transduction pathway that responds to DSBs (Lavin 2008). Six core components of NHEJ have been identified that associate as two distinct complexes (Mahaney et al., 2009). The Ku protein, encompassing subunits Ku70 and Ku80, rapidly binds to DSBs and protects them from nucleolytic degradation. Once DNA bound, Ku recruits the DNA protein kinase catalytic subunit (DNA-PKcs), creating the DNA-PK complex and activating DNA-PK activity. The precise function of DNA-PK remains unclear, but increasing evidence suggests a role in promoting DNA end processing. DNA-PK also facilitates the recruitment of DNA ligase IV, XRCC4, and XLF/Cernunnos, which carry out the rejoining step of NHEJ. XRCC4 and DNA ligase IV interact very tightly and XRCC4 is required for the stabilization of DNA ligase IV (Grawunder et al., 1998). XLF/Cernunnos, in contrast, is a weaker binding partner of the DNA ligase IV/XRCC44 complex. In vitro it stimulates the ability of DNA ligase IV to rejoin incompatible DNA ends but has also been suggested to promote the in situ recharging of DNA ligase IV to effect the dual ligations required for DSB rejoining (Riballo et al., 2009; Tsai et al., 2007). In G1-phase cells, these core NHEJ proteins are required for the majority of DSB rejoining, and hence cells lacking any of these proteins display dramatic radiation sensitivity (O'Driscoll and Jeggo, 2006). Following exposure to X- or gamma-rays, two components to DSB rejoining can be distinguished: 85 percent of the DSBs are rejoined with fast kinetics, while approximately



Gene	Disorder
ATM	Ataxia telangiectasia (A-T)
NBS1	Nimegen breakage syndrome (NBS)
MRE11	A-T-like Disorder
RAD50	NBS-like disorder
RNF168	RIDDLE syndrome
DNA-PKcs	DNA-PKcs-dependent-SCID
ARTEMIS	Artemis-dependent-SCID
XLF/Cernunnos	XLF-Cernunnos-dependent SCID
DNA LIG IV	LIG4 syndrome

Figure 46.2 *Disorders conferring genomic instability and immunodeficiency: the point of impact of the defective protein in the DNA damage response.* DNA DSBs are an important lesion induced during immune development to create genetic diversity. Thus, there is a strong overlap between disorders affecting the damage response to DSBs and immune development. The DSB damage response encompasses pathways of DSB repair and a signal transduction response. The signaling response is required for the repair of a subset of DSBs as well as cell-cycle checkpoint arrest and apoptosis. The figure shows where key proteins function in the DNA damage response and identifies disorders caused by their loss.

15 percent are rejoined with markedly slower kinetics (Lobrich et al., 1995; Wu et al., 2008). Recent studies have shown that the slow component of DSB repair requires a number of additional proteins, including ATM and the nuclease, Artemis (Riballo et al., 2004). Further, these have been suggested to be DSBs that arise within or close to heterochromatic (HC) DNA (Goodarzi et al., 2008). The role of ATM in this aspect of DSB repair has been proposed to be the phosphorylation of Kap1 (Kruppel-associated box [KRAB]-associated protein), a heterochromatic building factor, thereby relaxing chromatin compaction to promote DSB repair within this more compacted DNA region (Ziv et al., 2006). The role of Artemis is unclear but potentially represents the removal of secondary structures or damaged lesions at the DNA ends.

ATM-dependent signaling represents an elegantly choreographed assembly of factors at the DSB (Panier and Durocher, 2009). Despite extensive studies on understanding the assembly process, its precise function is still unclear, although aiding the repair of DSBs located within the compacted heterochromatic regions represents one critical endpoint (Goodarzi et al., 2008). Additionally, ATM-dependent signaling activates cell-cycle checkpoint arrest, a process that enhances the opportunity for DSB repair by delaying progression through critical cell-cycle stages (Lavin, 2008). Cell-cycle checkpoint arrest can also function as an alternative to apoptosis to permanently remove damaged cells from the cycling population (Wahl et al., 1997). The Mre11/Rad50/Nbs1 (MRN) complex represents the initial DNA damage sensor that, via its binding to ATM, recruits ATM to the DSB end, a process analogous to the way in which Ku recruits DNA-PKcs to the DNA end (ATM and DNA-PKcs are related phosphoinositol 3-kinase-like kinases) (Falck et al., 2005; Mirzoeva and Petrini, 2003; Uziel et al., 2003). In undamaged cells, ATM exists as a dimer but undergoes monomerization and activation when recruited to the DSB (Bakkenist and Kastan, 2003). An early target of ATM kinase activity is the histone H2A variant, H2AX. H2AX represents around 1 to 10 percent of the H2A molecules, and phosphorylated H2AX, designated γH2AX, can extend large distances from the DNA end to generate defined foci, which can be readily visualized by immunofluorescence using specific antibodies (Paull et al., 2000). γH2AX serves to recruit MDC1, one of several mediator proteins responsible for the formation of DSB "repair foci." MDC1 recruitment aids the recruitment of two ubiquitin ligases, RNF8 and RNF168, which ubiquitinate histone H2A residues, which in turn serves to recruit 53BP1, another mediator protein (Panier and Durocher, 2009). BRCA1 is also recruited to the DSB in an MDC1-dependent manner and appears to contribute to H2A ubiquitination. Significantly, all these proteins are also required for the slow component of DSB repair in G1 phase while being dispensable for the fast rejoining process (unpublished observations).

DSB REJOINING IN THE CONTEXT OF THE IMMUNE RESPONSE

V(D)J recombination and CSR represent two critical processes in the development of the immune response that involve the programmed introduction of DSBs (Gellert, 2002; Mahaney et al., 2009; Manis et al., 2002). Following this, both processes subvert the NHEJ rejoining pathway to promote sequence changes at the rejoined DNA junctions. The first step in V(D)J recombination is the creation of a DSB by the combined action of the RAG1 and RAG2 endonucleases (Gellert, 2002;

Oettinger et al., 1990) (see also Chapter 13 for further details of this process). RAG1/2 cleavage creates a single strand nick followed by a trans-esterification reaction that generates a DSB with one blunt opposing a hairpin-sealed DNA end (Kim et al., 2000). In fact, the broken ends are associated in a distinct manner to a radiation-induced DSB with four DNA ends generated from two cleavage events being associated as a synaptonemal complex. The two hairpin DNA ends undergo cleavage and rejoining to generate coding junctions that form the coding sequences of the immunoglobulin or T-cell-receptor genes. The two blunt ends are rejoined to generate signal junctions that are dispensable for the immune response. The rejoining step of V(D)J recombination involves the core NHEJ proteins, and cell lines or mice lacking Ku, DNA-PKcs, XRCC4, DNA ligase IV, or XLF/Cernunnos are impaired in their ability to carry out V(D)J recombination. The hairpin cleavage reaction requires the nuclease, Artemis. Since hairpin cleavage is a prerequisite for rejoining of the ends generated during V(D)J recombination, Artemis is an essential V(D)J recombination component: in contrast, it is only required for the repair of a subset (~15 percent) of the radiation-induced DSBs (as discussed above).

To date, patients with mutations in DNA ligase IV, XLF/Cernunnos, Artemis, and DNA-PKcs have been identified (see Chapters 9 and 13 for detailed discussion of these patients). Such patients display severe combined immunodeficiency (SCID) or CID consistent with an inability or impaired ability to carry out V(D)J recombination. Cell lines from such patients display radiosensitivity and DSB repair defects, a feature exploited for their clinical diagnosis. Importantly, such patients are likely to display clinical radiosensitivity, an outcome that, for at least one undiagnosed patient, proved fatal (Riballo et al., 2001). Moreover, these patients can also display sensitivity to DNA-damaging agents that, directly or indirectly, lead to enhanced DSB formation. This aspect is critical in considering conditioning regimens for bone marrow transplantation for such patients (O'Driscoll and Jeggo, 2008a).

Although neither ATM nor the MRN complex is essential for V(D)J recombination and neither ataxia-telangiectasia (A-T) nor Nijmegen breakage syndrome (NBS) patients (who are defective in *ATM* and *NBS1*, respectively) display the SCID or CID phenotypes characteristic of patients with mutations in NHEJ proteins, aberrant V(D)J junctions in the form of translocations involving chromosomes 7 and 14 are a characteristic feature of both conditions (Hsieh et al., 1993) (see Chapters 47 and 48). Additional recent studies have also demonstrated aberrant V(D)J recombination products in lymphocytes from A-T and NBS patients or mouse models (Bredemeyer et al., 2008b; Callen et al., 2007; Helmink et al., 2009; Huang et al., 2007). There are several possible mechanisms by which ATM might influence V(D)J recombination. Firstly, rather than being critical for the rejoining step, ATM may regulate the fidelity of the process. Evidence for this is the observation that hybrid joint formation, representing the aberrant rejoining of coding and signal ends, occurs at an elevated frequency in ATM-deficient lymphocytes via a process that requires the NHEJ proteins (Bredemeyer et al., 2008b). Secondly, apoptosis and/or cell-cycle checkpoint arrest appears to be an important physiological step in T- and B-cell development, most likely serving to remove cells that have failed to undergo productive rearrangements or those that retain unrejoined DSBs. The persistence of cells with chromosome breaks in the absence of ATM supports a role for ATM in preventing the transmission of lymphocytes that have failed to complete V(D)J recombination (Callen et al., 2007). Indeed, DSB formation in lymphocytes activates a specific signaling program that is essential for normal lymphocyte development and is distinct from the normal DSB response in other cell types (Bredemeyer et al., 2008a).

CSR is a second process that also involves the generation of a DSB via a very distinct mechanism. This process and its link to the DDR will be discussed later in this chapter.

DNA DAMAGE RESPONSES TO SSBs AND BASE DAMAGE

Despite the high level of formation of base damage and SSBs, they are rarely lethal lesions, which is due primarily to the abundant, overlapping, and highly efficient pathways for their repair and the fact that they induce mutational changes rather than lethality if not repaired efficiently. Base excision repair (BER) represents the major DNA pathway that removes base damages. This process will not be reviewed in detail (see Caldecott, 2008, for an excellent overview). In brief, the first step of BER is recognition of a damaged base by a DNA glycosylase. DNA glycosylases are not entirely lesion specific but have strong lesion preference, and thus a battery of distinct glycosylases recognize distinct forms of base damages. The glycosylase removes the damaged base, leaving either an apurinic or apyrimidinic site or an SSB if the glycosylase has associated lyase activity. Apurinic-apyrimidinic (AP) endonuclease I (APE1; also known as APEX1) readily converts the abasic site into a SSB. The SSBs generated by either these two mechanisms differ, but both require further processing to create the 5′ phosphate and 3′ hydroxyl ends necessary for ligation. DNA polymerase β carries out any fill-in of bases necessary during BER. Finally, XRCC1 and DNA ligase III carry out the rejoining step of BER.

Most base damage is repaired prior to replication. However, occasionally such damages are encountered at the replication fork and cause replication fork stalling or even replication fork collapse. Homologous recombination (HR) represents one process to bypass and subsequently repair such lesions at the replication fork. Another process is translesion synthesis (TLS). In this process, the stalled replicative polymerase is switched to one of several specialized error-prone polymerases, which have reduced fidelity and can replicate past a damaged base or lesion, albeit with inaccuracy. The current understanding is that distinct error-prone polymerases may preferentially replicate past distinct lesions. The use of these error-prone polymerases is carefully regulated during DNA repair since they provide a balance between continuing replication with mutagenic potential (see Sale et al., 2009, for a more detailed overview of this process).

HOW THE IMMUNE RESPONSE CREATES BASE DAMAGE AND SUBVERTS BER TO CREATE VARIATION

Although spontaneous deamination of deoxycytidine to deoxyuridine is relatively infrequent, this process is enhanced in B cells during the development of the immune response by activation-induced cytidine deaminase (AID) to promote antibody gene diversification via the processes of somatic hypermutation (SHM) or CSR (Muramatsu et al., 2000; Neuberger et al., 2003; Petersen-Mahrt et al., 2002). Further, as described above, although the BER machinery can efficiently repair deoxyuridine residues with exquisitely high efficiency in somatic cells to limit mutational changes, the immune response subverts the processing of the deoxyuridine residues in B cells to enhance antibody gene diversification by exploiting the process of TLS or by promoting DSB formation. The core processes of SHM and CSR are described in Chapter 27. Here, we will specifically consider the process in the context of genomic instability and chromatin disorders. SHM involves the creation of missense mutations and, less frequently, deletions or insertions at high frequency into the V regions of the immunoglobulin genes. The uracil residues generated by deamination of cytidine either spontaneously or via AID are recognized by a specific uracil-recognizing glycosylase termed uracil-N-glycosylase 2 (UNG2) (UNG1 is an additional uracil glycosylase that is specifically expressed in the mitochondria). The current model is that AID deaminates cytosine to deoxyuridine residues on single-stranded DNA, which, following removal by UNG2 and the action of an apyridiminic endonuclease (APE1) on the abasic site, leads to the formation of an SSB. Although such SSBs can be readily repaired in somatic cells, their processing during SHM appears to involve the use of the error-prone polymerases η and ζ in a modified process of TLS (Sale et al., 2009). Interestingly, the mismatch correction complex, MSH2/MSH6, is also required for SHM. A potential role of this complex is the recruitment of exonuclease I (Exo1), to enlarge the gap and create the possibility of further mutational changes, and the error-prone polymerases (Xue et al., 2006).

CSR, the process of DNA recombination between two different switch (S) regions upstream of the immunoglobulin (Ig) constant (C) region encoding genes, generates isotypic variation from IgM. CSR involves the generation of a DSB via two AID-induced deamination events. Although the precise mechanism leading to a DSB is unclear, the generation of such an intermediate is strongly suggested by the observation that ATM-dependent damage-response signaling is activated during CSR in an AID-dependent manner, with the subsequent recruitment of the ATM-dependent signaling proteins, including the MRN complex, MDC1, and 53BP1 (Petersen et al., 2001). Moreover, γH2AX formation occurs during the process (Petersen et al., 2001). Further, mice lacking these damage-response proteins display defects in CSR (Celeste et al., 2002; Lou et al., 2006; Ward et al., 2003). Further support for the notion that CSR involves a DSB intermediate is the observation that the NHEJ enzymes are also required for the process, most likely carrying out the final rejoining step of CSR (see Durandy, 2009, for a review).

The mechanism of SHM and CSR has been further supported by the characterization of patients defective in these two processes. Patients deficient in AID have been described and will be considered in Chapter 27. As predicted, such patients show defective SHM and CSR but do not show genomic instability, since AID is specifically expressed in B cells, and additionally also likely reflects the redundancy of the glycosylases. A small number of UNG-deficient patients have also been reported who exhibit a hyper-IgM syndrome typical of impaired CSR (see Chapter 27).

In contrast, A-T and NBS patients show genomic instability in addition to defects in CSR (described in Chapters 47 and 48), consistent with the notion that the damage-signaling process is activated uniquely following DSB formation. Another disorder, (RIDDLE syndrome [radiosensitivity, immunodeficiency, dysmorphic features, and learning difficulties]) has been described with an immunodeficiency phenotype entirely consistent with impaired CSR (Stewart et al., 2007). Thegenetic defect in this condition was identified as lying in the ubiquitin ligase, RNF168, which was subsequently identified to be a critical component of the ATM-dependent damage-signaling response responsible for the recruitment of 53BP1 to the DSB (Stewart et al., 2009). Cell lines derived from this RIDDLE syndrome patient display an impaired ability to recruit 53BP1, radiosensitivity, and genomic instability. As mentioned, the precise function of the damage-response proteins in CSR remains unclear, however. Although 53BP1 and MDC1 are essential for CSR, they are only required for the repair of a subset of DSBs induced by ionizing radiation (Riballo et al., 2004).

Finally, since patients lacking the core NHEJ proteins usually present with dramatically reduced T- and B-cell numbers, an overt defect in CSR cannot be readily observed. However, one study using mice with a hypomorphic mutation in *DNA ligase IV* strongly suggested there was a further decrease in CSR (Nijnik et al., 2009).

IMPACT OF CHROMATIN STRUCTURE ON DNA DAMAGE RESPONSES AND IMMUNODEFICIENCY

There is increasing evidence to suggest that the core histones can hinder the access of critical DNA processing enzymes, including those required for repair, transcription, and replication, and that they are displaced or mobilized at the sites of DNA damage. The precise mechanisms underlying such chromatin remodeling are only just emerging, albeit with amazing alacrity (for a review see van Attikum and Gasser, 2009). To date, these studies have been best characterized in yeast, but the process is now being dissected in mammalian cells. Two critical complexes in this context are IN080 and SWRI (van Attikum and Gasser, 2009). Additionally, a subfraction of DNA is tightly compacted as heterochromatic DNA via a range of DNA and histone modifications as well as the binding of specific proteins such as heterochromatin protein 1 (HP1) and Kap1. DNA and histone methylation represent important classes of modification associated with

heterochromatinization as well as histone acetylation (for a review see Cedar and Bergman, 2009). Heterochromatin can be subdivided into constitutive and facultative heterochromatin, with the former representing regions such as pericentric DNA that is compacted in all cell types and the latter representing regions that may be compacted in a developmentally regulated manner (Trojer and Reinberg, 2007). Generally, heterochromatinized DNA is more transcriptionally inactive than euchromatic DNA sequences, although transcriptionally active or silent sequences can be located in both subtypes of DNA.

Recent studies have provided strong evidence that the higher-order DNA structure has a strong impact upon DSB repair and signaling (Goodarzi et al., 2008). As discussed above, in mammalian cells, DSBs are repaired with fast and slow kinetics, and the slow component of DSB repair has been shown to represent the repair of DSBs located within or close to heterochromatic (HC) DNA (Goodarzi et al 2008). Further, the repair of HC-DSBs appears to require ATM and ATM-dependent damage-response signaling proteins as well as the core NHEJ proteins. The available evidence suggests that the critical HC building factor, Kap1, is phosphorylated by ATM after DNA damage and that this affects its chromatin-binding capacity, potentially enhancing relaxation of the compacted HC in the vicinity of the DSB. This step appears to be a prerequisite for repair of DSBs located within HC regions. Indeed, multiple laboratories have reported that HC serves as a barrier to γH2AX signal expansion (Kim et al., 2007; Kruhlak et al., 2007). Taken collectively, the findings suggest that a critical role of ATM might be to overcome the barrier to DSB repair and signaling that is posed by higher-order chromatin structure. Moreover, ATM likely has a broader impact on chromatin architecture after DNA damage; indeed, mounting evidence suggests that it effects significant and broad changes to the chromatin in the vicinity of a DSB. It is thus highly likely that ATM has a similar role during immunodevelopment, although the precise details have not yet been elucidated (Fig. 46.3).

Although several disorders that have an impact upon higher-order chromatin structure have been described, immunodeficiency with centromere instability and facial anomalies (ICF) is of most relevance in the present context, since an impaired immune response is a prominent clinical feature of ICF syndrome and, indeed, many patients succumb to infections at an early age (see Chapter 49). ICF will be introduced here in the context of its overlap with genomic instability disorders. A diagnostic feature of ICF syndrome is hypomethylation of the classical satellite repeat sequences, which are the pericentromeric satellite regions on chromosomes 1, 9, and 16 (Probst and Almouzni, 2008). These regions are normally heavily methylated in an epigenetic context and are specifically hypomethylated in ICF syndrome (Hassan et al., 2001). Two DNA methyl transferases, MT3a and MT3b, which are encoded by *DNMT3a* and *b*, respectively, have been shown to

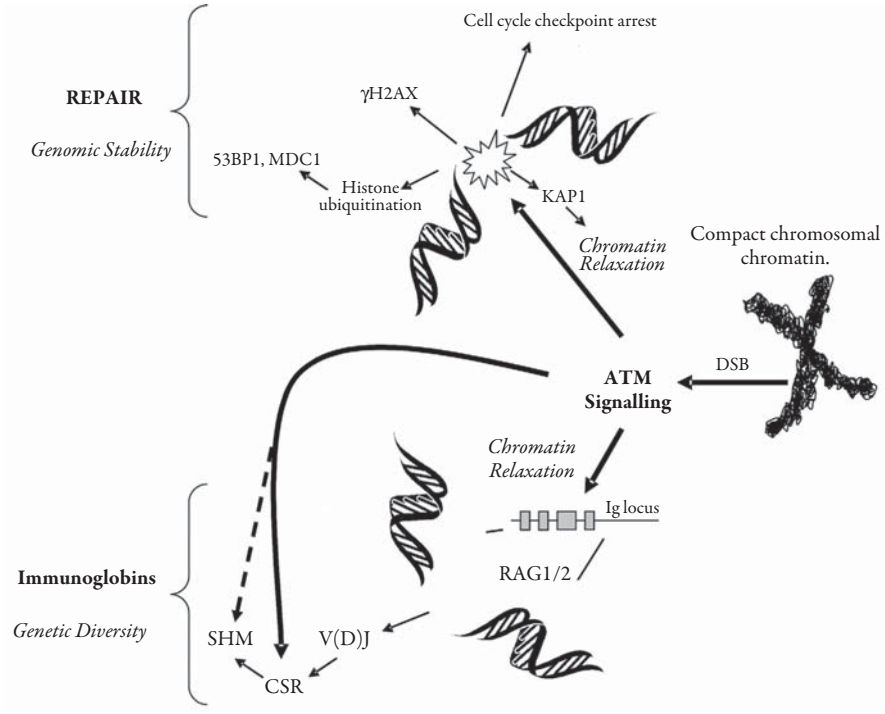


Figure 46.3 *The impact of chromatin structure and ATM damage-response signaling on the DNA damage response and immune development.* DNA is compacted by histone binding and an array of DNA and histone modifications, as well as repressor proteins. This compaction hinders the DNA damage response and developmental processes, including immune development. Increasing evidence points to ATM playing a central role in promoting chromatin changes to enhance the DNA damage response. Current studies suggest that it may play a similar role during immune development. The figure highlights potential roles of ATM signaling during these processes, although the precise contribution of ATM signaling is still emerging.

contribute specifically to these methylation events while not affecting other classes of methylation (Okano et al., 1999). It is now a decade since pathogenic mutations in *DNMT3B* have been described in some ICF patients (Hansen et al., 1999; Okano et al., 1999). Consistent with the notion that ATM is required to relieve the barrier posed by heterochromatin DNA to DSB repair and that in the ICF syndrome heterochromatin is more relaxed, ICF syndrome cells have been shown to have a less marked requirement for ATM for DSB repair (Goodarzi et al., 2008).

ICF syndrome patients have impaired humoral and cellular immunity with low levels of immunoglobulins IgG, IgA, and IgM, decreased numbers of CD3-, 4-, and 8-positive cells, and impaired lymphoproliferation following phytohemagglutinin A (PHA) or pokeweed mitogen (PWM). Exactly how these changes in methylation status of the satellite DNA sequences affect immune development is currently unclear. However, given that the ATM-dependent DNA damage-response signaling proteins serve to relax the chromatin structure to facilitate processing of DNA ends, and given the requirement of these proteins for CSR, it is possible that a relaxed or less compacted chromatin structure is required to ensure that appropriate processing can occur during CSR. There is also mounting evidence that methylation changes take place during immune development to allow the transcriptional activation of specific genes during CSR and that aberrant transcriptional regulation in ICF may affect lymphocyte development. Also, the timing of replication is regulated by heterochromatic status, and alterations in the regulation of replication may contribute to the features of this disorder (Ehrlich et al., 2008; Jin et al., 2008).

IMPACT OF THE DNA DAMAGE RESPONSE AND HIGHER-ORDER CHROMATIN STRUCTURE ON OTHER DEVELOPMENTAL PROCESSES

Both ICF and the genomic instability disorders display other characteristic features in addition to immunodeficiency, which result from a broader role of the defective pathway or gene during development. A brief overview of these roles will be considered here since they represent important factors in the differential diagnosis of many of these conditions but also need to be carefully considered in optimizing patient care.

CANCER PREDISPOSITION

As mentioned above, DNA is constantly subjected to damage, and a critical role of the proteins that function in DDR is the maintenance of genomic stability. Cells with unrepaired DSBs show increased lethality. Thus, cell loss can represent an important contribution to the clinical manifestation of DDR defects. However, in most cases the defect in the genomic instability disorders decreases rather than completely blocks DSB repair. DSBs that are not repaired in a timely fashion frequently undergo misrepair, allowing the proliferation of cells with genetic changes. Additionally, loss of the ATM signaling pathway impairs cell-cycle checkpoint arrest and apoptosis, processes that serve to prevent the proliferation of damaged cells (Lavin, 2008). Thus, tumor predisposition is an important phenotype observed in some of the DDR defective syndromes.

Artemis and the core NHEJ proteins are dispensable for both cell-cycle checkpoint arrest and apoptosis, in marked distinction to ATM. Indeed, the most consistent consequence of loss of NHEJ proteins is elevated cell death after agents that induce DSBs, demonstrating the significance of an unrejoined DSB as a lethal lesion. Since DNA ligase IV is essential, the mutations causative of LIG4 syndrome are hypomorphic and residual, but slow DSB rejoining remains (O'Driscoll et al., 2001). XLF/Cernunnos patients also show substantial residual DSB rejoining activity (Riballo et al., 2009). Most LIG4 syndrome and XLF/Cernunnos-deficiency patients display CID rather than SCID, providing further support for the notion that residual V(D)J recombination occurs. Strikingly, leukemia or lymphoma is observed in approximately 25 percent of LIG4 syndrome patients and, perhaps not surprisingly, is more marked in patients with less severe immunodeficiency, most likely due to the higher number of target T and B cells present (O'Driscoll and Jeggo, 2006). One possible explanation is that aberrant V(D)J recombination promotes oncogene expression and enhances the onset of lymphoid tumors. An alternative explanation is that the impaired immune response attenuates immune surveillance, allowing Epstein-Barr virus (EBV)–type infections and hence the onset of EBV-induced tumorigenesis. Consistent with this possibility, most, although crucially not all, tumors are of B-cell origin. Artemis, which, in contrast to DNA ligase IV, is nonessential since it is required for only a subset of DSB repair, is essential for V(D)J recombination due to its requirement in hairpin cleavage (Ma et al., 2002). Because Artemis patients harboring null mutations are T^- and B^- SCID, they do not have target cells for the induction of lymphoma or leukemia onset. Consequently, predisposition to lymphoid tumors is not common in radiation-sensitive SCID patients due to Artemis mutations. Patients with hypomorphic Artemis mutations have been described, however, and a predisposition to leukemia and lymphoma has been reported among these patients (Ege et al., 2005; Evans et al., 2006; Moshous et al., 2003). Such tumors are frequently of EBV origin (Moshous et al., 2003). ATM and NBS patients have a very high predisposition to tumors of lymphoid origin, which may be a consequence of an impaired fidelity of V(D)J recombination or CSR and/or the inability to remove damaged cells. ICF has not been reported as a cancer predisposition syndrome to date, although currently the number of patients and their early death from infections precludes a realistic evaluation of cancer predisposition. It will be interesting to evaluate this as patient care improves and increases the life expectancy of affected individuals.

NEURONAL DEVELOPMENT

A further marked characteristic of damage-response disorders is impaired neuronal development and/or enhanced neurodegeneration (O'Driscoll and Jeggo, 2008b). In most instances,

including LIG4 syndrome, XLF/Cernunnos deficiency, and NBS, this is manifest as the occurrence of microcephaly at birth. The microcephaly is rarely progressive postnatally. This feature is also frequently observed in other DDR disorders that are not associated with immunodeficiency, most strikingly in ATR-Seckel syndrome and Blooms syndrome (O'Driscoll et al., 2003). In marked contrast, patients with A-T and A-T–like disorders (due to mutations in the *MRE11* encoding component of the MRN complex) display progressive ataxia, which is normally manifest in the early years of childhood but not immediately evident at birth. Loss of Artemis, in contrast, does not confer any overt neuronal development (Moshous et al., 2001). The most likely explanation for these differences is that NHEJ represents a critical process required for the propagation of neuronal stem cells or their early progenitors. The embryonic neuronal stem cells, the ventricular-zone cells, undergo a high rate of cell division during embryogenesis, and since these stem cells disappear shortly after birth, loss of early progenitor cells cannot be readily regained. It is possible that the rapid cell division of the ventricular-zone cells during embryogenesis results in high oxidative damage or that DSBs arise during this rapid phase of replication. Thus, DSBs generated either via oxidative damage or replication stress may have a critical requirement for NHEJ for their repair. Interestingly, the embryonic brain is also highly sensitive to radiation, consistent with the possibility that unrepaired DSBs readily cause apoptosis or cell loss in this compartment. Since loss of Artemis affects only the repair of a subset of DSBs, Artemis may be less critical for this aspect of development. Indeed, Artemis-SCID patients do not exhibit microcephaly.

The basis underlying the striking difference between A-T and NBS patients in their neuronal phenotype is currently unclear. A recent study, however, raised the possibility that the mutation in NBS patients does not have an impact upon apoptosis (Shull et al., 2009). Thus, cells with unrepaired DSBs may be lost in NBS patients but not in A-T patients, where DSB-induced apoptosis does not occur. Further work, however, is required to substantiate such a model.

CONCLUDING REMARKS

Immune development and the DDR represent two processes that superficially appear to have opposite goals. Immune system development is underscored by the need to generate diversity, while the DDR serves to preserve genomic stability. Fascinatingly, the immune system co-opts elements of the DDR machinery in processes such as V(D)J recombination, CSR, and SHM as a fundamental tool to cut, splice, and alter the coding properties of DNA in a highly complex and ordered fashion to generate its requisite diversity. Consequently, human disorders, including those discussed in the subsequent chapters, caused by defective DDR frequently manifest with some form of immune dysfunction. Furthermore, disorders such as ICF syndrome, where the primary defect is in chromatin structure, provide an additional element of overlap between DNA processing and immune development. Changes to chromatin structure are essential during the response to DNA damage, and a critical role of ATM signaling appears to be to implement such changes. The role of ATM and its signaling proteins during immune development is very likely to involve chromatin alterations. Thus, the ability to modify chromatin architecture appropriately is likely to be a critical, and still understudied, step during immune development. The basis underlying the immunodeficiency observed in ICF could play a useful role in understanding the intricate balance between chromatin, DNA processing, and immune development.

ATAXIA-TELANGIECTASIA

Leman Yel, Martin F. Lavin, and Yosef Shiloh

Ataxia-telangiectasia (A-T) (OMIM 208900) is a complex multisystem disorder characterized by progressive neurological impairment, oculocutaneous telangiectasia, variable immunodeficiency with recurrent sinopulmonary infections, cancer susceptibility, and sensitivity to ionizing radiation. First described in 1926 (Syllaba and Henner, 1926) and established as a disease entity in 1957 by Boder and Sedgwick, A-T has evolved from a rare disorder to a paradigm for cell signaling and cancer (Chen et al., 1978; Gatti et al., 1988; Gotoff et al., 1967; Lavin, 2008; Morgan et al., 1968; Peterson et al., 1963; Savitsky et al., 1995a; Taylor et al., 1975). Localization of the responsible gene *ATM* (Ataxia-Telangiectasia Mutated) to chromosome 1 1q22-23 by Gatti et al. (1988), and then identification of *ATM* by Savitsky et al. (1995a) as a member of the phosphatidylinositode 3-kinase-related protein kinase (PIKK) family genes, which are involved in cellular responses to DNA damage, cell-cycle control, and intracellular protein transport, provided a basis for understanding of the pleiotropic nature of A-T.

The disease A-T is inherited as an autosomal recessive trait with full penetrance (Ferak et al., 1968; McKusick and Cross, 1966; Tadjoedin and Fraser, 1965). A-T, represented equally in males and females, has been reported in all ethnic groups throughout the world, with a disease prevalence from 1 in 40,000 (Boder and Sedgwick, 1970) to 1 in 88,000 live births (Swift et al., 1986; Woods et al., 1990).

In this chapter, we will provide insight into the clinical, cellular, and molecular abnormalities in A-T and an overview of the *ATM* gene and the ATM protein with our current understanding of their functions and the pathways from the defective gene to the clinical manifestations.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

In the initial report of A-T, Syllaba and Henner (1926) observed progressive choreoathetosis and ocular telangiectasia in three members of a single family. In 1941, Louis-Bar described progressive cerebellar ataxia and cutaneous telangiectasia in a Belgian child, hence the name "Louis-Bar syndrome." Boder and Sedgwick (1957) and Biemond (1957), with the aid of autopsies, reported organ developmental abnormalities, neurological manifestations, and recurrent sinopulmonary infections. Later on, several additional reports confirmed the major manifestations of this syndrome (Boder and Sedgwick, 1958; Centerwall and Miller, 1958; Sedgwick and Boder, 1960; Wells and Sly, 1957). The main clinical features of the disease are outlined in Table 47.1 (Boder, 1985; Boder and Sedgwick, 1963).

CEREBELLAR ATAXIA

In A-T, it is evident from the earliest reports that neurological features are prominent (Boder, 1985). Ataxia, generally the presenting symptom in this syndrome, becomes apparent when a child begins to walk at the end of the first year of life, by ataxic gait and truncal movements. Similar to other major characteristics of A-T, ataxia is progressive, affecting the extremities and then the speech. Eventually, involuntary movements dominate, and the child may require a wheelchair by the end of the first decade of life. However, there are some recent reports of rare patients who had slow progression of ataxia (Dörk et al., 2004) or manifest neurological findings only in adulthood (Saviozzi et al., 2002; Sutton et al., 2004).

Table 47.1 CLINICAL FEATURES IN ATAXIA-TELIANGIECTASIA (A-T)

CLINICAL FEATURE	CASES WITH FEATURE (NO.)	CASES WITH DATA AVAILABLE (NO.)
I. Neurological abnormalities		
Cerebellar ataxia, infantile or childhood onset	101	101
Diminished or absent deep reflexes	54	61
Flexor or equivocal plantar response	60	61
Negative Romberg sign	28	36
Intact deep and superficial sensation	51	52
Choreoathetosis	61	67
Oculomotor signs		
Apraxia of eye movements	47	56
Fixation of gaze nystagmus	48	58
Strabismus	7	15
Dysarthric speech	70	70
Drooling	43	49
Characteristic facies and postural attitudes	60	61
II. Telangiectasia, oculocutaneous	101	101
III. Frequent sinopulmonary infection	60	72
IV. Familial occurrence	43	96
V. Reported mental deficiency	22	66
VI. Equable disposition	34	34
VII. Retardation of somatic growth	42	58
VIII. Progeric changes of hair and skin	46	52

SOURCE: From Boder (1985).

The underlying pathology appears to be primarily progressive cerebellar cortical degeneration. The neuropathological features of A-T are comprehensively detailed in two reviews by Boder (1985) and Sedgwick and Boder (1991). Cortical cerebellar degeneration involves primarily Purkinje and granular cells, but basket cells are also affected. While degenerative changes in the brain are seen predominantly in the cerebellum, it is clear from an increasing number of autopsies that changes to the central nervous system (CNS) in A-T are more widespread. Degenerative changes in the dentate and olivary nuclei were noted in early studies, and these observations were extended to include changes in the spinal cord and spinal ganglia, the cerebrum, the basal ganglia, and the brain stem, especially in older patients. Amromin et al. (1979) have described distinctive gliovascular abnormalities in the cerebral white matter and also in the brain stem and spinal cord. These consist of dilated capillary loops, many with fibrin thrombi, with perivascular hemorrhages and hemosiderosis, surrounded by demyelinated white matter, reactive gliosis, and numerous atypical astrocytes (Boder, 1985). These vascular changes are seldom seen in the basal ganglia or cerebral cortex and have not been reported in the cerebellum. Since they are seen only in older patients, it is unlikely that they are a primary cause of cerebellar or spinal cord degeneration.

TELANGIECTASIA

The second major clinical feature of the disease is telangiectasia. In general, it has a later onset than ataxia, between 2 and 8 years of age (Boder, 1985; McFarlin et al., 1972). However, telangiectasia can be detected much earlier, particularly with a high index of suspicion in children with a family history of A-T. Telangiectasia represents a dilation of blood vessels, primarily in the ocular sclerae, and often gives the impression of bloodshot eyes (Color Plate 47.I). The telangiectasias may also appear in the butterfly area of the face and as hairline telangiectasias on the ears. Patches of telangiectasia elsewhere in the skin are less common. Ocular telangiectasias may be mistaken for conjunctivitis but can be readily distinguished because they are characterized by dilated vessels against a white background, whereas in conjunctivitis the background is pink. It is not clear how the defective ATM protein would give rise to telangiectasia. It has been suggested that the blood-vessel abnormality represents a progeric change, as it mimics telangiectasias in normal aged individuals (Boder, 1985). The occurrence of telangiectasias in tissue of normal individuals undergoing radiotherapy may also be related to the telangiectasia in A-T. Since hypersensitivity to radiation and to compounds capable of generating active oxygen radicals is a characteristic of this disease, a decreased ability to cope with endogenously generated damage from oxygen radicals may be a factor in the development of telangiectasias in A-T. Indeed, there is now good evidence that A-T cells are in a state of oxidative stress (Barlow et al., 1999; Cosentino et al., 2011; Gatei et al., 2001a; Guo et al., 2010; Kamsler et al., 2001; Patel et al., 2011; Watters et al., 1999). However, light or sun damage may also be contributing to telangiectasias in the eyes and on the skin.

PREDISPOSITION TO SINOPULMONARY INFECTION

The third major feature of A-T is susceptibility to infections. Recurrent infections are reported in up to 80 percent of patients in some studies (Waldmann, 1982). Infections become apparent by the age of 3 (Andrews et al., 1960; Centerwall and Miller, 1958; McFarlin et al., 1972). Major sites of infection are the upper and lower respiratory system. The infections include otitis and sinusitis as well as recurrent pneumonia, which may progress into bronchiectasis and pulmonary fibrosis severe enough to cause clubbing of fingers and toes, and, eventually, respiratory insufficiency and death (Sedgwick and Boder, 1991). Boder and Sedgwick (1963) have reported frequent respiratory infections in 83 percent of cases, and chronic bronchitis with or without bronchiectasis

in 52 percent of cases. Patients with A-T are particularly susceptible to common bacterial pathogens and viruses but do not appear to be subject to generalized or persistent fungal or protozoan infections (McFarlin et al., 1972; Nowak-Wegrzyn et al., 2004; Peterson and Good, 1968).

McFarlin et al. (1972) demonstrated a correlation between the severity of the respiratory infections and reduced immune responses. The observation of Boder and Sedgwick (1957) that the thymus is absent or poorly developed in A-T, together with reports of hypogammaglobulinemia (Gutmann and Lemli, 1963; Williams et al., 1960), suggested a basis for the infection susceptibility. It is now known that there is a more generalized defect in multiple aspects of the immune response in A-T patients (Exley et al., 2011; Waldmann, 1982).

IMMUNODEFICIENCY

Immunodeficiency in A-T is highly variable, involving both antibody production and cellular immunity (McFarlin et al., 1972; Peterson et al., 1963). Some patients have a history of chronic sinopulmonary infections, others have recurrent infections, and yet another group may show no higher incidence of infections than their unaffected siblings (McFarlin et al., 1972; Nowak-Wegrzyn et al., 2004).

ANTIBODY-MEDIATED IMMUNITY

The presence of hypogammaglobulinemia has been equated with the high frequency of infections in A-T (Andrews et al., 1960; Centerwall and Miller, 1958; Gutmann and Lemli, 1963; Williams et al., 1960). The first insight into the nature of the immune defect was provided by Thieffry et al. (1961), who showed that serum IgA was absent in a number of patients with A-T. It was subsequently found that up to 80 percent of patients had low or undetectable serum IgA levels (Boder, 1975; Epstein et al., 1966; Ersoy et al., 1991; McFarlin et al., 1972). IgE deficiency has been reported with almost the same frequency (Ammann et al., 1969; McFarlin et al., 1972). In a smaller percentage of patients, IgG, especially IgG2, is reduced (Oxelius et al., 1982). The presence of low-molecular-weight IgM has also been reported in up to 80 percent of patients (McFarlin et al., 1972; Stobo and Tomasi, 1967). Serum IgD concentrations in A-T were found to be significantly elevated compared to the control group in one study (Sanal et al., 1998). The abnormalities in immunoglobulin levels in A-T are not due to reduced B-cell numbers but appear to result from a defect in B-cell differentiation (Gail-Peczaska et al., 1973; Lawton et al., 1972). A spectrum of responses to bacterial antigens, from normal to severely reduced, is observed in A-T patients (McFarlin et al., 1972; Sanal et al., 1999, 2004; Sedgwick and Boder, 1972). On the other hand, natural antibody and antibody responses to challenges with viral antigens are dramatically decreased compared with those of controls (Waldmann, 1982). Circulating autoimmune antibodies against immunoglobulin, muscle, and mitochondria may also be found in A-T patients (Ammann and Hong, 1971). Although the deficiency in IgA and IgE is primarily due to a reduced rate of synthesis, autoimmune antibodies against these molecules may also cause an increase in their destruction rates (Strober et al., 1968; Waldmann, 1982).

An intrinsic defect in the maturation of B cells and/or reduced T-cell helper activity was suspected in A-T. Since two of the chromosomes that contain the immunoglobulin and T-cell–receptor genes, chromosomes 14 and 7, respectively, show frequent breaks, rearrangements, and translocations in lymphocytes from A-T patients, a defect in gene regulation or in the recombination mechanisms required to generate mature B- and T-cell–receptor genes was suspected earlier (Cohen et al., 1975; Hecht et al., 1973; Taylor et al., 1976. Now, it is known that, in A-T, there is a defect in class-switch recombination (CSR) (Bredemeyer et al., 2008; Kracker et al., 2010; Kracker and Durandy, 2011; Pan-Hammarström et al., 2003, 2006; Perkins et al., 2002; Reina-San-Martin et al., 2004; Zha et al., 2011). Being a DNA damage sensor, ATM, along with NBS1, is activated by the DNA breaks in the switch (S) regions during CSR. ATM phosphorylates a large number of substrates that activate the DNA damage response, including histone H2AX. Phosphorylated H2AX, called γH2AX, leads to recruitment of other DNA damage-response factors, which eventually results in effective CSR. Therefore, in the setting of ATM deficiency, chromosomal VDJ recombination is disturbed and the process of immunoglobulin class switch is impaired. In fact, patients with A-T commonly have normal or elevated serum levels of IgM (Ersoy et al., 1991; Exley et al., 2011). There are even reports of patients with A-T initially diagnosed with hyper-IgM syndrome, in whom the diagnosis of A-T was established later by identification of missense mutations in the *ATM* gene (Aghamohammadi et al., 2010; Pietrucha et al., 2010).

CELL-MEDIATED IMMUNITY

Faulty development of the thymus is very characteristic of A-T (Fireman et al., 1964; McFarlin et al., 1972; Peterson et al., 1964b). The thymus often cannot be identified grossly at autopsy, but is only recognized microscopically as a scattered collection of thymic reticular elements with a marked paucity of thymocytes and absence of Hassell's corpuscles and corticomedullary demarcations. These abnormalities reflect a developmental defect rather than atrophy of the thymus (Peterson et al., 1964b). Approximately one third of patients with A-T have unequivocal lymphocytopenia, which is usually mild in degree (Roifman and Gelfand, 1985). The proportion of lymphocytes bearing T-cell markers is reduced, and cells with receptors for IgM may also be diminished in number (Waldmann, 1982). In vivo and in vitro functional activity of T cells is variable; however, when considered as a group, A-T patients are deficient in their responses (Epstein et al., 1966; Ersoy et al., 1991; Fireman et al., 1964; McFarlin et al., 1972). Variability is evident in delayed-type hypersensitivity skin test response to phytohemagglutinin (PHA) and to antigens such as mumps, tuberculin purified protein derivative (PPD), and dinitrochlorobenzene as well as in in vitro lymphocyte proliferation to PHA and pokeweed mitogen (PWM). Delayed rejection of a skin graft from a human leukocyte antigen (HLA)-incompatible donor has been described in up to

80 percent of A-T patients (Waldmann, 1982). O'Connor and Scott-Linthicum (1980), who demonstrated that bound PHA could be efficiently internalized by A-T lymphocytes, proposed that a defect existed at the intracellular signaling level.

Disruption of the *Atm* gene in mice gives rise to a phenotype that largely reflects that seen in the human disease (Barlow et al., 1996; Elson et al., 1996; Xu et al., 1996). Immune defects observed in $Atm^{-/-}$ mice include a smaller size of lymphoid tissues, a reduction of CD4 and CD8 single-positive T lymphocytes, an increase in premature double-positive mature T lymphocytes, greatly reduced peripheral T cells, and defective T-cell responses. Productively rearranged TCRαβ gene is required for thymocyte proliferation and rearrangement for the transition of double-positive to single-positive T cells (Shinkai et al., 1993; von Boehmer, 1994). Since $Atm^{-/-}$ mice were defective in both processes, Chao et al. (2000) introduced a functional TCRαβ transgene into these mutant mice. This approach led to the rescue of defective T-cell differentiation and partial rescue of thymus hypoplasia, indicating that positive selection of thymocytes is normal in $Atm^{-/-}$ mice. It is also of interest that when quiescent mature T cells are exposed to DNA intercalating agents, they readily undergo apoptosis in an Atm-dependent manner (Bhandoola et al., 2000). Immature thymocytes, by contrast, are resistant to apoptosis induced by this DNA damage-signaling pathway, even though double-strand breaks (DSBs) are present in DNA. This resistance may be due to downregulation of this pathway in immature cells, consistent with the observation that freshly prepared peripheral blood mononuclear cells from humans have low levels of ATM protein and a low basal level of ATM kinase (Fukao et al., 1999).

The CD4/CD8 ratio in A-T patients is reversed compared with controls because of a decrease in the total number of CD4 T cells (Fiorilli et al., 1983). Furthermore, A-T patients have a relative increase in T cells bearing γ/δ antigen receptors compared with those with α/β receptors, unlike the T-cell populations in most other immunodeficiency syndromes. Carbonari et al. (1990) suggested that a defect in recombination might explain the defects in both T-cell and B-cell differentiation more than 20 years ago. Such a defect could also account for the high incidence of chromosomal rearrangements involving primarily chromosomes 7 and 14 (Aurias et al., 1980). Four common sites of chromosome breakage have been described in A-T patients: 7p14, 7q35, 14q11.2, and 14q32. Since the T-cell–receptor genes and the Ig heavy-chain genes map to these sites (Hedrick et al., 1984; Sim et al., 1984), a defect in DNA recombination could explain the immunodeficiency, the hypersensitivity to radiation, and the lymphoid malignancies seen in A-T. In support of this concept, Meyn et al. (1993) demonstrated spontaneous intrachromosomal recombination rates 30 to 200 times higher in A-T fibroblasts than in fibroblasts from controls. This observation was not confirmed using extrachromosomal test DNA substrates (Hsieh et al., 1993). Taken together, these studies suggested that a defect in intrachromosomal recombination could contribute to genetic instability and predisposition to cancer as well as cellular immunodeficiency in A-T. Now, it is apparent that ATM plays a major role in maintaining TCR-α expression during the recombination process (Matei et al., 2007), and its deficiency impairs thymocyte maturation because of defective resolution of TCR-α locus coding end breaks (Vacchio et al., 2007). Finally, it has been discovered that ATM is instrumental in the repair of physiological DSBs in the processes of Ig CSR and B- or T-cell–receptor V(D)J recombination in lymphoid cells (Kracker and Durandy, 2011), providing a better explanation into the characteristic features of A-T.

Immunodeficiency in A-T has been proposed to resemble premature aging of the immune system by multiple cellular and molecular immune parameters (Exley et al., 2011). In A-T, a relative deficiency of naïve $CD19^+IgD^+$ B cells, and classical naïve $CD4^+$ $CD45RA^+$, thymic naïve $CD4^+CD31/45RA^+$, and naïve $CD8^+CD27/28/45RA^+$ T cells has been observed. No deficit has been seen in $CD56^+$ NK cells. Thus, immunodeficiency in A-T particularly affects naïve B and T cells, which is a typical feature in physiological aging.

CANCER PREDISPOSITION

One of the major hallmarks of A-T is the predisposition to develop malignancies, most lymphoid in origin (Boder and Sedgwick, 1963). The association between a defective thymus, immunodeficiency, and the high frequency of lymphoid malignancy became evident early (Leveque et al., 1966; Miller, 1967; Peterson et al., 1964a). Chromosome instability as an explanation for the increased incidence of malignancy was proposed with the observation that leukemic cells from an A-T patient had a translocation involving chromosomes 12 and 14 (Hecht et al., 1966). Regular monitoring of this patient revealed a progressive increase in translocation-bearing, abnormal lymphocytes to 78 percent of the total lymphocytes before the patient succumbed to infection (Hecht et al., 1973). However, while translocations involving chromosome 14 have been associated with malignancy in Burkitt's lymphoma (Klein, 1981), patients with A-T without signs of leukemia or lymphoma may have clonal expansion of cells with chromosome 14/14 translocations to as much as 80 percent of the total lymphocytes (Al Saadi et al., 1980; Beatty et al., 1986).

Lymphoid malignancies in A-T are of both B-cell and T-cell origin and include non-Hodgkin's lymphoma, Hodgkin's lymphoma, and several forms of leukemia (Hecht and Hecht, 1990; Spector et al., 1982). At autopsy, non-Hodgkin's lymphoma accounted for approximately 40 percent of neoplasms detected, leukemias about 20 percent, and Hodgkin's lymphomas 10 percent. The increased frequency of lymphoid tumors in A-T could be accounted for by a defect in immune surveillance as part of the underlying immunodeficiency; however, the picture is more complex, as malignancies are not confined to the lymphoid system. In an analysis of 108 A-T patients with 119 neoplasms, Hecht and Hecht (1990) reported that 31 of these (26 percent) were solid tumors varying in type and location. Determination of subsequent risk in A-T

patients diagnosed with one type of neoplasm revealed that approximately 25 percent of patients with solid tumors subsequently developed non-Hodgkin's lymphoma or leukemia. A very low risk of subsequent neoplasms existed when the first tumor was lymphoid in origin. In a retrospective study in the United States, mortality from all causes in A-T was 50-fold and 147-fold higher for white and black A-T patients, respectively, than expected, based on overall U.S. mortality rates (Morrell et al., 1986). Among 263 A-T patients, there were 52 primary cancers—a 61-fold cancer excess for white probands and a 184-fold excess for black probands. Morrell et al. (1986) also found that the cancer excess was most pronounced for lymphoma, with 252-fold and 750-fold excesses observed for whites and blacks, respectively. As a cause of death in A-T, neoplasia is the second most frequent after pulmonary disease. Of 62 complete autopsy reports (Sedgwick and Boder, 1991), 29 deaths (47 percent) were caused by pulmonary complications, 14 (22 percent) by malignancy, and 16 (26 percent) by a combination of both. The lifetime cancer risk among A-T patients has been estimated to be between 10 and 38 percent (Morrell et al., 1990; Spector et al., 1982).

Recently, in patients with oral cancer, one of the polymorphisms in ATM, rs189037, has been found to be more prevalent compared to controls (Bau et al., 2010). A study by Lee et al. (2011) has shown that reduced *ATM* mRNA expression in laryngopharyngeal tumors is correlated with poor outcome, implying a role for ATM in solid tumor development and host response.

PHENOTYPIC HETEROGENEITY

Phenotypic heterogeneity has long been recognized in both the clinical and laboratory features of A-T. Susceptibility to pulmonary infections, presence and degree of mental retardation, and predisposition to leukemia were used as a tentative classification of subgroups (Hecht and Kaiser-McCaw, 1982). Initially, genetic heterogeneity underlying this phenotypic variability was proposed with the description of four cellular complementation groups (Chen et al., 1984; Jaspers and Bootsma, 1982; Murnane and Painter, 1982). However, identification of *ATM* (Savitsky et al., 1995a) made it clear that all complementation groups with a classical A-T phenotype represented mutations in the same gene.

In addition, there are separate genetic disorders resulting from defects in a DNA damage-response pathway that is functionally linked to ATM, which share phenotypic features with classical A-T (Nahas and Gatti, 2007) The first, Nijmegen breakage syndrome (NBS), shares the radiosensitivity, immunodeficiency, and cancer predisposition of A-T; unlike A-T, NBS involves microcephaly with various degrees of mental deficiency, and patients do not have ataxia or telangiectasias (Curry et al., 1989; Digweed et al., 1999; Digweed and Sperling, 2004; Jaspers et al., 1988a, 1988b). The link between A-T and NBS became more clear with the identification of NBS1 (nibrin), the product of the gene defective in NBS that is functionally linked to ATM (Carney et al., 1998; Matsuura et al., 1998; Varon et al., 1998) (Table 47.2).

The second disease, A-T–like disorder (ATLD), was first described by Taylor et al. (1993) in a family in which two first cousins presented with some A-T features. The clinical course of the disease was mild. Unlike classical A-T patients, these cousins were still ambulatory in their third decade of life. Both had progressive unsteadiness in walking, dysarthria, drooling, vertical nystagmus, and intention tremors, all characteristic of A-T, but there was no evidence of telangiectasia, and immunoglobulin and α-fetoprotein (AFP) levels were normal. Stewart et al. (1999) identified the gene responsible

Table 47.2 **COMPARISON OF ATAXIA-TELANGIECTASIA (A-T), ATAXIA-TELANGIECTASIA-LIKE DISORDER (ATLD), AND NIJMEGAN BREAKAGE SYNDROME (NBS)**

A-T	ATLD	NBS
ATM-null mutations	*MREII* hypomorphic mutations	*NBS1* hypomorphic mutations
Immunodeficiency	Immunodeficiency	Immunodeficiency
Neurodegeneration	Neurodegeneration	Neurodegeneration
Telangiectasia	—	Telangiectasia
—	—	Microcephaly
—	No evidence	Mental retardation
Radiosensitivity	Radiosensitivity	Radiosensitivity
Chromosomal translocations	Chromosomal translocations (+/–)	Chromosomal translocations
Radiosensitivity	Radiosensitivity (intermediate)	Radiosensitivity
Defective cell cycle checkpoints	Intermediate defect in cell-cycle checkpoints	Defective cell-cycle checkpoints
Defective DSB repair	?	Defective DSB repair
No ATM activity	Normal ATM basal activity, defective ATM activation	Normal basal ATM activity, defective ATM activation?
Genomic instability	Genomic instability	Genomic instability
Cancer predisposition	?	Cancer predisposition

for ATLD as *MRE11* that encodes the MRE11 protein, which is part of the hMrell/Rad50/Nbsl (MRN) complex that senses DSBs in DNA (Nelms et al., 1998; Stracker et al., 2004). The *MRE11* gene locus is close to the *ATM* locus on human chromosome 11q21, and only detailed linkage analysis allows separation of these loci, necessitating analysis of the *ATM* and *MRE11* genes to distinguish between A-T and ATLD. Mutations in the *MRE11* gene lead to many of the characteristics observed in both A-T and NBS. These results provide evidence for a common involvement of both ATM and members of the MRN complex in the cellular response to DSBs in DNA.

Ataxia without telangiectasia has also been reported by Aicardi et al. (1988), so-called "Aicardi syndrome," by Maserati et al. (1988), and by Chessa et al. (1992). According to current classification, there are two types of autosomal recessive ataxias with oculomotor apraxia (AOA). In type 1 (AOA1; i.e., Aicardi syndrome), aprataxin encoded by *APTX* gene is defective (Date et al., 2001; Moreira et al., 2001). In type 2 (AOA2), there is a defect in senataxin encoded by *SETX* (Moreira et al., 2004). More recently, other DNA repair defects have been discovered in humans: a female patient with RAD50 deficiency, who phenotypically resembled NBS patients (Waltes et al., 2009), and a male patient with ubiquitin-ligase ring-finger protein (RNF168) deficiency, with A-T–like features (Devgan et al., 2011).

Even in classical A-T with ataxia and telangiectasia, the onset of clinical symptoms and the rate of progression are variable. Several reports describe differences in the age of presentation and rates of progression (Dörk et al., 2004; Hernandez et al., 1993; Sedgwick and Boder, 1991; Sutton et al., 2004). In a study of 70 A-T patients, ataxia started prior to 1 year of age in 20 percent, before 2 years in 65 percent, and by 4 years of age in 85 percent of patients (Taylor et al., 1993; Woods and Taylor, 1992). Variability in the appearance of telangiectasias, even between affected siblings, has also been reported (Sedgwick and Boder, 1991). Sanal et al. (1993) identified 30 A-T patients with variant characteristics, including severity of the ataxia, presence of telangiectasia, degree of growth retardation, mental ability, facial appearance, and immunological abnormalities.

The types and frequencies of spontaneous chromosome aberrations including translocations and inversions, largely involving chromosomes 7 and 14, are remarkably consistent in A-T patients (Taylor and Edwards, 1982). These translocations are also observed in lymphocytes from normal individuals, but at a much lower frequency. Exposure of A-T cells to ionizing radiation gives rise to increased levels of chromatid damage compared to controls (Kidson et al., 1982; Taylor et al., 1976). Comparison of lymphocytes from different A-T patients indicates that heterogeneity exists in the extent of induced damage. This is also observed when cell survival is the endpoint (Cox et al., 1978; Fiorilli et al., 1985; Jaspers et al., 1988b; Ziv et al., 1989). Chessa et al. (1992) designated 14 A-T patients from several studies as being intermediate in their response to ionizing radiation. In 13 of the 14 cases, there was a correlation between radiosensitivity as determined by chromosomal breakage and cell survival. On the other hand, radioresistant DNA synthesis ranged from normal to equally defective as in classical A-T, indicating that this parameter is less significant in causing the radiosensitivity in A-T. Twelve of the 14 patients in this study had definite ataxia and either frank telangiectasia or an increase in conjunctival vascularity.

The considerable phenotypic heterogeneity in A-T is not clearly understood even in light of the identified *ATM* gene. Several studies on *ATM* mutations predict that 70 to 80 percent give rise to truncated proteins, while the remainder represent small to large in-frame deletions and missense mutations (Byrd et al., 1996; Chun and Gatti, 2004; Gilad et al., 1996a, 1996b; Lavin et al., 2004; Savitsky et al., 1995a; Telatar et al., 1996; Wright et al., 1996). Most patients are compound heterozygotes with different mutations in the two *ATM* alleles. This information has been useful in accounting for milder forms of the disease in some A-T patients. A missense mutation in *ATM* that activates a cryptic splice/donor acceptor site resulting in the insertion of 137 nucleotides of intronic sequence (5762ins137) was present in the heterozygous state in 15 percent of A-T patients in the United Kingdom with a milder phenotype (McConville et al., 1996). A second missense mutation 7271T-G is also associated with a mild-variant A-T phenotype (Stankovic et al., 1998). Thus, allelic diversity might explain much of the heterogeneity in clinical severity in A-T. However, there are some interesting cases—for instance, two siblings with mild A-T who were found to have a truncating *ATM* mutation and severe cellular phenotype (Alterman et al., 2007). Therefore, influences other than *ATM* mutations seem to play a role in heterogeneity.

OTHER CLINICAL CHARACTERISTICS

In addition to the major clinical hallmarks, a variety of other features characterize A-T (Table 47.1). Retardation of somatic growth has been reported for about 70 percent, particularly in adolescents and older patients, whose heights are often below the third percentile. Stunting of growth may be due to the pulmonary complications, hypogonadism, and/or thymic dysplasia (Boder, 1985; Good et al., 1964). Female hypogonadism, as absence or hypoplasia of the ovaries, is quite common in A-T. This is usually associated with infantile uterus and fallopian tubes (Boder and Sedgwick, 1957; Bowden et al., 1963). Its appearance in A-T may be due to an underlying mesenchymal abnormality (Dunn et al., 1964; Miller and Chatten, 1967). Hypogonadism is also observed in male A-T patients, but to a lesser extent than in females (Boder and Sedgwick, 1958). Puberty is delayed, there is abnormal testicular histology, and spermatogenesis is impaired (Aguilar et al., 1968; Strich, 1966).

An unusual type of diabetes mellitus has been described in patients with A-T, with marked hyperinsulinism, hyperglycemia without glycosuria or ketosis, and peripheral resistance to insulin (Barlow et al., 1965; Schlach et al., 1970). Insulin resistance can partly be explained by abnormalities in the number

and affinity of insulin receptors in A-T (Bar et al., 1978). More importantly, ATM protein, being related to phosphatidylinositol 3-kinase (Jackson and Jeggo, 1995; Lavin et al., 1995; Savitsky et al., 1995a; Zakian, 1995), is involved in signal transduction and glucose transport. The kinase activity of ATM is activated by insulin through a non-DNA-damage signaling pathway to phosphorylate 4E-BP1 (PHAS-1), a regulator of protein synthesis (Yang and Kastan, 2000). Thus a loss of ATM function in A-T patients could disrupt insulin signaling, thereby contributing to insulin resistance, glucose intolerance, and diabetes. In fact, a single nucleotide polymorphism (SNP), rs11212617 at a locus containing ATM, has been associated with glycemic response to metformin in diabetes mellitus type 2 (GoDARTs and UKPDS Diabetes Pharmacogenetics Study Group, 2010).

Mild hepatic dysfunction, as evidenced by abnormalities of serum alkaline phosphatase, serum glutamic oxalocetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and lactate dehydrogenase (LDH), is also seen in A-T (McFarlin et al., 1972). Diffuse fatty infiltration of hepatic parenchymal cells, round cell infiltration in portal regions, and parenchymal cells with nuclear swelling and vacuolation are characteristic changes. It is likely that the hepatic dysfunction is related to the generalized metabolic changes in A-T. Elevated serum levels of AFP and carcinoembryonic antigen (CEA) in A-T patients are common and thought to be indicative of some form of abnormal development in the liver (Sugimoto et al., 1978; Waldmann and McIntyre, 1972). A widespread cellular histological abnormality, nucleocytomegaly, manifested as large, bizarre, hyperchromatic nuclei (Aguilar et al., 1968; Amromin et al., 1979; Boder and Sedgwick, 1958), occurs in most organs, including the central nervous system, anterior pituitary, thyroid, adrenal glands, liver, kidney, lung, heart, and thymus, in smooth muscle cells, and in capsular cells of the spinal ganglia.

LABORATORY FINDINGS AND CELLULAR CHARACTERISTICS

CELLULAR RADIOSENSITIVITY AND CHROMOSOMAL INSTABILITY

A number of cellular and molecular features characterize A-T (Lavin, 1992) (Table 47.3). Frequent chromosome breakage, described more than four decades ago (Hecht et al., 1966; Miller, 1967), led to the classification of A-T as a chromosomal instability syndrome together with Bloom's syndrome and Fanconi's anemia (Cohen et al., 1975; Gropp and Flatz, 1967; Hecht et al., 1973; Higurashi and Conen, 1973). Clinical radiosensitivity was noted when adverse reactions in A-T patients treated with X-rays occurred (Feigin et al., 1970; Gotoff et al., 1967; Morgan et al., 1968) (Table 47.1). This adverse response was also demonstrated in A-T cells in vitro (Higurashi and Conen, 1973; Rary et al., 1975). Taylor et al. (1975) observed that A-T fibroblasts were more sensitive to ionizing radiation than control fibroblasts. These observations were confirmed and extended by others for radiation (Chen et al., 1978; Edwards and Taylor, 1981; Lehmann et al., 1982; Paterson et al., 1976), bleomycin (Cohen and Simpson, 1982; Morris et al., 1983), and treatment with neocarzinostatin (Cohen and Simpson, 1982; Shiloh et al., 1982a, 1982b, 1983).

While A-T cells are hypersensitive to ionizing radiation and radiomimetic chemicals, they have a gross repair defect in DSBs rather than in single-strand breaks. Residual DSBs can be detected in A-T cells up to 72 hours after irradiation (Table 47.3). Approximately 10 percent of breaks remain unrepaired. A number of other cellular and molecular abnormalities have been reported in A-T cells exposed to radiation (Table 47.3). A specific DNA binding protein, induced by ionizing radiation in control cells to translocate from the cytoplasm to the nucleus, was shown to be constitutively

Table 47.3 **CELLULAR AND MOLECULAR FEATURES OF A-T RELATED TO RADIATION RESPONSE**

CHARACTERISTIC	ASSAY	REFERENCE

present in the nucleus in several A-T cell lines (Singh and Lavin, 1990; Teale et al., 1992, 1993). As discussed below, specific molecular tests, including mutation analysis of *ATM*, immunoblotting to detect the ATM protein, and specific ATM kinase assays, have all been added to laboratory tests for A-T.

CELL-CYCLE ANOMALIES

Eukaryotic cells progress through the cell cycle in an ordered series of events called G1, S (DNA synthesis), G2, and M (mitosis). Events occurring later in the cycle depend on the completion of earlier events, with control maintained through a series of checkpoints (Hoyt et al., 1991; Kastan et al., 1991; Weinert et al., 1994). Checkpoints introduce pauses to ensure the integrity of the genome by allowing for correction of episodic DNA damage or replication delays (Lukas et al., 2004). A series of yeast checkpoint null mutants have been described that lose chromosomes spontaneously and are hypersensitive to ionizing radiation (Al-Khodairy and Carr, 1992; Jimenez et al., 1992; Li and Murray, 1991; Weinert and Hartwell, 1990). These mutants fail to undergo arrest at either the G1/S or G2/M checkpoints in response to radiation damage and/or they fail to maintain the dependence of mitosis upon completion of DNA synthesis.

There are obvious parallels between the data for these yeast mutants and some of the early observations with A-T cells. The first evidence for an abnormality in cell-cycle control in A-T cells came from the observation that DNA synthesis continued after irradiation (radioresistant DNA synthesis), allowing cells to proceed through S phase unchecked (de Wit et al., 1981; Edwards and Taylor, 1981; Houldsworth and Lavin, 1980; Painter and Young, 1980). A defect in a signaling pathway from ATM through the checkpoint kinase Chk2 and Cdc25A phosphatase may be partly responsible for the unchecked cell cycle in G1/S and G2/M. Falck et al. (2001) have shown that ionizing radiation exposure normally leads to the loss of Cdc25A, preventing dephosphorylation of Cdk2 kinase and producing a transient blockade in DNA replication. This blockade is defective in A-T cells, allowing DNA replication to proceed. A delay in radiation-induced phosphorylation of replication protein A, a component of the single-strand DNA binding protein complex, has also been implicated (Liu and Weaver, 1993). Furthermore, ultraviolet (UV)-induced hyperphosphorylation of RPA (p34 subunit) depends on expression of ATM (Oakley et al., 2001).

The physiological transitory delay in DNA synthesis after irradiation also appears to be mediated through a calmodulin-dependent regulatory cascade (Mirzayans et al., 1995), and this pathway is also defective in A-T. A reduction of radiation suppression of the mitotic index in A-T fibroblasts resulted from a failure to prevent cells irradiated in G2 phase from proceeding into mitosis (Scott and Zampetti-Bosseler, 1982). This finding appeared at first to contradict evidence that A-T lymphoblastoid cells and SV40-transformed fibroblasts experienced more prolonged delay in G2/M at longer times after irradiation (Bates et al., 1985; Ford et al., 1984; Smith et al., 1985). However, it is now evident that A-T cells that are in G2 phase at the time of irradiation undergo less delay in proceeding into mitosis at short times after irradiation, but cells irradiated at other phases of the cycle proceed through to G2 phase, where they are for the most part irreversibly blocked (Beamish and Lavin, 1994). A-T cells also fail to undergo normal delay in progression from G1 to S phase after irradiation (Imray and Kidson, 1983; Nagasawa and Little, 1983). The overall picture that emerges for A-T is a failure of cell-cycle checkpoints at G1/S, during DNA synthesis, and at G2/M to respond to radiation damage (Beamish and Lavin, 1994).

An understanding of the molecular defect in A-T at the level of cell-cycle checkpoints was enabled by advances in cell-cycle control in yeast and mammalian cells (Hartwell and Smith, 1985; Lukas et al., 2004; Nurse, 1985). Passage of cells through the cycle is controlled by cyclin-dependent kinases (Pines and Hunter, 1991; Xiong et al., 1991), cyclin-kinase inhibitors (El-Deiry et al., 1993; Gu et al., 1993; Harper et al., 1993), other kinases and phosphatases, and a variety of other proteins, including the retinoblastoma protein and the transcription factor E2F (Hall et al., 1993; Hinds et al., 1992). The best-described disruption of this intricate pattern of control is the inhibition of DNA synthesis and slowing of cell division in response to radiation damage (Painter, 1985; Weinert and Hartwell, 1988). Kastan et al. (1991) provided an explanation for this inhibition when they demonstrated that the normal product of the tumor-suppressor gene p53 is induced by radiation and brings about delay in the passage of cells from G1 to S phase. These investigators subsequently showed that the G1/S checkpoint in A-T cells was impaired because of a defect in the p53 radiation signal transduction pathway at the level of p53 (Kastan et al., 1992). Khanna and Lavin (1993) then found that the defect in p53 induction by radiation extended to all four complementation groups of A-T, but there was normal induction of p53 in A-T cells in response to UV damage. In addition, inhibitors of protein kinase C and serine/threonine phosphatases interfered with the pathway.

Failure to observe a correlation between absence of p53 or mutated p53 and radiosensitivity (Clarke et al., 1993; Lee and Bernstein, 1993; Lowe et al., 1993; Slichenmyer et al., 1993) suggested that the ATM operates in more than one pathway affecting cell-cycle control and perhaps at other levels of cellular control. Sensitivity to ionizing radiation might be explained by a defect at the level of the G2/M checkpoint, since A-T cells accumulate at this checkpoint with time after exposure to radiation (Beamish and Lavin, 1994; Hong et al., 1994). ATM-dependent stabilization and activation of p53 are of central importance to the operation of the G1/S checkpoint in response to radiation damage to DNA. Radiation induces phosphorylation, dephosphorylation, and acetylation of p53 (Meek, 2004). Some of these modifications are ATM-dependent (Banin et al., 1998; Canman et al., 1998; Saito et al., 2002). ATM is responsible for the rapid phosphorylation of human p53 at serine 15 after irradiation, and serine 20 phosphorylation is carried out by Chk2 in an ATM-dependent manner (Chehab et al., 1999). Serine 20 phosphorylation interferes with p53's binding to its inhibitor, Mdm2, which plays a major role in its degradation. ATM also phosphorylates Mdm2 itself, to inhibit the nuclear export of the p53Mdm2

complex, thus ensuring the stabilization of p53 after irradiation (Khosravi et al., 1999; Maya et al., 2001). Thus it is evident that ATM controls G1/S checkpoint through multiple interactions.

Stabilization of p53 by radiation and other DNA-damaging agents leads to the induction of a cyclin kinase (Cdk) inhibitor, WAF1 (p21, Cip1) (El-Deiry et al., 1993; Gu et al., 1993; Harper et al., 1993; Xiong et al., 1993). WAF1 binds to cyclin E/cdk2 and cyclin A/cdk2 kinase complexes, and by inhibiting their activities prevents the progress of cells from G1 to S phase (Dulic et al., 1994; Waga et al., 1994). In keeping with the defective p53 response in A-T cells, Canman et al. (1994) showed a defective induction of WAF1, and the induction of Mdm2, another downstream effector of p53, was also shown to be defective (Price and Park, 1994). Khanna et al. (1995) subsequently demonstrated that the radiation signal transduction pathway operating through p53, its target gene *WAF1*, cyclin-dependent kinases, and the retinoblastoma protein (Rb) are all defective in A-T cells. Correction of the defect at the G1/S checkpoint was observed when wild-type p53 was constitutively expressed in A-T cells (Khanna et al., 1995). As expected, the WAF1 response in irradiated control cells resulted in an inhibition of cyclin-dependent kinase activity including cyclin E/cdk2, which plays an important role in the transition from G1 to S phase. No inhibition of cyclin-dependent kinase activity was observed in A-T cells, correlating with the delayed WAF1 response. An accumulation of the hypophosphorylated form of Rb protein occurred in irradiated control cells compatible with the G1/S-phase delay observed in these cells after exposure to radiation. In unirradiated A-T cells the amount of Rb protein was much higher than that in controls, and it was mainly in the hyperphosphorylated (inactive) form.

In agreement with the expected role of *ATM,* Beamish et al. (1996) demonstrated that several cyclin-dependent kinases in A-T cells are not inhibited by ionizing radiation, associated with insufficient induction of WAF1. Exposure of control lymphoblastoid cells to radiation during S and G2 caused rapid inhibition of cyclin A/cdc2 and cyclin B/cdc2 activities, respectively. Irradiation led to a 5- to 20-fold increase in cdk-associated WAF1 in these cells, accounting at least in part for the decrease in cyclin-dependent kinase activity. In contrast, radiation did not inhibit any of the cyclin-dependent kinase activities in A-T cells at short times after irradiation, nor was there any significant change in the level of cdk-associated WAF1 compared to unirradiated cells (Beamish et al., 1996). These results were similar to those reported previously for the G1 checkpoint and provided additional evidence for the involvement of ATM at multiple points in cell-cycle regulation. In relation to the abnormality in S phase, Mirzayans et al. (1995) had indirect evidence that radiation-induced cessation of DNA synthesis is mediated through a calmodulin-dependent signal transduction pathway, independent of protein kinase C (PKC) and p53; in addition to the p53 pathway, this signaling system is also defective in A-T cells.

As referred to above, A-T cells exhibit radioresistant DNA synthesis and defective S-phase checkpoint activation (Houldsworth and Lavin, 1980; Painter and Young, 1980). Falck et al. (2001) provided a functional link between ATM, the checkpoint signaling kinase Chk2, and the Cdc25A phosphatase that activates the cyclin kinase Cdk2 and control of the S-phase checkpoint. Exposure of cells to radiation leads to the activation of ATM kinase, which in turn activates Chk2 to phosphorylate Cdc25A phosphatase. This leads to the degradation of Cdc25 A, and thus Cdk2 remains phosphorylated and inactive, giving rise to a transient block in DNA replication. In cells with absent or mutated ATM, this pathway does not function, Cdc25A remains stable, and cells continue to replicate DNA in the presence of damage (radioresistant DNA synthesis).

While considerably less is known about activation of the G2/M checkpoint, maintenance of inhibitory phosphorylations on Cdc2 leads to arrest of cells in G2 (Jin et al., 1996). In response to DNA damage, Cdc25C phosphatase is phosphorylated and inactivated, again in this case preventing the dephosphorylation of Cdc2 kinase, which is required for passage of cells through G2 phase (Nilsson and Hoffmann, 2000). It is not established which kinase phosphorylates Cdc25C, but both Chk1 and Chk2 can phosphorylate this protein at serine 216 in vitro (Matsuoku et al., 1998; Sanchez et al., 1997). Phosphorylation creates a binding site for 14-3-3 protein, which results in inactivation of the phosphatase (Peng et al., 1997). Since ATM phosphorylates and activates Chk2 in response to DNA damage, it is likely that this is the pathway operating to activate the G2/M checkpoint (Blasina et el al., 1999; Brown et al., 1999).

To account for the defective radiation response in A-T cells, a "damage surveillance network" model has been proposed in which certain types of DNA damage trigger a signal transduction network with resulting activation of a group of pathways to promote genetic stability by temporarily arresting the cell cycle and enhancing DNA repair (Meyn, 1995; Meyn et al., 1994). It appears likely that ATM is recruited to sites of DSBs in DNA and subsequently signals via downstream substrates such as p53 and Chk2 to the cell-cycle machinery to delay the passage of cells between the various phases prior to completion of DNA repair. Evidence for recruitment of ATM to DNA breaks was provided by Smith et al. (1999a), who showed that ATM binds preferentially to DNA ends in both monomeric and tetrameric forms. In addition, a combination of single-strand and sheared DNA is capable of stimulating ATM kinase activity for RPA substrate (Chan et al., 2000; Gately et al., 1998). Resistance to detergent extraction of a fraction of the ATM pool after irradiation, together with colocalization of this ATM with the phosphorylated form of histone H2AX and with Nbs1 foci, suggests further that ATM associates with sites of DSBs (Andegeko et al., 2001).

THE ATM GENE AND A-T MUTATIONS

The placement of an A-T locus by Gatti et al. (1988) on chromosome 11q22–23 spurred extensive positional cloning efforts (Lange et al., 1995; McConville et al., 1994; Rotman et al., 1994; Vanagaite et al., 1995), which culminated in

identification of *ATM*, the gene mutated in A-T patients (Savitsky et al., 1995a, 1995b). *ATM* occupies 150 kb of genomic DNA and encodes a large transcript of about 13 kb representing 66 exons (Platzer et al., 1997; Savitsky et al., 1995b, 1996; Uziel et al., 1996). There is no evidence of alternative splicing within the open reading frame of the *ATM* transcript. However, extensive variability has been detected in the untranslated regions (UTRs) of the transcript, creating multiple species of ATM mRNA. Several 3′ UTRs are formed via polyadenylation of alternative sites, while at least 12 5′ UTRs are obtained via alternative splicing of the first four exons of the gene (Savitsky et al., 1997). This complex pattern suggests that synthesis of the ATM protein might be subject to posttranscriptional regulation. It has recently been shown that human microRNA, miR-421, suppresses ATM expression by targeting the 3′ UTR of *ATM* transcripts (Hu et al., 2010).

Deficiency of the ATM protein is indeed responsible for the A-T cellular phenotype. Ectopic expression of recombinant ATM protein in A-T cells complemented various features of this phenotype (Zhang et al., 1997; Ziv et al., 1997), while downregulation of ATM by means of antisense strategies conferred A-T features to various cell lines (Fan et al., 2000; Uhrhammer et al., 1999; Zhang et al., 1998). Furthermore, expression of ATM fragments containing the leucine zipper of this protein abrogated the S-phase checkpoint and increased the radiosensitivity of the human tumor cell line RKO (Morgan et al., 1997). Such protein fragments appear to act in a dominant-negative fashion, possibly by competing with ATM for specific interactor(s).

Extensive screening of the *ATM* transcript for mutations in A-T cells has been performed using a variety of methods (Angele et al., 2003; Becker-Catania et al., 2000; Broeks et al., 1998; Byrd et al., 1996; Concannon and Gatti, 1997; Fukao et al., 1998; Gilad et al., 1996a, 1996b, 1998a, 1998b; Laake et al., 1998, 2000; McConville et al., 1996; Pagani et al., 2002; Sandoval et al., 1999; Sasaki et al., 1998; Saviozzi et al., 2003; Savitsky et al., 1995a; Telatar et al., 1996; Teraoka et al., 1999; Watters et al., 1997; Wright et al., 1996). To date, over 400 separate mutations have been described. These mutations are distributed along the length of the gene, with the majority predicted to cause premature truncations (70–80 percent) and others causing small deletions, in-frame deletions, and missense changes (Hu and Gatti, 2009; Stankovic et al., 1998). Thus, *ATM* gene mutations in patients with classical A-T are expected to inactivate the ATM protein by truncating it or by deleting large segments from it. This mutation profile points to predominance of null alleles in classical A-T. Hence, mutations with milder effects on the protein might lead to non–A-T phenotypes.

Most A-T mutations are unique to single families, and the majority of patients in Europe and North America are compound heterozygotes. Interestingly, a founder effect was observed among patients of Moroccan Jewish origin, in whom one mutation is predominant (Gilad et al., 1996b). Evidence for founder mutations has also been reported for patients in Japanese (Ejima and Sasaki, 1998), Norwegian (Laake et al., 1998), and other populations (Teletar et al., 1998).

Compared to the predominance of null alleles among patients with classical A-T, a different mutation profile is emerging in "A-T variants," which show a milder phenotype, usually with later age of onset and less pronounced radiosensitivity. These patients may have leaky splicing mutations giving rise to a mixture of normal and aberrant transcripts, small in-frame deletions, or truncations of just the last few carboxy-terminal amino acids, or the defect may be in another gene (e.g., *MRE11* gene) (Dörk et al., 2004; Eng et al., 2004; Gilad et al., 1998a; McConville et al., 1996; Saviozzi et al., 2002; Stewart et al., 2001; Sutton et al., 2004; Teraoka et al., 1999).

FUNCTION OF THE ATM PROTEIN

ATM PROTEIN AND PIKK FAMILY

The open reading frame of *ATM* transcripts predicts a 370 kDa protein of 3,056 amino acids (Savitsky et al., 1995b). The ATM protein is a serine/threonine protein kinase and a member of the phosphoinositode 3-kinase-related protein kinase (PIKK) family. All members of the PIKK family are large serine/threonine protein kinases involved in signaling following cellular stress. The ATM consensus phosphorylation motif is hydrophobic-X-hydrophobic-[S/T]-Q (Derheimer and Kastan, 2010; Kim et al., 1999). The other members of the PIKK family include ATR (ATM and RAd3 related protein kinase), DNA-PKcs (DNA dependent protein kinase catalytic subunit), mTOR (mammalian target of rapamycin), and hSMG1. These members share common domain structures such as N-terminal HEAT repeats, a FAT domain, a protein kinase domain, and a C-terminal FAT-C domain (Abraham, 2004b; Derheimer and Kastan, 2010). These kinases function at the top of various signaling cascades that sense specific types of stresses or stimuli related to cellular growth and are critical for the activation of cellular responses to these stimuli. Most of the PIKK family members are involved in sensing and responding to DNA damage and in maintaining genomic stability (Table 47.4). PIKK family members, as another common feature, associate with proteins or protein complexes that facilitate their activation and function. ATM binds to the MRN (Mre11, Rad50, Nbs1) heterotrimer at DSB sites. This binding places the ATM on chromatin, to efficiently activate the downstream signaling and DNA repair mechanisms (Falck et al., 2005; Lovejoy and Cortez, 2009).

The ATM ortholog in the budding yeast *Saccharomyces cerevisiae* is Tel1p, whose ectopic expression in human A-T cells partially complements their phenotype (Fritz et al., 2000). Tel1p and another PIKK member in the budding yeast, Mec 1p, closely collaborate in maintaining telomere length and mediating cellular responses to DNA damage. Tel1p, which has a protein kinase activity (Mallory and Petes, 2000), has been studied mainly with regard to its role in maintaining telomere length (Greenwell et al., 1995; Ma and Greider, 2009; Morrow et al., 1995; Ritchie et al., 1999; Seidel et al., 2008). *TEL1* mutations lead to shortened telomeres, a typical characteristic of human A-T cells. Interestingly, in this function, Tel1p cooperates with the double-strand breakage repair

Table 47.4 ATM-RELATED PROTEINS CONTAINING A PI3-KINASE–LIKE DOMAIN

PROTEIN	ORGANISM	SIZE (A.A.)	MUTANT PHENOTYPE	PREDICTED FUNCTION (ENZYMATIC ACTIVITY)
Te11p	Budding yeast	2789	Teleomere shortening	Regulation of telomere length
Meclp	Budding yeast	2368	Sensitivity to DNA-damaging agents; mitotic instability; defects in meiotic recombination and cell cycle checkpoints	Regulates cell-cycle checkpoints responding to DNA damage
Rad3p	Fission yeast	2386	Sensitivity of DNA-damaging agents; mitotic instability; defective DNA repair and cell cycle checkpoints	Regulates cell-cycle checkpoints responding to DNA damage
Mei-41	Fruit fly	2356	Sensitivity to DNA-damaging agents; mitotic instability; defective DNA repair and cell cycle checkpoints	Regulates cell-cycle checkpoints responding to DNA damage
Tor1p	Budding yeast	2470	Rapamycin resistance; perturbation of G1 cell-cycle progression	Binds rapamycin, FKBP12; Heitman et al., 1991 involved in G1/S transition
Tor2p	Budding yeast	2473	Rapamycin resistance; perturbation of G1 cell-cycle progression	Binds rapamycin, FKBP12; involved in G1/S transition
MTOR (FRAP)	Mammalian	2549	Rapamycin resistance; perturbation of G1 cell-cycle progression	Binds rapamycin, FKBP12
RAFT1	Mammalian	2550		Involved in G1/S transition; activates $p70^{S6}$ kinase (autophosphorylation on Ser)
FRP1/ATR	Mammalian	2644	Embryonic lethal in mice; no known human syndrome	Protein kinase responding to UV, hydroxyurea
DNA-PKcs	Humans	4096	SCID phenotype in mice; radiation sensitivity; immunodeficiency; defective repair of double-strand breaks and V(D)J recombination	Signals presence of DNA damage to cellular regulatory systems (Ser/Thr protein kinase)
TRAPP	Mammalian	3828	DNA repair; recruits histone acelylases, oncogene activation	No kinase activity

complex Mre11/Rad50p/Xrs (Ritchie and Petes, 2000), whereas in human cells, ATM functionally interacts with the orthologous protein complex in the DNA damage response. The synergism between Tel1p and Mec1p in both telomere maintenance and cellular responses to DNA damage has been clearly documented in double-mutant *tel1/mec1* yeast, which are extremely sensitive to DNA damage and senesce prematurely (Greenwell et al., 1995; Ritchie et al., 1999; Vialard et al., 1998). While *tel1* mutants are not hypersensitive to DNA damaging agents, an extra copy of *TEL1* can largely complement such sensitivity in *mec1* mutants (Morrow et al., 1995).

The closest human ATM homolog is the ATR protein, which represents a separate branch of the PIKK family. ATR is a protein kinase that shares many substrates with ATM and acts in partial redundancy with ATM in a number of damage response pathways (Shechter et al., 2004). ATR and ATR-interacting protein (ATRIP) control S-phase progression in response to DNA damage and replication fork stalling, ultimately resulting in the downstream inhibition of the S-phase kinases that function to initiate DNA replication at origins of replication (Shechter et al., 2004). Disruption of the *ATR* gene in mice leads to early embryonic lethality before embryonic day 8.5 (Brown and Baltimore, 2000; de Klein et al., 2000). A hypomorphic mutation (A2101G) in the human *ATR* gene causes a rare form of Seckel syndrome (O'Driscoll et al., 2003) designated ATR-Seckel (Alderton et al., 2004; O'Driscoll et al., 2004). Genetically and clinically, Seckel syndrome is a heterogeneous disorder characterized by severe intrauterine growth retardation, proportionate dwarfism, and microcephaly, with skeletal and brain abnormalities (OMIM #210600) (reviewed by O'Driscoll et al., 2004). Although lymphoma has been reported in some Seckel patients, they tend not to have ataxia or immunodeficiency. Patients with Seckel syndrome display features including microcephaly and dysmorphic facies that are commonly found in other syndromes associated with impaired responses to DNA damage. Alderton et al. (2004) found that ATR-Seckel cells exhibit a range of aberrant responses to agents that cause replication stalling. They also exhibit supernumerary centrosomes in mitotic cells, demonstrating a novel role for ATR in the maintenance of centrosome stability.

Overexpression of a "kinase-dead" form of ATR gives rise to a dominant-negative effect leading to increased sensitization to DNA damaging agents and defective cell-cycle checkpoint activation (Cliby et al., 1998; Wright et al., 1998). ATR-deficient cells are hypersensitive to UV and hydroxyurea (HU), in contrast to A-T cells, in which γ-radiation causes hypersensitivity. Indeed, the phosphorylation of Rad17 induced by UV and HU is dependent on ATR, whereas that

induced by γ-rays is dependent on ATM (Bao et al., 2001). ATR appears to lie directly upstream from the checkpoint protein Chk1, which is activated in response to DNA replication blockage and agents that cause genotoxic stress to delay cells at the G2 checkpoint (Zhao and Piwnica-Worms, 2001).

In contrast to ATM, whose intrinsic kinase activity is contained in a single protein molecule, ATR is constitutively complexed and dependent on the accessory protein, ATRIP (Cortez et al., 2001). ATRIP is phosphorylated by ATR, regulates ATR expression, and is essential for proper ATR activity. ATR and ATRIP both localize to intranuclear foci after DNA damage or inhibition of replication. Small, interfering RNA directed against ATRIP causes the loss of both ATRIP and ATR expression and the loss of checkpoint responses to DNA damage, indicating the mutual dependence of these two proteins (Cortez et al., 2001). Replication protein A (RPA), a protein complex that associates with single-stranded DNA (ssDNA), is required for the recruitment of ATR to sites of DNA damage and for ATR-mediated Chk1 activation in human cells. In vitro, RPA stimulates the binding of ATRIP to ssDNA. The binding of ATRIP to RPA-coated ssDNA enables the ATR/ATRIP complex to associate with DNA and stimulates phosphorylation of the Rad17 protein that is bound to DNA (Zou and Elledge, 2003). In fact, ATM and ATR are involved together in phosphorylation of many cell-cycle checkpoint and DNA repair proteins (Lavin and Kozlov, 2007; Matsuoka et al., 2007). Encompassing 700 proteins, more than 900 regulated phosphorylation sites that contain a consensus ATM and ATR phosphorylation motif (S/T-Q) have been identified by a large-scale proteomic analysis (Matsuoka et al., 2007).

ATR orthologs are typically involved in maintaining genome stability and responding to DNA damage. The yeast ATR orthologs, Mec1p in the budding yeast and Rad3p in the fission yeast, maintain genomic stability and activate DNA damage responses by phosphorylating key proteins in these pathways (reviewed in Zhou and Elledge, 2000; Humphrey, 2000). As mentioned above, Mec1p collaborates with the ATM ortholog, Tel1p, in the damage response pathway and telomere maintenance in *S. cerevisiae* (Longhese et al., 2000; Neecke et al., 1999). Notably, Mec1p-dependent processes include cell-cycle checkpoints induced by DNA damage or replication arrest (Clarke et al., 1999; Santocanale and Diffley, 1998; Vallen and Cross, 1999); redistribution of the Sir3 silencing protein from telomeres to DSBs (Mills et al., 1999); meiotic recombination (Grushcow et al., 1999); and silencing of gene expression at telomeres (Craven and Petes, 2000). The Rad3p of *Schizosaccharomyces pombe* is critical for the immediate activation of cell-cycle checkpoints following DNA damage and for the activation and maintenance of responses to replication arrest. The mechanisms in each response are different and carried out by different effectors (Martinho et al., 1998). Many of the relevant pathways are conserved through evolution; hence, in mammalian cells, ATM and ATR phosphorylate orthologs of Mec1p and Rad3p substrates. In *Drosophila melanogaster* mutants in the ATR ortholog *mei-41* exhibit chromosomal instability, radiation sensitivity, and defective activation of cell-cycle checkpoints by ionizing radiation (Hari et al., 1995). Recombination-defective lines of flies reveal a role for Mei-41 protein in meiotic precocious anaphase in females (McKim et al., 2000).

The catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs) is another major member of the PIKK family (reviewed by Burma and Chen, 2004). DNA-PKcs is recruited to DSB sites by the Ku70/Ku80 heterodimer and appears to play a central role in the rejoining process, in V(D)J recombination, and in triggering apoptosis in response to severe DNA damage or critically shortened telomeres. DNA-PK also appears to be involved in mounting an innate immune response to bacterial DNA and to viral infection. Because DNA-PK localizes very rapidly to DNA breaks and phosphorylates itself and other damage-responsive proteins, it appears that DNA-PK serves as both a sensor and a transducer of DNA-damage signals. ATM- and ATR-dependent pathways appear to be independent of DNA-PK (Araki et al., 1999; Khosravi et al., 1999). However, the critical role of DNA-PK in DSB response is underscored by the *scid* phenotype of DNA-PK–deficient mice, which includes radiosensitivity, chromosomal instability, immunodeficiency, and cancer predisposition (Jhappan et al., 1997).

The TOR subfamily of the PIKKs represents a group of proteins whose role is to convey, via their kinase activity, extracellular signals rather than dealing with DNA damage (Proud, 2004). The TOR proteins signal nutrient availability (e.g., amino-acid levels) and pass on certain mitogenic stimuli to the mRNA translation machinery. One known mechanism is TOR-dependent phosphorylation of the $p70^{S6k}$ kinase. The pathways controlled by the mammalian homolog in this group, mTOR/FRAP/RAFT, may end up regulating both protein translation and transcription of rRNA and tRNA. Importantly, TOR-mediated pathways appear to intersect with certain P13K pathways.

A more recent addition to the PIKK family is the hSMG1 protein (Abraham, 2004a). The protein kinase activity of hSMG-1 resembles that of ATM, both in terms of substrate specificity and its sensitivity to inhibition by the fungal metabolite wortmannin. hSMG-1 is the ortholog of a *Caenorhabditis elegans* protein, CeSMG-1, which has been genetically linked to a critical mRNA surveillance pathway termed *nonsense-mediated decay* (NMD). The function of NMD is to mark for rapid degradation mRNAs that bear a premature termination codon. hSMG-1 is also a central player in the NMD pathway in human cells. In addition, hSMG-1, like ATM, appears to be involved in the recognition and/or repair of damaged DNA in these cells.

Finally, members of the TRRAP (transformation/transcription domain-associated protein) branch of the PIKK family are devoid of kinase activity because of inactivating sequence alterations in their kinase domains. The mammalian (TRRAP/PAF400) and yeast (Tra1p) homologs are part of large protein complexes involved in transcriptional regulation and chromatin remodeling via their histone actetyltransferase activity (Grant et al., 1998; Saleh et al., 1998; Vassilev et al., 1998). TRRAP/PAF400 is a co-activator of the c-Myc and E2F transcription factors and recruits the histone acetyltransferase GCN5 to c-Myc (McMahon et al., 1998, 2000).

The existence of the TRRAP group in the PIKK family raises the possibility that members residing in other branches of the PIK-related kinase phylogenetic tree are involved in gene regulation and shaping of chromatin. In general, despite the apparently diverse functions of the different branches of this important protein family, they may share more functions than meet the eye.

ATM FUNCTIONS

ATM Activation

ATM is a predominantly nuclear protein with a strong serine/threonine kinase activity. Similar to DNA-PK and ATR, ATM's kinase activity appears to be directed at serine or threonine residues that are immediately followed by a glutamine (Kim et al., 1999; O'Neil et al., 2000). ATM plays a crucial role in the early response to the induction of DSBs in the DNA (Kurz and Lees-Miller, 2004; Shiloh, 2003). Immediately after the formation of DSBs in the DNA, ATM's kinase activity is enhanced (Banin et al., 1998; Canman et al., 1998; Khanna et al., 1998). The activated ATM then phosphorylates an extensive array of target proteins, each of which is a key player in a specific damage response pathway (Fig. 47.1). Bakkenist and Kastan (2003) discovered that ATM molecules are inactive in undamaged cells, being held as dimers or higher-order multimers. In this configuration, the kinase domain of each molecule is blocked by the *FAT domain* of the other. Following DNA damage, each ATM molecule phosphorylates the other on a serine residue at position 1981 within the FAT domain, an autophosphorylation that releases the two molecules from each other's grip, turning them into fully active monomers. Additional phosphorylation sites of Ser(367), Ser(1893), Thr(P)(1885), and Ser(P)(2996) (Kozlov et al., 2006, 2011) and other post-translational modifications also play a role in ATM activation. The ubiquitously expressed histone acetyl-transferase, TIP60, acetylates ATM on Lysine 3016, along with autophosphorylation (Sun et al., 2010) to activate ATM. Within minutes after the infliction of as few as several DSBs per genome, most ATM molecules become vigorously active. Another immediate step in ATM activation following DNA damage is rapid adherence of a portion of activated ATM to DSB sites (Andegeko et al., 2001). Both chromatin-bound ATM and free ATM are autophosphorylated on serine 1981 (Uziel et al., 2003). Therefore, following DSB induction, activated ATM seems to divide between two fractions: one is chromatin bound and the other is free to move throughout the nucleus. Importantly, many ATM substrates are phosphorylated by the chromatin-bound fraction of ATM, at the damaged sites (Lukas et al., 2003).

One of the first processes initiated by DSBs is the massive phosphorylation of the tail of a histone protein variant H2AX (Fernandez-Capetillo et al., 2004). H2AX phosphorylation is ATM-dependent following DSB induction (Burma et al., 2001) and ATR-dependent following replicative stress (Ward and Chen, 2001). Foci of γH2AX, visualized by immunofluorescence as a marker for DNA breaks (Rogakou et al., 1999), are rapidly formed at the DSB sites and are essential for further recruitment of repair factors such as the Mre11/Rad50/Nbs1 (MRN) complex, Rad51, and Brca1 (Celeste et al., 2002). Disappearance of γH2AX foci, probably representing the restoration of the local chromatin environment, correlate with completed DNA repair (Derheimer and Kastan, 2010; Kinner et al., 2008). A-T cells show persistent γH2AX foci following ionizing radiation (Riballo et al., 2004). For efficient DNA repair, the surrounding heterochromatin structure needs to decondense and relax to provide access to the damaged DNA. This relaxation is somewhat achieved by ATM via phosphorylating and inhibiting the transcriptional repressor KAP1 (KRAB-associated protein 1), a core component of heterochromatin (Cann and Dellaire, 2011; Derheimer and Kastan, 2010; Goodarzi et al., 2008; Ziv et al., 2006).

The Mre11/rad50/Nbs1 (MRN) complex serves as a sensor of DSBs caused by DNA-damaging agents (Stracker et al., 2004). It is involved in the initial processing of such DSBs by virtue of the nuclease activity of one of its components—the Mre11 protein. MRN is also involved in processing DSBs that are formed during meiotic recombination and in telomere maintenance. The Nbs1 protein is a direct substrate of ATM but also seems to serve as an adaptor in the phosphorylation of other ATM substrates such as Chk2 (Buscemi et al., 2001; Girard et al., 2002) and Smc1 (Kim et al., 2002b; Yazdi et al., 2002), particularly at low damage levels. Similarly, the Brca1 protein, itself an ATM substrate, is an adaptor in the phosphorylation of other ATM substrates (Foray et al., 2003). Therefore, phosphorylation of one substrate is required for the phosphorylation of others. A molecular explanation for the adaptor role of the MRN complex was provided by Lee and Paull (2004), who showed that MRN facilitates in vitro the binding between ATM and some of its substrates. MRN also plays a role in the actual activation of ATM. The presence of a functional MRN complex is required for full activation of ATM, particularly at low damage levels (Carson et al., 2003; Horejsi et al., 2004; Uziel et al., 2003) and for recruitment of ATM to the damaged sites (Kitagawa et al., 2004). A molecular explanation for these observations was provided by Costanzo et al. (2004), who showed that in *Xenopus* extracts, ATM, MRN, and broken DNA fragments assemble into an "activation complex" whose formation is required for full activation of ATM.

Another protein that appears to facilitate the phosphorylation of certain ATM substrates is p53 binding protein 1 (53BP1) (Mochan et al., 2004). Like Nbs1, 53BP1 contains a BRCT (breast cancer C-terminus) domain, is recruited to DSB-induced nuclear foci, is required for proper activation of certain cell-cycle checkpoints, and is itself an ATM substrate (DiTullio et al., 2002; Fernandez-Capetillo et al., 2002; Wang et al., 2002). Another BRCT-containing protein phosphorylated by ATM is MDC1/NFBD1 (Stucki and Jackson, 2004). MDC1, bound to γH2AX and phosphorylated by ATM, serves as a docking station for DNA-repair proteins. Ring-finger ubiquitin ligases RNF8 and RNF168 are recruited to the DSB site, followed by ubiquitination of γH2AX and maintenance of 53BP1 and BRCA1, and ATM at the DSB site (Derheimer and Kastan, 2010; Lavin, 2008).

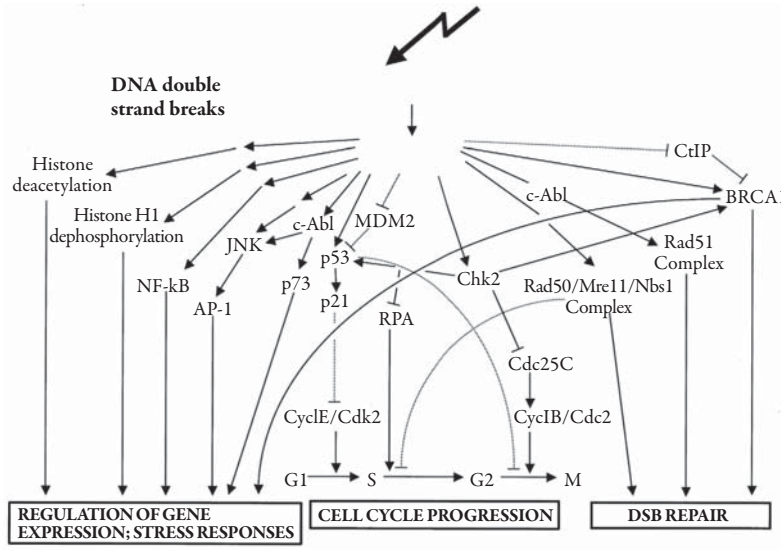

Figure 47.1 Scheme of ATM-dependent pathways in the double-strand break (DSB) response network, highlighting ATM effectors. Arrows indicate stimulation, while T-shaped lines represent inhibition. The transition from inactive ATM homodimers into active monomers and the role of the Rad50/Mre11/Nbs1 (MRN) complex upstream of this process are indicated. ATR phosphorylates at least some of ATM's substrates in response to these DNA lesions at later time points and slower kinetics. (Reproduced from Shiloh et al., 2004, with permission.)

ATM, apart from being activated by DSBs as described above, can be directly activated by oxidative stress in the absence of MRN complex (Guo et al., 2010). Thus, ATM appears to act as a redox sensor and may be regulating global cellular responses to oxidative stress. In fact, A-T cells have impaired mitochondrial function and increased levels of reactive oxygen species (ROS) as well as mitochondrial DNA deletions in the region that encodes cytochrome *c* oxidase (COX) (Lavin, 2008; Patel et al., 2011). More recently, Valentin-Vega et al., 2012 have shown that ATM-deficient thymocytes in mice have significant reductions in mitochondrial electron transport chain activity, decreases in intracellular ATP levels, altered mitochondrial ultrastructural organization, and enhanced mitochondrial ROS in the presence of increased mitochondrial numbers possibly due to decreased mitophagy. Therefore, the authors have suggested that ATM plays direct roles in modulating mitochondrial homeostasis and A-T should be considered partly a mitochondrial disease.

ATM SUBSTRATES AND DOWNSTREAM PATHWAYS

ATM has multiple substrates. Proteomic analyses of proteins phosphorylated in response to DNA damage on consensus sites recognized by ATM and ATR suggest as many as 700 substrates (Linding et al., 2007; Matsuoka et al., 2007). The high number of ATM targets suggests that ATM plays a role in many cellular responses and signaling pathways yet to be discovered. These proteomic analyses also draw attention to the cytoplasmic ATM in peroxisomes, endosomes, or in soluble form, as a protein with a more general role in cellular pathways such as in insulin signaling (Guo et al., 2010; Lavin, 2008; Patel et al., 2011; Yang et al., 2011; Yang and Kastan, 2000).

ATM orchestrates a remarkably broad cellular response to DSBs. A simplified network of ATM-mediated pathways (Fig. 47.1) uses several sophisticated strategies. The first strategy is to approach the same effector from several different directions. A prime example is the G1/S checkpoint (reviewed by Shiloh, 2003; Kurz and Lees-Miller, 2004). A main component in this cell-cycle checkpoint is activation and stabilization of p53, which in turn activates transcription of the gene that encodes the CDK2-cyclin-E inhibitor WAF1 (also known as p21 and CIP1) (Meek, 2004; Oren, 2003). p53 is phosphorylated by ATM on Ser15 (Banin et al., 1998; Canman et al., 1998). This contributes primarily to enhancing p53's activity as a transcription factor (Ashcroft et al., 1999; Dumaz and Meek, 1999; Khosravi et al., 1999). ATM also phosphorylates and activates Chk2 (Ahn et al., 2004), which phosphorylates p53 on Ser20. This process interferes with the p53–MDM2 interaction. The oncogenic protein Mdm2 is both a direct and indirect inhibitor of p53, as it serves as a ubiquitin ligase in p53 ubiquitylation, which mediates its proteasome-mediated degradation (Alarcon-Vargas and Ronai, 2002; Brooks and Gu, 2004). ATM also directly phosphorylates Mdm2 on Ser395, which interferes with nuclear export of the p53Mdm2 complex and hence the degradation of p53 (Khosravi et al., 1999; Maya et al., 2001). Phosphorylations of p53 on Ser9 and Ser46 (Saito et al., 2002) and dephosphorylation of Ser376 (Waterman et al., 1998) are ATM-dependent as well, although the function of these changes is unclear.

This series of ATM-dependent modifications that activate and stabilize p53, although perhaps not complete, illustrates the elaborate way in which ATM handles a single effector. This principle is also seen in ATM-mediated activation of the Brca1 tumor-suppressor protein following DNA damage. Brca1 is involved in the early stage of the DNA-damage response as well as in activating downstream pathways (Ting and Lee, 2004). Brca1 was found to be associated

with large protein complexes that contain DSB repair and mismatch repair enzymes as well as ATM (Wang et al., 2000b). It also activates the expression of certain damage-responsive genes and is involved in the S-phase and G2/M checkpoints (El-Deiry, 2002; Jasin, 2002; Venkitaraman, 2002; Yarden et al., 2002). ATM phosphorylates Brca1 on several sites (Cortez et al., 1999; Gatei et al., 2000a, 2001b). Importantly, whereas ATM-mediated phosphorylation of Brca1 on Ser1387 activates Brca1 as a regulator of the intra–S-phase checkpoint (Xu et al., 2002), its phosphorylation by ATM on Ser1423 spurs its involvement in the G2/M checkpoint (Xu et al., 2001). Thus, phosphorylation on different sites may direct an effector to act in different pathways. The Chk2 kinase, which is activated by ATM, adds yet another phosphorylation on the Brca1 molecule (Lee et al., 2000), while at the same time ATM phosphorylates CtIP, an inhibitor of Brca1, on two residues, inhibiting its function and further stimulating Brca1 (Li et al., 2000). ATM's hold on downstream pathways is demonstrated by not only its multipronged grip of specific pathways but also its ability to approach the same endpoint from several different directions. A notable example is, again, the intra-S checkpoint: several ATM-controlled pathways converge to regulate this crucial cellular response to DSBs (Fig. 47.1). At least five ATM-mediated pathways seem to be involved in this checkpoint. In addition to Brca1, ATM phosphorylates Nbs1 (Gatei et al., 2000b; Lim et al., 2000; Wu et al., 2000; Zhao et al., 2000), a component of the multifunctional Mre11Rad50Nbs1 (MRN) complex involved in DSB sensing (Stracker et al., 2004). Of several ATM phosphorylation sites on Nbs1, Ser343 and Ser278 seem to be particularly important for its unknown role in this checkpoint (Lim et al., 2000; Zhao et al., 2000). Another ATM substrate in the intra-S checkpoint pathway is the Smc1 (structural maintenance of chromosomes 1) protein. This protein, known primarily for its involvement in sister chromatid cohesion, is phosphorylated by ATM on two serine residues; interference with this phosphorylation abrogates the S-phase checkpoint (Kim et al., 2002b; Yazdi et al., 2002). Importantly, cells from mice in which ATM phosphorylation sites on Smc1 had been abolished had an S-phase checkpoint defect, decreased survival, and increased chromosomal aberrations after DNA damage (Kitagawa et al., 2004). A recently identified effector of ATM in the intra-S checkpoint is the FancD2 protein, which is phosphorylated by ATM on Ser222 following DSB induction and undergoes Brca1-mediated mono-ubiquitylation (Taniguchi et al., 2002). FancD2 is a member of a multiprotein complex, defects of which lead to another genomic instability syndrome, Fanconi's anemia. At the same time, Chk2 and another ATM/ATR-activated kinase, Chk1, take care of several checkpoints. Both of them phosphorylate the checkpoint phosphatase Cdc25A, which marks it for degradation (Falck et al., 2001, 2002; Mailand et al., 2000, 2002; Zhao et al., 2002). Cdc25A's duty is to dephosphorylate—and hence maintain the activity of—the cyclin-dependent kinases Cdk2 and Cdk1. Cdk2 drives both the G1/S transition and S phase, and Cdk1 mobilizes the G2 phase onto mitosis. Therefore, the destruction of Cdc25A contributes to the G1/S, intra-S, and G2/M checkpoints (Fig. 47.1). The Cdc25A-mediated component of the G1/S checkpoint is rapid and, unlike the p53-mediated component, is not dependent on gene activation and protein synthesis (Falck et al., 2002).

Notably, in addition to ATM's versatility as a protein kinase with numerous substrates, the ATM web contains protein kinases that are themselves capable of targeting several downstream effectors simultaneously, and so concomitantly control subsets of pathways. Chk2 is known to phosphorylate p53, BrcA1, Cdc25A, and Cdc25C (Bartek et al., 2001; McGowan, 2002) (Fig. 47.1). The Chk2-Cdc25C pathway is similar to the previously mentioned Chk2-Cdc25A pathway, but may act instead at the G2/M transition. Here, phosphorylation of Cdc25C by activated Chk2 is thought to lead to cytoplasmic sequestration of Cdc25C, which prevents activation of Cdk1.

Most of these pathways have not been completely characterized, and the involvement of ATM substrates in them has been inferred from defective activation of specific checkpoints following abrogation of ATM-mediated phosphorylation of these proteins. An interesting pathway is mediated by phosphorylation of hRad17, the human ortholog of Rad17 from the fission yeast *Schizosaccharomyces pombe*. hRad17 is phosphorylated in an ATM/ATR-mediated manner on two serine residues, and this phosphorylation is important for proper G1/S and G2/M checkpoint functions (Bao et al., 2001; Post et al., 2001). hRad17 is involved in a very early event in the DSB response: it loads a trimolecular complex onto the DNA that consists of the human orthologs of the fission yeast proteins Rad9, Hus1, and Rad1 ("the 9-1-1 complex"). This complex acts as a sliding clamp, probably a damage sensor (Parrilla-Castellar et al., 2004). Although this process may be upstream of the transducer recruitment, two essential proteins in this process, hRad17 and hRad9, are also phosphorylated in an ATM/ATR-dependent manner and participate in downstream checkpoint pathways (Bao et al., 2001; Chen et al., 2001; Post et al., 2001).

ATM AND GENE TRANSCRIPTION

Many damage responses modulate expression of genes. Indeed, a major ATM target, p53, is a transcription factor. Another transcription factor with a central role in cell-cycle control, E2F1, has been reported to be phosphorylated and stabilized in an ATM-dependent manner (Lin et al., 2001). In addition, it is becoming evident that stress-response pathways that are best known for responding to other triggers in an ATM-independent manner, such as those mediated by the mitogen-activated protein kinases or the transcription factor NF-KB, also contain a DNA damage-responsive component (Pearce and Humphrey, 2001). Interestingly, when these pathways are activated by DSBs, their response becomes ATM-dependent (Bar-Shira et al., 2002; Li et al., 2001; Wang et al., 2000a). The direct targets of ATM in these pathways have not been elucidated, but these observations expand the ATM-dependent network considerably.

ATM AND DAMAGE-INDEPENDENT GENOMIC STABILITY

ATM helps maintain genomic stability through mechanisms other than responding to DSBs caused by damaging agents. T cells from A-T patients have abnormally shortened telomeres, abnormal association of chromosome ends, telomere clustering, and altered interaction between the telomeres and the nuclear matrix (Pandita, 2001). ATM is functionally linked to telomere maintenance, a process crucial to aging and cancer (Chan and Blackburn, 2002; Kim et al., 2002a; Maser and DePinho, 2002; Misri et al., 2008; Pandita, 2001). Here, ATM may be responding continuously to an ongoing process rather than abruptly and vigorously to an acute insult (Karlseder et al., 1999). The functional relationships between ATM and the telomere maintenance machinery have been illuminated by a study that generated mice doubly null for Atm and the telomerase RNA component Terc (Wong et al., 2003). These animals showed increased genomic instability, enhanced aging, and premature death, with a general proliferation defect extending into stem- and progenitor-cell compartments. Interestingly, the rate of T-cell malignancies in these mice was reduced rather than enhanced.

Free ends of the chromosome are masked by a protein complex, Shelterin, so that they are not recognized as free ends of a DSB (Palm and de Lange, 2008). Multiple proteins, including TIN2, TRF1, TRF2, TPP1, POT1, and RAP1, compose this telomeric protection complex. TRF1 and TRF2 are substrates of ATM (Derheimer and Kastan, 2010; Tanaka et al., 2005). Phosphorylation of TRF1 seems to suppress TRF1-mediated apoptosis following DNA damage (Kishi et al., 2001). Inhibition of TRF1 in A-T cells rescues telomere shortening and decreases the radiosensitivity of these cells, providing further evidence of the link between telomere metabolism and the DNA damage response (Kishi and Lu, 2002). Inhibition of TRF2 causes disruption of the Shelterin complex, thereby exposing the free telomeric ends to be recognized as DSBs, and activation of an ATM-dependent DNA damage response that would result in telomere dysfunction (Derheimer and Kastan, 2010; Palm and de Lange, 2008).

Further evidence of ongoing activity of ATM at sites of normally occurring breakage and reunion of DNA was provided by its presence at sites of V(D)J recombination (Bredemeyer et al., 2008; Kracker and Durandy, 2011; Perkins et al., 2002). At those sites, p53 phosphorylated at the ATM target residue was also present, indicating that ATM continuously surveys the V(D)J recombination process and can induce a damage response if DSBs are not sealed in a timely manner. Indeed, A-T patients often show clonal translocations involving the sites of the T-cell receptor and immunoglobulin genes, demonstrating the consequences of absence of this surveillance. These translocations often herald the onset of lymphoid malignancy (Xu, 1999).

ATM-DEFICIENT MICE: AN ANIMAL MODEL OF A-T

Mouse models of A-T were established in several laboratories by forming null alleles of the mouse homolog, *Atm* (Barlow et al., 1996; Elson et al., 1996; Herzog et al., 1998; Xu et al., 1996; Borghesani et al., 2000). $Atm^{-/-}$ mice share many clinical features of human A-T and highlight several features that have not received sufficient attention in humans and might be essential to understanding the functions of ATM. The reduced number and abnormal function of B and T cells, radiosensitivity, and a strong predisposition to cancer are similar between humans and mice. However, $Atm^{-/-}$ animals die almost exclusively from thymic lymphomas, whereas human patients develop leukemias, lymphomas, and solid tumors. Growth retardation is much more pronounced in $Atm^{-/-}$ mice than in human A-T patients. Fibroblasts from $Atm^{-/-}$ mice grow slowly and exhibit inefficient progression from G1 to S phase following serum stimulation (Xu and Baltimore, 1996). Atm-deficient mouse fibroblasts manifest radiosensitivity, genome instability, and defective radiation-induced cell-cycle checkpoints. An *Atm* knock-in mutant mouse harbors a 9 nucleotide in-frame deletion (7666del9) corresponding to a common human mutation (7636del9) and producing near-full-length Atm protein (Spring et al., 2001). The overall phenotype is similar to $Atm^{-/-}$ mice except for longer lifespan in nonspecific pathogen-free conditions, a lower incidence of thymic lymphomas, and more varied tumor types in older animals.

The neurological deficit in $Atm^{-/-}$ mice is much less pronounced than in humans and can be elicited only by special testing. Moreover, the cerebella of these animals appear normal upon histopathological examination. The use of electron microscopy has provided evidence for degeneration of several different neuronal cell types in the cerebral cortex in 25 percent of neuronal profiles of 2-month-old $Atm^{-/-}$ mice (Kuljis et al., 1997). Degenerating Purkinje cells had abnormalities in nucleoplasm and cytoplasm as well as crenated cell membranes from which filiform appendages originated. Degeneration was also observed in other types of neurons and glial cells. Replacement of the Rad3 homology domain of Atm with a *neoIr* gene generated an $Atm^{-/-}$ mouse with ectopic and abnormally differentiated Purkinje cells (Borghesani et al., 2000). Although gross neurological abnormalities were found, none of the other $Atm^{-/-}$ mice exhibited such changes. However, $Atm^{-/-}$ mice show age-dependent defects in Ca^{2+} spike bursts and calcium currents (Chiesa et al., 2000), and cerebellar Purkinje cells from $Atm^{-/-}$ animals are in a state of oxidative stress (Barlow et al., 1999; Kamsler et al., 2001; Watters et al., 1999).

Male and female sterility due to absence of mature gametes is another striking feature that has not received special attention in humans. Atm is clearly essential for mouse germ-cell development. Xu et al. (1996) noticed that meiosis is arrested in these mice at the zygotene/pachytene stage of the first meiotic prophase as a result of abnormal chromosomal synapsis and subsequent fragmentation. Using electron microscopy, Barlow et al. (1998) showed that male and female gametogenesis is disrupted in $Atm^{-/-}$ mice as early as leptonema of prophase 1, resulting in apoptotic degeneration. These results are corroborated by the observation that Atm is physically associated with synapsed chromosomal axes at meiosis (Keegan et al., 1996; Plug et al., 1997). These findings provide direct evidence of the role of Atm in

recognizing specific DNA structures formed during meiotic recombination.

In summary, observations in mouse knockout models highlight the role of Atm in normal somatic cell growth and chromosomal recombination in meiosis, in addition to its recognized function in radiation-induced signal transduction. Further genetic manipulation of $Atm^{-/-}$ mice will enable the elucidation of additional features of A-T previously undisclosed in the human disease (Barlow et al., 1996; Elson et al., 1996; Xu and Baltimore, 1996; Xu et al., 1996).

DIAGNOSIS OF A-T

As in all primary immunodeficiency disorders, diagnosis of A-T starts with a high index of suspicion. In the absence of family history, the disease is usually detected by a pediatric neurologist on the basis of anomalies in station and gait accompanied by telangiectasias. However, telangiectasias usually appear later than ataxia, between 2 and 8 years of age. Before then, differential diagnosis of ataxia is crucial. Ataxia may be a part of another syndrome such as Friedreich's ataxia, which typically has a later onset with pes cavus and kyphoscoliosis, unusual manifestations in A-T. Ataxia may also be due to a cerebral neoplasm or hematoma, infectious encephalitis, postinfectious encephalomyelitis, progressive rubella panencephalitis, or subacute sclerosing panencephalitis. A number of metabolic diseases of infancy and childhood, including Gaucher disease, Niemann-Pick disease, GM1 and GM2 gangliosidoses, metachromatic leukodystrophy, or Krabbe leukodystrophy, may manifest with ataxia. A thorough medical history and physical examination allows discrimination between A-T and two other metabolic disorders, Hartnup disease and maple syrup urine disease; in both of these, ataxia is episodic rather than progressive as in A-T. Laboratory assays are quite helpful in diagnosing metabolic diseases.

A-T can also be readily distinguished from the hereditary motor-sensory neuropathies Charcot-Marie-Tooth disease (distal weakness, pes cavus, hyporeflexia, and mild to moderate sensory loss), type III disease (distal weakness, nerve hypertrophy, and electromyographic abnormalities), and Refsum disease (polyneuropathy and ataxia). Other syndromes exhibiting ataxia include Machado-Joseph disease, dentatorubral degeneration of Ramsay Hunt, and olivopontocerebellar atrophy. Each of these differs from A-T by having a different pattern of inheritance or age of onset.

A number of laboratory tests have been used to support the clinical diagnosis of A-T (Table 47.5) since the description of the disease. Reduced or absent IgA and elevated AFP levels are nonspecific but supportive of the clinical diagnosis. The demonstration of frequent chromosome breakages (Hecht et al., 1966), the observation of cellular hypersensitivity to ionizing radiation in culture, and radioresistant DNA synthesis provided the basis for tests developed in several laboratories to aid in the diagnosis of A-T (Houldsworth and Lavin, 1980; Lavin and Schroeder, 1988; Painter and Young, 1980). However, none of these assays has been successful in identifying family members at risk, with the occasional exception of their application to prenatal diagnosis. An assay for radioresistant DNA synthesis has been used for prenatal diagnosis in A-T (Jaspers et al., 1981).

After identification of the *ATM* gene, diagnosis of A-T has tremendously improved by means of measuring ATM protein levels (Butch et al., 2004; Chun et al., 2003), ATM kinase activity, and mutation analysis of *ATM* (Chun and Gatti, 2004). Mutation detection for carrier and prenatal diagnosis, particularly in the light of specific mutations in the family, has become feasible, although there are a large number of described mutations widely distributed in *ATM.* Alternatively, it is possible to carry out immunoblotting or immunoassay, which has a considerably shorter turnaround time than immunoblotting, to detect ATM protein (Butch et al., 2004). Since most mutations in *ATM* are truncating and some missense mutations also destabilize the protein, ATM protein is either undetectable or reduced in amount in most A-T patients. In cases where mutant ATM protein is detectable, ATM kinase activity can be measured. This is determined by immunoprecipitation of ATM and assay using a substrate such as p53 and ^{32}P-ATP (Banin et al., 1998; Canman et al., 1998).

Mutation analysis of *ATM* has enabled definitive diagnosis of patients with manifestations consistent with A-T (hence presumed to have "A-T") or in patients who are classified as having "A-T variant" based on presence of atypical symptoms (Chun and Gatti, 2004). Now, A-T can reliably be distinguished, at the gene level, from the Mre11 deficiency (A-T–like disease), the oculomotor apraxia 1 (AOA1) (aprataxin deficiency) (Date et al., 2001, Moreira et al., 2001), the oculomotor apraxia 2 (AOA2) (senataxin deficiency) (Moreira et al., 2004), and other "A-T variants," including NBS (nibrin/Nbs1 deficiency) and $A\text{-}T_{Fresno}$. NBS manifests with microcephaly, mental retardation, apraxia, and telangiectasia in the absence of ataxia. On the other hand, $A\text{-}T_{Fresno}$ is a phenotype that combines the features of both NBS and A-T, with mutations in the *ATM* gene. Perhaps the closest to A-T is AOA2, which is characterized by progressive ataxia, choreoathetosis, and oculomotor apraxia. However, these patients do not have the immunodeficiency seen in A-T, nor the other laboratory markers; most importantly, they have normal *ATM* gene. Now that we are able to define the molecular defect, protein expression, and function in A-T, all patients with a "classical A-T" or "A-T variant" phenotype deserve genetic analysis to assign an accurate diagnosis, which would be instrumental in prognosis and genetic counseling.

A-T and Newborn Screening: Newborn screening using dried blood spots (DBS) for T cell receptor excision circles (TRECs) to identify severe combined immunodeficiencies (SCID) is increasingly being performed in the US (Mallot et al., 2013). It has recently been shown that more than half of A-T patients can actually be identified as abnormal by newborn screening for SCIDs because of the T lymphocytopenia which may be a feature of A-T in newborns. Subsequently, whole exome sequencing for mutation analysis performed in abnormal infants may enable an early genetic diagnosis of A-T. Early detection of the disease would be helpful in prevention of complications in the patient, and to

Table 47.5 LABORATORY TESTS TO SUPPORT DIAGNOSIS OF A-T

ASSAY	A-T PHENOTYPE	REFERENCE
Antibodies		
Serum IgA, IgE	Reduced	Thieffry et al. (1961)
Serum IgM	Monomeric form	Peterson et al. (1963)
Serum Proteins		
α-fetoprotein	Elevated	Waldmann and McIntire (1972)
Carcinoembryonic antigen	Elevated	Sugimoto et al. (1978)
Radiosensitivity		
Cell survival	Reduced	Taylor et al. (1976)
Chromosome aberrations	Elevated	Hecht et al. (1965); Higurashi and Conon (1973)
G2 phase delay	Exaggerated	Ford et al. (1984); Beamish and Lavin (1994)

Radioresistant DNA synthesis	Present	Houldsworth and Lavin (1980)

provide genetic counseling and carrier detection for the family (Mallot et al., 2013)

MUTATION-TARGETED THERAPY

In A-T, as in other genetic diseases, the mutations can be classified into four groups as nonsense, splicing, frameshift, and missense mutations. Each group of mutations can potentially be targeted with chemicals or oligonucleotides to correct the gene defect (Hu and Gatti, 2008).

NONSENSE MUTATIONS

Of 434 reported gene defects in A-T, 17 percent are nonsense *ATM* mutations, which create premature stop codons (UAA, UAG, or UGA) to terminate translation at that point, resulting in a truncated unstable protein (Hu and Gatti, 2008). Suppressing (i.e., reading through) the resulting premature stop codons with chemicals to allow translation to continue to the true end of the transcript is a promising approach to correct nonsense mutations. Proof of concept has been shown for aminoglycosides in a number of genetic diseases (Zingman et al., 2007). Aminoglycosides bind to the decoding site of the 16S ribosomal RNA. This binding results in a local conformational change that allows translation through what would otherwise be read as a premature termination codon. Paromomycin and G418 were the first aminoglycosides shown to partially restore the full-length protein of nonsense mutation in mammalian cells (Burke and Mogg, 1985). Gentamicin was tested in clinical trials for cystic fibrosis (Wilschanski et al., 2003), Duchenne muscular dystrophy (Politano et al., 2003), and hemophilia (James et al., 2005). Lai et al. (2004) studied aminoglycosides ex vivo in A-T lymphoblastoid cell lines. They used radiosensitivity, radioresistant DNA synthesis, and irradiation-induced autophosphorylation of ATM Ser-1981 to show that the aminoglycoside-induced full-length ATM protein was functional and corrected to various extents. Studies have shown some limitations of this approach: (1) true stop codons are not affected by the read-through compounds, (2) there is a need for high concentration of aminoglycosides to read through, which may be toxic to cells, and (3) most antibiotics do not cross the blood–brain barrier efficiently, which would compromise the use in central nervous system diseases. Paromomycin is a newly designed compound that seems to have an effective read-through activity at nontoxic concentrations (Pokrovskaya et al., 2010). PTC124 appears to be another small molecule, nonsense-suppression read-through compound shown to be effective in mouse models of Duchenne muscular dystrophy and cystic fibrosis (Du et al., 2008; Welch et al., 2007). To discover additional read-through chemicals, as well as structure–activity relationship (SAR) groups, Gatti's laboratory developed a high-throughput screen assay based on the protein truncation test (PTT) (Du et al., 2008). They have identified more than 50 nonaminoglycoside chemicals with read-through activity, some of which are promising for clinical use (Du et al., 2009).

SPLICE DEFECTS

Splicing mutations account for approximately 26 percent of the *ATM* gene defects, which affect pre-mRNA splicing. Antisense oligonucleotides have been successfully used to modulate splicing site selection (Vacek et al., 2003). Antisense oligonucleotides block the targeted splice sites and redirect the splicing machinery to a more appropriate nearby splice site by targeting pre-mRNA in a sequence-specific manner. Du et al. (2007) have used antisense morpholino oligonucleotides (AMOs) to redirect and restore normal splicing in the ATM gene for splicing mutations. High concentrations of antisense oligonucleotides are needed in the nucleus for efficiency of this approach. Recent improvements in the delivery vehicles, such as arginine-rich, cell-penetrating peptides (CPP) and nine-arginine tags fused to rabies virus glycoprotein peptides (RVG-9R), have rendered direct delivery of antisense oligonucleotides into mammalian leukocytes

and neurons (Kumar et al., 2007; Marshall et al., 2007). Du and Gatti (2011) have achieved considerable correction of intranuclear ATM protein levels with CPP-mediated AMOs. The fact that RVG-9R–mediated oligonucleotide delivery can cross the blood–brain barrier is also promising in A-T as well as in other genetic disorders with central nervous system involvement.

FRAMESHIFT MUTATIONS

Forty percent of *ATM* mutations are frameshifts resulting from nucleotide insertions or deletions (Hu and Gatti, 2008). Gene therapy, antisense oligonucleotide–mediated exon skipping, and revertant mosaicism approaches are potentially promising to correct a frameshift mutation in A-T.

MISSENSE MUTATIONS

Missense and in-frame mutations that produce proteins with variable functions represent about 16 percent of *ATM* mutations (Hu and Gatti, 2008). Different therapeutic approaches can be developed based on the resultant function of the protein with small molecule compounds and chimeraplast, which are RNA/DNA oligonucleotides.

Mutation-targeted approaches in A-T, as well as in other primary immunodeficiency disorders, are definitely promising in treatment.

A-T HETEROZYGOTES AND ELEVATED CANCER RISK

Although A-T heterozygotes do not exhibit symptoms of the disease, they do have radiosensitivity to a lesser extent than homozygotes, a finding first reported by Chen et al. (1978). A number of other assays have been used to confirm this finding (Chen et al., 1994; Paterson et al., 1985; Roisin and Ochs, 1986; Rudolph et al., 1989; Shiloh et al., 1986). However, there is considerable variation among heterozygotes, and none of the assays is sufficiently reliable for A-T carrier diagnosis without reference to a known homozygote relative.

A Hardy-Weinberg estimate for heterozygotes using the early data of Boder and Sedgwick (1970) predicts a frequency of 1 in 100 individuals, whereas that of Swift et al. (1986) would give a value between 0.3 and 0.4 per 100. Because A-T is autosomal recessive, it would be expected that heterozygotes would show no symptoms. However, mortality from cancer among blood relatives of A-T patients is higher than expected. Swift et al. (1991) found an increased cancer risk in 1,599 adult blood relatives of A-T patients from 161 A-T families, compared to 821 of their spouses as controls. A subgroup of 294 obligate heterozygotes had relative risks of 3.8-fold above controls for men and 3.5-fold for women for all types of cancer. The relative risk for breast cancer in women was 5.1-fold. Several other epidemiological studies also support an increased risk of breast cancer in A-T heterozygotes but with smaller relative risk (Geoffroy-Perez et al., 2001; Inskip et al., 1999; Janin et al., 1999; Olsen et al., 2001; Pippard et al., 1988). Molecular genotyping and mutation analysis have produced apparently conflicting data on the incidence of *ATM* mutations in different cohorts of breast-cancer patients. In A-T family studies, Athma et al. (1996) detected 25 heterozygotes among 33 women with breast cancer, where only 15 were expected by chance alone. Fitzgerald et al. (1997) detected heterozygous mutations in 2 of 202 healthy women with no history of cancer, whereas the figure was 2 of 410 for women with early-onset breast cancer. Other smaller studies support these observations (Bay et al., 1998; Bebb et al., 1999; Chen et al., 1998). However, Broeks et al. (2000) detected 7 germline *ATM* mutations in 82 breast-cancer patients with either early-onset disease or bilateral breast cancer. In most of these studies truncating mutations were screened for, since they represent the bulk of mutations seen in A-T patients. One explanation for the disparate findings might reside in possible differences between truncating and missense mutations in *ATM*. Indeed, Gatti et al. (1999) proposed a model to explain the relationship between ATM mutations and cancer susceptibility discriminating between missense and truncating mutations. They envisaged that an *ATM* missense mutant expressing mutant protein could act in a dominant-negative capacity to interfere with normal ATM function. There is evidence that missense mutations in the kinase domain of *ATM* have a dominant interfering effect (Lim et al., 2000). Recent evidence for an increased frequency of *ATM* missense mutations in breast-cancer patients adds support for this model (Broeks et al., 2000; Dörk et al., 2001; Izatt et al., 1999; Teraoka et al., 2001).

Swift et al. (1991) asked whether diagnostic or occupational exposure to ionizing radiation increases the risk of breast cancer in women heterozygous for A-T. However, Norman and Withers (1993), estimating that annual mammography for 35 years would give a woman a total exposure of only 10 cGy, argued that on the basis of an increased sensitivity to radiation on the order of 30 percent (Cole et al., 1988), the lifetime risk for breast cancer from mammography would be 2 cases per 100 women. This would not significantly add to the natural lifetime risk of 1 in 9 in the general population. Additional studies of cancer and heterozygous *ATM* mutation are needed that also address the potential combined effects of mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* as well as better-defined environmental risk factors.

FUTURE DIRECTIONS

Our understanding of A-T has expanded enormously since the defective gene *ATM* was cloned. However, the more we learn, the more we become aware that we know little. With the advent of large-scale proteomic analyses, the number of potential substrates for the ATM protein has risen up to 700, meaning that there is still much more to learn about A-T and the ATM. Clearly, ATM is involved in many different signaling pathways, and it may have a regulatory role in crucial cellular functions not only in the nucleus but also in the cytoplasm. Challenges ahead include defining the substrates, establishing

the physiological importance of ATM-mediated phosphorylations, and assembling these events into signaling pathways. Better understanding of these mechanisms will be helpful in elucidating the connections between the lack of ATM and the various abnormalities in A-T to develop novel treatment strategies. More importantly, the role of ATM in more common diseases with high impact on public health, such as diabetes and cancer, will be better defined, paving the way to target ATM for global therapeutic purposes.

CHROMOSOMAL INSTABILITY SYNDROMES OTHER THAN ATAXIA-TELANGIECTASIA

Rolf-Dieter Wegner, James J. German, Krystyna H. Chrzanowska, Martin Digweed, and Markus Stumm

A number of syndromes exist in which an increased incidence of spontaneous and/or induced chromosomal aberrations is the unifying diagnostic criterion. These disorders, called *chromosomal instability syndromes,* include the classical chromosomal instability syndromes—namely, ataxia-telangiectasia (A-T), Fanconi anemia (FA), and Bloom syndrome (BS). On the basis of this definition, Nijmegen breakage syndrome (NBS) and A-T–like disorder (A-TLD) must also be added to this group. More recently, case reports of patients with deficiencies of ligase I (LIG1), ligase IV (LIG4), nonhomologous end-joining (NHEJ), and RAD50 have provided evidence for the existence of a long list of diseases belonging to this group.

There is growing evidence that the following genes mutated in chromosomal instability syndromes are involved in protecting—directly or indirectly—human genome integrity by contributing to the complex regulation of double-strand break (DSB) repair: *ATM* in A-T, *NBS1* in NBS, *BLM* in BS, *MRE11* in A-TLD, *Lig1* in ligase I deficiency, *Lig4* in ligase IV deficiencies, *NHEJ1* in Cernunnos deficiency, *RAD50*, and the group of at least 13 genes known to be affected in the heterogeneous disorder of FA. Recent studies of protein–protein interactions suggest that the normal gene products associated with most of these genetic defects are in fact involved in forming or regulating a huge protein complex active in the surveillance and maintenance of genomic integrity. Results from these studies indicate that the gene products of *ATM*, *BLM*, *NBS1*, *MRE11*, and *RAD50* are all members of a complex named *BASC* (*BRCA1*-associated genome surveillance complex). They might appear as a single protein subunit or as a stable subcomplex such as nibrin, MRE11, and RAD50 (Wang et al., 2000). As described below, most of the known FA genes may be also linked indirectly or even directly to the BASC complex (Ahmad et al., 2002).

Most of these syndromes exhibit features of immunodeficiency or at least hematological symptoms resulting from a clinically relevant deficiency of cells belonging to the immune system. In this chapter, the term *immunodeficiency* is used in this broader sense. The triad of immunodeficiency, neoplasia, and infertility is typical for most of the syndromes associated with chromosomal instability. This observation can best be explained by defects in the complex system of DSB repair, affecting either NHEJ or homologous rejoining (HR). Thus tumor development in these syndromes is a direct consequence of defective DNA repair, which leads to mutations of cancer susceptibility genes acting as gatekeepers or caretakers (Duker, 2002; Kinzler and Vogelstein, 1997). Since meiotic recombination requires the production and repair of DSBs, the high incidence of infertility observed in patients with chromosomal instability syndromes is not surprising. Because the production of immunoglobulins relies on the network of proteins supporting the process of NHEJ (reviewed in van Gent et al., 2001), failure of a member of this group of proteins could lead to immunodeficiency. Thus, although primary immunodeficiency is not a typical symptom of chromosomal instability syndromes, these disorders may further our understanding of the relationship between DSB induction, DSB repair, and immunoglobulin production.

In this chapter, we will focus on three clinically defined syndromes—FA, NBS, and BS—followed by a short presentation of more recently discovered chromosomal instability syndromes that show A-T–like or NBS-like phenotypes due to specific gene mutations (*Mre11*, *Rad50*, *Lig1*, *Lig4*, *NHEJ1*). Other diseases, for example Rothmund-Thomson syndrome (MIM 268400), Werner syndrome (MIM 277700) (Table 48.1), and Riddle syndrome (MIM 611943), will either be briefly described or are beyond the scope of this text because the clinical presentation does not suggest a defect of the immune system or published data are insufficient to classify them as

Table 48.1 FEATURES OF CHROMOSOMAL INSTABILITY SYNDROMES

	A-T	A-TLD	NBS	NHEJ1	LIG4	RAD50	LIG1	BLOOM	WRNS	FA	RS-SCID

immunodeficiency diseases. Chapter 47 has been dedicated to A-T, a chromosomal instability syndrome with specific expression of immunodeficiency. Moreover, subgroups of patients with severe combined immunodeficiency (SCID) expressing radiosensitivity, and most probably also chromosomal instability, are excluded from this chapter. This subgroup of SCID is presented in greater detail in Chapter 13.

FANCONI ANEMIA

FA (MIM 227650) is an autosomal recessive chromosome instability syndrome characterized by bone marrow failure and an increased risk of neoplasia, particularly leukemia. In addition, a range of congenital abnormalities, such as growth retardation, radius aplasia, and hyperpigmentation of the skin, are observed in some patients.

The clinical presentation of FA is highly variable. As is often the case, the more severe phenotypes have been overemphasized, while one third of FA patients have no congenital anomalies (Giampietro et al., 1997; Glanz and Fraser, 1982). The generally accepted critical diagnostic criterion for FA is an increase in chromosome breakage after in vitro treatment of patient cells, usually peripheral blood lymphocytes, with bifunctional alkylating agents such as mitomycin C (MMC) (Sasaki and Tonomura, 1973).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Hematological Complications

The bone marrow of FA patients deteriorates, usually within the first decade of life, although this aspect varies considerably. Thrombocytopenia and macrocytosis, for example increased erythrocyte volume (mean cell volume > 100 fl) associated with increased fetal hemoglobin levels, are followed by granulocytopenia, leukopenia, and eventually pancytopenia. Although aplastic anemia is accompanied by recurrent infections, FA is clearly a genetic hematological disorder rather than a primary immunodeficiency. Pancytopenia, however, results in a clinically relevant deficiency of cells considered to be part of the immune system.

Acute myeloblastic leukemia occurs 15, 000 times more frequently in FA patients than in the general population. In addition, squamous cell carcinoma of the skin and gastrointestinal tract are frequent complications. The true cancer risk is difficult to estimate, since some patients die prematurely from infections or as a consequence of bone marrow transplantation; one estimate suggests that at least 15 percent of FA patients develop neoplasia (Alter, 1996).

CYTOGENETICS

The involvement of the FA gene(s) in the "metabolism and mechanics of the chromosome" was postulated by Schroeder and German (1974) on the basis of characteristic chromosome breaks observed in lymphocytes of FA patients (Fig. 48.1). These breaks are particularly chromatid breaks, and translocations involve nonhomologous chromosomes, leading to triradial and quadriradial forms. This increased somatic mutation rate in lymphocytes of FA patients is thought to explain the predisposition to acute myelogenic leukemia and other malignancies. A highly specific feature is a hypersensitivity to cross-linking agents. This phenomenon is still used as the diagnostic marker for FA when a gene mutation cannot be proven. Detailed protocols describing common cytogenetic techniques are provided by Wegner and Stumm (1999).

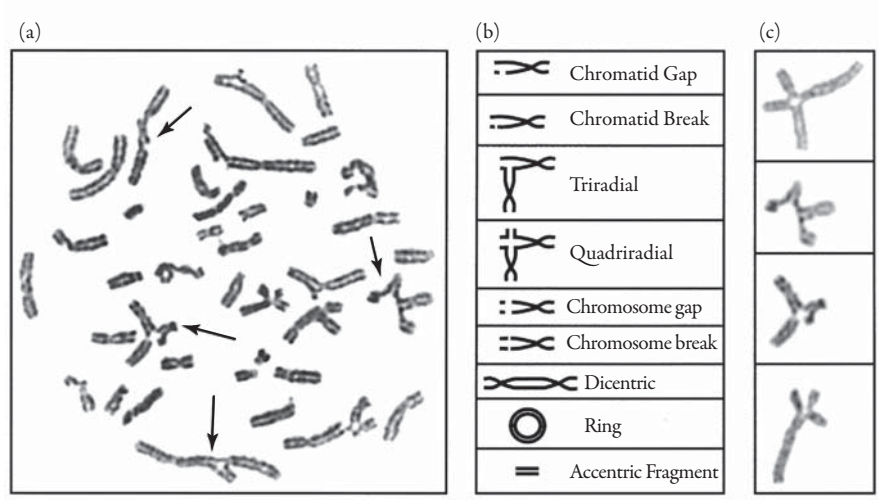

Figure 48.1 Chromosomal instability in Fanconi anemia (FA). (A) Lymphocyte chromosomes of a patient with Fanconi anemia. Only some of the chromatid breaks in this massively damaged metaphase are indicated. (B) Schematic representation of the chromosome aberrations seen in lymphocyte chromosomes from patients with chromosomal instability syndromes. (C) Examples of characteristic chromosome reunion figures seen in FA patients.

The observation that peripheral blood lymphocytes from a subgroup of FA patients apparently contain two populations of cells was first reported in 1983 by Kwee et al. Increasing doses of MMC shift one population to higher levels of chromosome damage, while a second population remains as unaffected as wild-type cells. Although chromosome breakage analysis probably does not detect low-level mosaicism due to reversion of the genomic mutation, such cases can be revealed by the isolation of MMC-resistant Epstein-Barr virus (EBV)-immortalized lymphoblasts. On the basis of this criterion, up to 25 percent of all FA patients are likely to be mosaic (Lo Ten Foe et al., 1997). In all mosaic patients analyzed, skin fibroblasts show the characteristic chromosome instability, suggesting that the reversion events leading to a wild-type cell population are specific for lymphocyte progenitors (Gregory et al., 2001;Waisfisz et al., 1999a). The high incidence of mosaics may require cytogenetic analysis of fibroblasts from patients suspected of having FA but no increased breakage in standard lymphocyte cultures.

CELL CYCLE

Analysis of the cell cycle in FA has consistently shown increased numbers of cells in G2 phase (Seyschab et al., 1993), where they are presumably arrested to repair DNA lesions. Treating FA cells with cross-linkers increases the proportion of cells in G2 and has become an alternative and/or substantiating diagnostic criterion for FA. This disturbance of the cell cycle explains the poor growth of FA cells in vitro.

Interestingly, the slow growth of FA cells and their accumulation in G2 can be normalized by keeping the cell cultures at reduced oxygen tension (Schindler and Hoehn, 1988). Even the spontaneous chromosomal breakage is lost at 5 percent O_2 (Joenje et al., 1981). These and other findings have led to the suggestion that the primary defect in FA is related to the avoidance of oxygen radicals or to the repair of the DNA lesions caused by these highly reactive molecules.

GENETICS

FA is genetically heterogeneous, and this heterogeneity can be assessed by somatic cell fusion and analysis of cross-linker sensitivity in the cell hybrids. Currently 13 complementation groups are known; these are denoted by the abbreviation *FA* followed by a letter—for example, FA-A, FA-B. FA-A is the largest group (approximately 60 percent), followed by FA-G (approximately 10 percent) and FA-C (approximately 10 percent). Identification of the underlying gene has been achieved for all of the groups, mostly by the technique of functional cloning by selecting cDNAs that enable patient cells to survive an otherwise lethal dose of MMC. The genes are denoted by the abbreviation *FANC* followed by a letter—for example, *FANCA, FANCG.* In some cases a chromosomal localization for the gene had been previously established by linkage analysis in families (Pronk et al., 1995; Saar et al., 1998; Waisfisz et al., 1999b). After the demonstration by Garcia-Higuera et al. (2001) that FANCD2 interacts with BRCA1, *BRCA2* was identified as an FA gene after analysis of FA-B and FA-D1 patients for mutations in this gene (Howlett et al., 2002). *FANCL* (Meetei et al., 2003), *FANCM* (Meetei et al., 2005), and the X-chromosomal gene *FANCB* (Meetei et al., 2004) were identified through the finding that many FA proteins interact to form a stable complex. *FANCJ* was identified by a candidate gene approach as the BRCA1 binding protein BRIP1 (Levran et al., 2005). The current status of gene identification is given in Table 48.2, together with some details of the known FA genes.

While many FA genes were novel when they were identified, some were previously known or showed significant homology to known genes. *FANCG* proved to be identical to the gene *XRCC9* (de Winter et al., 1998), which had been

Table 48.2 **FA COMPLEMENTATION GROUPS AND GENES**

FA-N	rare	yes	*FACN/ PALB2*	16p12.1	13	131

isolated through its ability to correct (or cross-complement) an X-ray–sensitive hamster cell mutant from complementation group 9 (Liu et al., 1997a). *FANCD1* is identical to *BRCA2* and *FANCJ* is a BRCA1 binding protein. *FANCM* shows homology to the archaeal *Hef* gene that has ATP-dependent helicase activities and is involved in DNA repair (Meetei et al., 2005). *FANCD2* shows homology with sequences in lower organisms, such as *Drosophila* (Timmers et al., 2001). The protein products of the *FANCD2* and *FANCI* genes are rather unusual among FA proteins, as discussed below. Other functional motifs have so far not been identified in FA proteins.

Despite repeated efforts, a correlation between complementation group and clinical features or course of the disease has not generally been possible. Patients with and without congenital abnormalities are found in all groups with sufficient numbers of patients for analysis. Leukemia seems to occur earlier in FA-G patients than in FA-A or FA-C patients (Faivre et al., 2000).

MUTATION ANALYSIS

The FA genes have been extensively analyzed for mutations. Most patients are compound heterozygotes with private mutations, but there are also founder mutations in the three largest groups, FA-A, FA-C, and FA-G. Whereas particular deletions of *FANCA* exons are common in the Afrikaner population in South Africa (Tipping et al., 2001), a nonsense mutation, E105X, accounts for 44 percent of mutant *FANCG* alleles in Germany (Demuth et al., 2000). In *FANCC,* the mutation IVS4 + 4a > t is homozygous in the majority of Ashkenazi Jewish FA patients and is associated with a particularly severe disease in terms of both congenital abnormalities and hematopoietic failure (Whitney et al., 1993). In contrast, Japanese patients with the same mutation are not severely affected (Futaki et al., 2000). This finding indicates the strong influence of genetic background on disease manifestation and explains the difficulties in establishing a genotype–phenotype correlation, even within one complementation group. On the whole, truncation mutations strongly outweigh missense mutations in the FA genes. *FANCA* in particular has many deletions due to the Alu-repeat elements in and around the gene (Levran et al., 1998). So far, no null mutations have been observed in FANCD2, and cells from all patients show residual protein that is monoubiquitinated after DNA damage. Nevertheless, FANCD2 mutation correlates with a more severe clinical course in comparison to the other groups (Kalb et al., 2007).

The biallelic mutations in the *BRCA2/FANCD1* gene found in FA-D1 patients are hypomorphic (Howlett et al., 2002). Presumably the amorphic mutations are embryonically lethal in the homozygous state, as in *Brca2* null-mutant mice (Ludwig et al., 1997).

For diagnostic purposes, the complementation group can be established by fusion of patient cells to reference cell lines or by retroviral transfer of the known FA genes, followed by examination of cross-linker sensitivity. DNA from patients assigned to a complementation group can be analyzed for mutations, and this information is then available for further diagnoses in the family, including prenatal diagnosis. The ongoing collection of clinical data and mutation analyses in Europe and the United States is facilitating attempts at a genotype–phenotype correlation (Faivre et al., 2000; Gillio et al., 1997).

FA MOSAICS

The molecular basis of reversion has been elucidated for at least six mosaic cases (Lo Ten Foe et al., 1997; Waisfisz et al., 1999a). In one case, mitotic recombination with a breakpoint within the *FANCC* gene placed both mutations on one allele and generated a heterozygous cell. In another patient, one mutation was lost in the reverted cells; retention of heterozygosity indicated that gene conversion was probably responsible for this reversion. The same mechanism was responsible

for reversion in cells of this patient's affected brother. In three additional cases, all homozygous for *FANCA* or *FANCC* mutations, reversion was due to additional de novo mutations in *cis*. Thus, a single base deletion was corrected by two further single base deletions that restored the reading frame. Similarly, a 5 bp insertion corrected the effects of an inherited single base insertion. Finally, a C>T transition corrected a missense mutation. This latter correction was found independently in two affected mosaic siblings, suggesting a specific molecular mechanism, whereas the other reversions are presumably due to random insertion or deletion events and selection.

Although reversions have been shown to occur in lymphohematopoietic stem cells and may be associated with a seemingly milder hematological disease, bone marrow failure and leukemia have been reported for several patients with revertant mosaicism (Gregory et al., 2001).

MOLECULAR BIOLOGY OF FA

The chromosome breakage observed in FA is specific for agents like MMC, which are capable of intercalating into a DNA double helix and forming covalent cross-links between the two strands. Thus the DNA lesion to which FA cells are particularly sensitive is the interstrand cross-link. The hypothesis based on this observation postulates that FA cells are deficient in the repair of DNA cross-links.

The similarity in the cellular and clinical phenotype within the complementation groups was taken as evidence for involvement of the FA proteins in a common pathway. Indeed, association of the FA proteins in multimeric complexes has been proven by immunoprecipitation studies and by yeast two-hybrid analyses (Medhurst et al., 2001). In the nucleus, most FA proteins join to form the FA core complex (Fig. 48.2) (de Winter et al., 2000; Meetei et al., 2003, 2004).

A direct link to DNA repair processes in the cell was not made until the cloning of *FANCG*, which was found to be identical to the gene mutated in UV40, a hamster cell DNA-repair mutant, and implicated in postreplicational repair (Busch et al., 1996; Liu et al., 1997a). Further and even stronger evidence for a role in DNA repair was provided by the cloning of the *FANCD2* gene and the discovery that its protein is monoubiquitinated as a response to DNA damage and relocates to discrete nuclear foci, where it associates with BRCA1 (Garcia-Higuera et al., 2001). These nuclear foci are almost certainly sites where DNA lesions (e.g., DSBs, cross-links) are being actively repaired (see also the section on NBS, below). A further FA protein, FANCI, is also monoubiquitinated by the FA core complex and colocalizes to FANCD2 nuclear foci (Smogorzewska et al., 2007). While monoubiquitination of FACNI requires monoubiquitination of FANCD2, the modification of FANCD2 is independent of FANCI monoubiquitination. FANCI is phosphorylated by ATM and/or ATR.

BRCA1 is a binding partner of BRCA2/FANCD1, and both of these are required for the recruitment of RAD51, the RecA homolog, to the sites of DSBs for error-free repair by homologous recombination and gene conversion. BRCA2/FANCD1-deficient cells have been shown to be inefficient in the formation of RAD51 foci (Yuan et al., 1999).

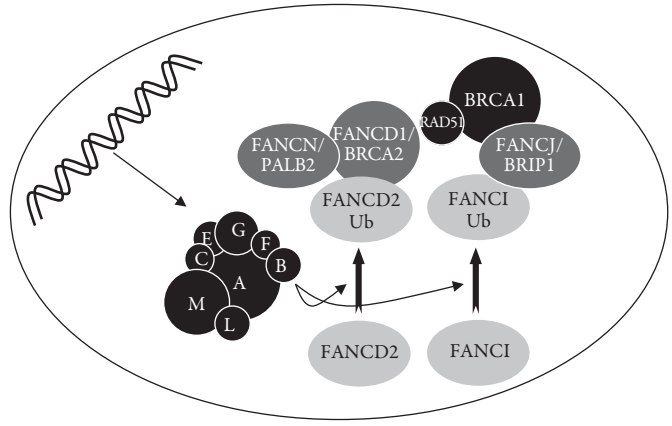

Figure 48.2 Network of FA proteins. A highly simplified schematic representation of interactions of the FA gene products. A core complex of eight of the FA proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, and FANCM) is required for monoubiquitination of further FA proteins, FANCD2 and FANCI, in response to DNA damage. Modified FANCD2 and FANCI then relocate to the sites of DNA damage, where they associate with BRCA1 and BRCA2, which is identical to FANCD1. Other proteins, FANCN and FACNJ, are not involved in the modification of FANCD2 and FANCI. BRCA1 and BRCA2 bind the important effector of homologous recombination, RAD51.

This finding correlates with a loss of repair by gene conversion, an increase in repair by alternative error-prone pathways, and extreme cross-linker–induced chromosomal instability (Tutt et al., 2001). The finding that the FA protein complex of FANCA, FANCB, FANCC, FANCG, FANCE, FANCF, and FANCL is required for modification of the FANCD2 protein (Fig. 48.2) has linked these proteins nicely into the same pathway (Garcia-Higuera et al., 2001; Meetei et al., 2003, 2004; Pace et al., 2002). The finding that RAD51 foci formation is reduced in FA cells from all complementation groups suggests that monoubiquitinated FANCD2, like BRCA1 and BRCA2/FANCD1, is involved in RAD51-mediated DNA repair (Digweed et al., 2002b). Furthermore, FANCD2 has been shown to interact directly with BRCA2/FANCD1 (Hussain et al., 2004). Figure 48.2 shows a model for these protein interactions.

The reliance on error-prone DNA repair pathways in the other FA complementation groups may lead to the characteristic chromosomal instability of FA and be a direct result of the inability to monoubiquitinate FANCD2 and FANCDI and efficiently recruit RAD51 for repair by gene conversion. Convincing data have been presented showing reduced homologous recombination in chicken DT40 cells mutated in *FANCG* (Yamamoto et al., 2003) and *FANCC* (Niedzwiedz et al., 2004). Similarly, using sophisticated plasmid reporters, defects in homologous recombination have been demonstrated in human and mouse cells with mutations in *FANCA*, *FANCD2*, and *FANCG* (Nakanishi et al., 2005; Yang et al., 2005). In contrast to previous studies, in mutant mouse and human cells the error-prone repair pathway of single-strand annealing (SSA) was also affected, suggesting further roles for the monoubiquitinated FANCD2 protein. It is possible, even likely, that the individual FA proteins are involved in

further interactions and that these may influence their activity in monoubiquitination of FANCD2. Thus, the demonstrated oxygen sensitivity and cell-cycle disturbance described in FA cells have yet to be incorporated logically into the FA pathway or, perhaps more appropriately, into the FA network. Interestingly, a functional link between FANCD2 and the NBS1/MRE11/RAD50 pathway has been indicated by several reports (Digweed et al., 2002a; Nakanishi et al., 2002; Pichierri et al., 2002). Upon replicative stress, FANCD2 localizes to discrete spots on mitotic chromosomes, indicating that the FA pathway is involved in the repair or rescue of damaged cells in anaphase and telophase of mitosis (Naim and Rosselli, 2009).

ANIMAL MODELS

Knockout mice for the *Fanca*, *Fancc*, and *Fancg* genes have been produced but show few of the disease symptoms observed in patients (Cheng et al., 2000; Whitney et al., 1996; Yang et al., 2001). They do not have skeletal malformations, nor, surprisingly, do they show anemia or increased neoplasia. Although cells from these animals show the characteristic chromosomal breakage and cross-linker sensitivity, the animals are hematologically healthy unless treated with cross-linkers, in which case they suffer bone marrow failure. The only feature that is similar to the human clinical phenotype is reduced fertility. Perhaps not surprisingly, double-knockout *Fanca/Fancc* mice are not more severely affected than the single-knockout animals, indicating that these genes probably do not have further functions over and above those of the protein core complex (Noll et al., 2002).

Spontaneous defective hematopoiesis has been reported in double-knockout mice, with disruptions in both *Fancc* and the Cu/Zn superoxide dismutase genes (Hadjur et al., 2001). These results provide evidence that abnormal regulation of the cellular redox state in FA may be involved in the bone marrow failure of patients. Increased tumorigenesis was reported for a *Fancc/p53* double-knockout mouse with a spectrum of malignancies similar to those of FA patients (Freie et al., 2003). Increased frequencies of epithelial tumors were reported for the *Fancd2* knockout mouse, suggesting perhaps a phenotypic overlap with hypomorphic *Brca2/Fancd1* mice (Houghtaling et al., 2003).

TREATMENT AND PROGNOSIS

Several treatment possibilities are available for patients with FA. Erythrocyte and thrombocyte transfusions can compensate for bone marrow failure, although hemosiderosis is a concern. The bone marrow abnormalities of many patients respond to androgen and cytokine therapy, even if only temporarily. Allogeneic bone marrow transplantation from a histocompatible sibling can cure the bone marrow failure. Transplantations from matched unrelated donors have had poor outcomes in FA (MacMillan et al., 2000). Bone marrow transplantation is complicated by the increased sensitivity of FA patients to pretransplant conditioning treatment. However, new cytoreductive regimens, particularly those including fludarabine, and the use of T-cell depletion, are encouraging (Kapelushnik et al., 1997; MacMillan and Wagner, 2010; McCloy et al., 2001; Stepensky et al., 2011; Thakar et al., 2011) and have improved outcome regardless of donor source. The occurrence of expanding clonal aberrations in bone marrow, particularly those involving chromosome 3q, has been shown to correlate with a poor prognosis (Tönnies et al., 2003).

The relative accessibility of hematopoietic stem cells made FA an obvious candidate disorder for gene therapy (reviewed by Tolar et all., 2012), and the first trials were conducted in 1997 (Liu et al., 1997b, 1999). The expectation was that corrected stem cells would have a strong selective advantage in the hypoplastic bone marrow of FA patients, as suggested by the finding of mosaic patients in whom total hematopoiesis is driven by a reverted clone. Gene transfer experiments with the knockout *Fancc* mouse have shown that positive selection can indeed be achieved (Gush et al., 2000). Currently the main obstacle to the development of gene therapy in FA is the poor efficiency of gene transfer into hematopoietic stem cells. A promising new approach to gene therapy in FA may be the correction of hematopoietic stem cells generated from patient-derived induced pluripotent stem cells (Raya et al., 2009).

FUTURE DIRECTIONS

The cloning of most of the FA genes and the final demonstration of a link to DNA repair have changed the course of current FA research. It is realistic to expect that much more detailed information on this novel network for DNA repair will be forthcoming. The availability of mouse models will enable the evaluation of treatment proposals including gene therapy, when gene transfer methodology is advanced enough to make this an alternative therapy for FA patients. In the meantime, the considerable improvement in bone marrow transplantation from unrelated donors must be extrapolated to the treatment of FA patients, and new therapies for the treatment of squamous cell carcinoma in FA patients have to be developed. The finding that modification of the FANCD2 protein does not occur in cells from most FA patients after DNA damage may be exploited in the future as a biochemical assay for diagnosis of the disease. Finally, the role of FA genes in the occurrence of malignancy in the general population will have to be addressed, in view of reports that indicate a role for *FANCF* silencing in acute myeloid leukemia (Tischkowitz et al., 2003) and cervical cancer (Narayan et al., 2004).

NIJMEGEN BREAKAGE SYNDROME

NBS (MIM 251260), a rare autosomal recessive disorder belonging to the group of chromosomal instability syndromes, was first described by a group of investigators at the University of Nijmegen (Hustinx et al., 1979) and has been recently reviewed in great detail (Chrzanowska et al., 2012). The clinical hallmarks of NBS patients are severe microcephaly, growth retardation, typical facial appearance, combined immunodeficiency, radiosensitivity, and an increased cancer risk. On the cellular level, the NBS abnormalities are closely related

to those observed in A-T patients. Cells of both syndromes reveal chromosomal instability, a marked sensitivity to ionizing irradiation (IR) and radiomimetic agents, a radioresistant DNA synthesis (RDS), and additional defects in cellular checkpoint control. On the molecular genetic level, however, both syndromes are clearly distinguishable from each other. Whereas A-T is caused by mutations in the *ATM* gene located on chromosome 11q23 (Savitsky et al., 1995), NBS is caused by mutations in the *NBS1* gene localized on chromosome 8q21 (Varon et al., 1998). The *NBS1* gene product, nibrin, is part of the hRAD50/hMRE11/nibrin complex (Carney et al., 1998), which seems to function in concert with ATM in a damage-response pathway that affects a DNA repair process as well as cell-cycle checkpoint control (Girard et al., 2000).

DEMOGRAPHICS

Whereas in the first edition of this text the number of diagnosed NBS patients amounted to 58, this figure increased to approximately 170 patients at the end of 2004. Detailed clinical data on 55 patients collected in the NBS Registry in Nijmegen are included in the report of an international study group (International Nijmegen Breakage Syndrome Study Group, 2000). While single NBS patients were reported from North America (Bakhshi et al., 2003; Cerosaletti et al., 1998), Chile (Pincheira et al., 1998), Bosnia (Kleier et al., 2000), Argentina (Rosenzweig et al., 2001), Morocco (Maraschio et al., 2001), Turkey (Tekin et al., 2002), Yugoslavia (Pasic, 2002), and Italy (Barth et al., 2003), the majority of NBS patients known thus far are of Slavic origin (particularly of Polish and Czech descent, with 83 and 35 patients identified to date, respectively, and of Russian descent [Resnick et al., 2002]) and carry a common founder mutation 657del5 in exon 6 of the *NBS1* gene (Varon et al., 1998, 2000). The prevalence of this founder mutation was estimated by Varon et al. (2000) in the Czech Republic, Poland, and the Ukraine by the screening of Guthrie cards. A mean prevalence of 1:177 for NBS heterozygotes was found in these three populations. The highest prevalence was found in the Czech population (1:154), followed by the Ukraine (1:182) and Poland (1:198). However, marked regional differences were observed in Poland, ranging from 1:90 to 1:314. Further studies performed recently on populations of three large regions in Poland established a mean prevalence of 1:166 for the 657del5 mutation in Poland (Cybulski et al., 2004; Steffen et al., 2004; M. Mosor, personal communication). All of these frequencies were much higher than the prevalence of 1:866 reported for the same mutation in Germany (Carlomagno et al., 1999). On the basis of these data, the prevalence for NBS homozygotes in the Czech Republic can be estimated at 1 per 95,000. Interestingly, the actual frequency of 1 per 271,000 is much lower than expected. The most likely explanation for this discrepancy is the underdiagnosis of NBS patients because of the rarity of NBS and its relatively mild phenotype. This assumption is corroborated by two observations: (1) the late diagnosis of many NBS patients, often in cases where a malignancy requires examinations that finally disclose the presence of NBS, and (2) detection of 3 new NBS patients in a cohort of 23 Czech patients with primary microcephaly tested for the major Czech mutation, the 657del5, in the *NBS1* gene (Seeman et al., 2004). This underdiagnosis is likely a general problem worldwide; thus, more attention should be spent on the correct diagnosis of this disease.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Since the first reports on two siblings from Nijmegen (Hustinx et al., 1979; Weemaes et al., 1981), NBS has been recognized as a multisystem disorder similar to A-T. The main clinical manifestations (Table 48.3) indicate that various tissues and organs are affected, including brain, skin, blood, and gonads.

Growth and Development

Microcephaly, the most striking symptom of the disorder, has been observed in the great majority of children at birth (van der Burgt et al., 1996). Those who are born with a normal head circumference (OFC) will develop progressive and severe microcephaly during the first months of life. The primary cause of small head size in NBS patients is the genetically determined stunted growth of the brain (see Pathological Findings, below). Thus, the observed premature closing of the sutures and fontanels can be considered a developmental consequence (no increased intracranial pressure was noted, except in the two cases with coexisting hydrocephalus). Among the observed Polish patients, the decrease in OFC ranged from −9.0 SDs to −4.4 SDs, whereas the proportions among the diminished head measurements (i.e., length and breadth) were retained. Only one case with a normal OFC has been described (Chrzanowska et al., 2001). Growth retardation may occur prenatally in some NBS patients, but in most cases birth weight and length correlate to gestational age. After an initial period of distinct growth retardation lasting from birth to about the second year of life, a slight improvement of growth rate (body height and weight, but not head circumference) is usually observed. Most affected individuals show growth below or around the third percentile, whereas a few

Table 48.3 **CLINICAL FEATURES OF NIJMEGEN BREAKAGE SYNDROME**

Normal or borderline in early childhood
Progressive deficiency of IQ scores in later life

patients achieve a height around the 10th or even 25th percentile (Chrzanowska et al., 2001; International Nijmegen Breakage Syndrome Study Group, 2000). Intestinal malabsorption, cardiac defects, or hormonal abnormalities related to thyroid or pituitary gland functions have all been excluded as a cause of the growth retardation.

Sexual maturation. Longitudinal studies of growth and development of Polish NBS patients, of whom three females and six males reached puberty, drew attention to the lack of development of secondary sexual characteristics in teenage girls. They presented with primary amenorrhea, absent breast development, and scanty pubic or axillary hair. In two of the three girls, all older than 18 years, repeated pelvic ultrasonography revealed small ovaries, resembling streak gonads, and infantile uteri. All three had markedly elevated plasma concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) and very low estradiol levels, indicating primary ovarian failure (Chrzanowska et al., 1996). A study of the pituitary-gonadal axis performed on a large group of Polish patients, including 25 females, confirmed the preliminary findings predicting a very high incidence of ovarian failure in this syndrome. Markedly elevated plasma concentrations of FSH, in relation to age, and very low estradiol levels (hypergonadotropic hypogonadism) were found in all but one of the tested females. Serum FSH concentrations exceeding 30 IU/L, a value indicative of ovarian failure, were documented in the majority (76 percent of those tested), both at pubertal and prepubertal ages (Chrzanowska, 1999; Chrzanowska et al., 2000). Single cases of hypergonadotropic hypogonadism had been reported earlier, including a 21-year-old woman with NBS phenotype (Conley at al., 1986) and a now 30-year-old woman described earlier (Wegner et al., 1988) who subsequently developed primary amenorrhea. In males there was only a slight delay in onset of puberty, and the levels of gonadotropins and testosterone corresponded to Tanner's classification of sexual maturity stages (Chrzanowska, 1999). Offspring from affected subjects have never been reported, and firm conclusions on fertility are hampered by the young age of the patients and their short lifespan. Thus, hypergonadotropic hypogonadism in females, indicative of either ovarian dysgenesis or hypoplasia, must be included in the clinical spectrum of NBS.

Psychomotor development and behavior. In general, developmental milestones are reached at expected times during the first years of life. Patients with normal intelligence (Barbi et al., 1991; Green et al., 1995; Seemanová et al., 1985; Wegner et al., 1988) or mental retardation of variable degree (Chrzanowska et al., 1995a; Conley et al., 1986; Stoppa-Lyonnet et al., 1992; Weemaes et al., 1981) have been reported. Follow-up studies of Polish patients showed that the level of intellectual function decreases with age. Most of the children tested in infancy and early childhood had IQ scores indicating a normal or borderline intelligence with striking psychomotor hyperactivity. When tested or retested after the age of 7, difficulties in concentration became more pronounced. At school age, lower levels of intellectual function were observed and became more evident in subjects over 14 years of age, when all tested patients were mildly or moderately delayed (Chrzanowska, 1999). Most of the mentally retarded patients need educational support and should attend special education classes or schools. All of the children have a gentle and cheerful personality and, despite being shy, are usually capable of good social interactions.

Craniofacial manifestations. The craniofacial characteristics become more obvious with age because of the severe and progressive microcephaly. The facial appearance is very similar among NBS patients and is characterized by a sloping forehead and receding mandible, prominent midface with a relatively long nose (slightly beaked in most patients or upturned in some), and upward slanting of palpebral fissures (Fig. 48.3). In some individuals the ears seem to be relatively large and dysplastic.

Other Manifestations

Central nervous system malformations. Developmental abnormalities of the brain are relatively frequent and appear to be more common than expected. Partial agenesis of the corpus callosum was documented in one third (6/18) of Polish patients who underwent cranial magnetic resonance imaging (MRI) (Bekiesinska-Figatowska et al., 2000, 2004; Chrzanowska et al., 2001) as well as in at least two others (Maraschio et al., 2001; Resnick et al., 2002). Agenesis of the corpus callosum was associated developmentally with colpocephaly (i.e., disproportionate enlargement of the trigones, occipital horns, and usually temporal horns of the lateral ventricles). Large collections of cerebrospinal fluid (arachnoid cysts) in the parieto-occipital and/or occipitotemporal regions were found in three patients (Bekiesinska-Figatowska et al., 2000; Chrzanowska et al., 2001; Stoppa-Lyonnet et al., 1992). The cysts resulted from an anomalous splitting of the arachnoid membrane and are a congenital anomaly of the developing subarachnoid system. Both defects, callosal hypoplasia and arachnoid cysts, may frequently be underdiagnosed in NBS patients because they are asymptomatic. Hydrocephalus was reported in several patients, including one pair of siblings (Bekiesinska-Figatowska et al., 2000; Muschke et al., 2004; Taalman et al., 1989). Neuronal migration disorder in the form of schizencephaly and focal pachygyria has been diagnosed each in a single patient (Bekiesiriska-Figatowska et al., 2000; Der Kaloustian et al., 1996).

Skin and vascular anomalies. Skin pigmentation abnormalities expressed as café-au-lait–like spots (rather irregular in shape) and/or depigmented spots can be seen in most patients; in three Polish patients, progressive vitiligo was observed at adolescence. Sun sensitivity of the eyelids is less frequent. Multiple pigmented nevi and cavernous or flat hemangiomas occur in a proportion of patients (Chrzanowska, 1999; International Nijmegen Breakage Syndrome Study Group, 2000; Peréz-Vera et al., 1997).

Skeletal anomalies. Minor skeletal defects such as clinodactyly of the fifth fingers and/or partial syndactyly of the second and third toes are encountered in about half of the patients (International Nijmegen Breakage Syndrome Study Group, 2000); less common is hip dysplasia (~15 percent) (Chrzanowska, 1999, and unpublished observation). Uni- or bilateral preaxial polydactyly was observed in four patients (Chrzanowska et al., 1995a; Maraschio et al., 2001), and

Figure 48.3 Characteristic facial features of a 7-year-old male patient with Nijmegen breakage syndrome (upper row) and his 5-year-old sister. Note microcephaly, microgenia, sloping forehead, slightly upward slanting of palpebral fissures, and prominent midface.

sacral agenesis was found in one (K. Chrzanowska, unpublished observation).

Urogenital, anal, and miscellaneous malformations. Anal atresia or stenosis was noted in several cases (Chrzanowska, 1999; Tekin et al., 2002; Wegner et al., 1988). Among the urogenital anomalies, ectopic single kidney or dystopic kidneys were diagnosed in eight patients (Chrzanowska, 1999; International Nijmegen Breakage Syndrome Study Group, 2000; Muschke et al., 2004) and hydronephrosis in three additional patients (Seemanová et al., 1985; Taalman et al., 1989). Congenital cardiovascular or heart defects were noted in two cases (Chrzanowska et al., 2001; Tekin et al., 2002). Hypospadias (Der Kaloustian et al., 1996), cryptorchism (Pincheira et al., 1998), and genitourinary fistula (Chrzanowska, 1999) were observed each in only a single patient, as were other miscellaneous congenital anomalies such as cleft lip/palate (Seemanová et al., 1985), choanal atresia (Seemanová et al., 1985), and tracheal hypoplasia (Chrzanowska, 1999). Ultrasonographic evaluation of a large group of Polish patients revealed a high frequency of polysplenia (20 percent), a peculiarity with no clinical significance (Chrzanowska, 1999).

Infections and Autoimmune Disorders

As in A-T (see Chapter 47), the extent of immunodeficiency or proneness to infection in NBS patients showed striking intra- and interfamilial variability. Respiratory tract infections were present in most children. Recurrent pneumonia and bronchitis may result in bronchiectasis, respiratory insufficiency, and premature death from respiratory failure (Seemanová et al., 1985; Weemaes et al., 1981). Meningitis, sinusitis, and otitis media with draining ears and mastoiditis were observed in some children, as were gastrointestinal infections with diarrhea and urinary tract infections. Opportunistic infections are very rare, as in A-T (International Nijmegen Breakage

Syndrome Study Group, 2000). Other diseases, probably caused by a defective immune system, have been observed in single cases: autoimmune hemolytic anemia, hemolytic anemia followed by thrombocytopenia, childhood sarcoidosis with ocular and cutaneous manifestations (Chrzanowska, 1999), and a juvenile rheumatoid arthritis-like polyarthritis (Rosenzweig et al., 2001). In two unrelated Polish patients, coexistence of NBS and Gilbert syndrome (familial idiopathic unconjugated hyperbilirubinemia associated with a partial reduction of hepatic glucuronyl transferase activity) has been noted (Chrzanowska, 1999).

Predisposition to Malignancies

Both the immunodeficiency and the chromosome instability may predispose NBS patients to tumor development at an early age. In A-T, approximately 10 to 15 percent of the homozygotes develop malignancy in early adulthood (Taylor et al., 1996). The rate is even higher in NBS. Cancer before the age of 21 years was noted in 40 percent (22/55) of the patients included in the NBS Registry in Nijmegen (International Nijmegen Breakage Syndrome Study Group, 2000). Updates from the two largest national NBS registries, the Polish registry (K. Chrzanowska, unpublished data) and the Czech registry (Seemanová et al., reported at the International Workshop on NBS, Prague, Czech Republic, 2002), indicated cancer development in 54 percent (45/83) and 65 percent (19/29) of patients, respectively. The great majority of malignancies were of lymphoid origin, found in 41 and 15 patients, respectively. In the Polish series, the most frequent malignancies were non-Hodgkin's lymphomas (NHL) in 30 patients (those of B-cell origin slightly exceeded those of T-cell origin), followed by lymphoblastic leukemia/lymphoma in 8 patients (T-LBL/ALL, T-ALL, pre-B-ALL) and Hodgkin's disease in 3 patients (Gladkowska-Dura et al., 2000). Acute myeloblastic leukemia (AML) has been diagnosed in two NBS patients (Resnick et al., 2002; K. Chrzanowska, unpublished observation). In a recent report from the Polish NBS Registry, 56 of 105 patients enrolled as of October 2007 had developed primary malignancies (53 percent), including 51 cases of lymphoma. Over half of those were classified as diffuse large B-cell lymphoma (DLBCL), followed by lymphoblastic T-cell lymphoma (T-LBL) and rarely Burkitt's and classic Hodgkin's lymphoma (Gladkowska-Dura et al., 2008).The first case of T-cell prolymphocytic leukemia (T-PLL) in NBS was reported by Michallet et al. in 2003.

Several patients are known to have developed a second malignancy. One German patient (Rischewski et al., 2000) and four Polish patients had two consecutive lymphomas of the same type, with complete remission of 5 to 7 years in between (Gladkowska-Dura et al., 2000, 2008). Two additional Polish patients developed a different type of lymphoma as a second event: in one case, the initial Burkitt-like lymphoma was followed by a DLBCL, and in the other case, a peripheral T-cell lymphoma developed 3 years after the DLBCL (Gladkowska-Dura et al., 2008). Two other patients (Dutch and Czech) developed a different type of tumor after 10 and 4 years of remission, respectively (Weemaes et al., 2002). One Polish patient was recently diagnosed to have a third consecutive lymphoma of the same type (time interval between the two relapses, 7 and 6 years, respectively; Gladkowska-Dura et al., 2005). Both concordance of tumor type in a pair of NBS siblings (Wegner, 1991) and discordance in another pair (Wegner et al., 1999) have been reported.

Solid tumors have been less frequently noted, probably because the tumors usually develop at an older age. Five patients have developed a medulloblastoma (Chrzanowska et al., 1997; Bakhshi et al., 2003; Distel et al., 2003; E. Seemanová, personal communication; F. Tzortzatou-Stathopoulou, personal communication) and two a rhabdomyosarcoma (Der Kaloustian et al., 1996; Tekin et al., 2002). Other tumors are represented only in single cases and include malignant meningioma, gonadoblastoma, Ewing sarcoma (E. Seemanova, personal communication), and ganglioneuroblastoma (K. Chrzanowska, unpublished observation).

At least three patients who had medulloblastoma and received radiation therapy before being diagnosed with NBS were fatally injured and eventually died from complications of the therapy (Bakhshi et al., 2003; Chrzanowska et al., 1997; Distel et al., 2003). Alopecia was a side effect observed in a Polish patient with AML given an 18-Gy dose of cranial irradiation for central nervous system (CNS) prophylaxis. However, another Polish patient with T-cell acute lymphoblastic leukemia (T-ALL) tolerated well an identical dose of prophylactic cranial irradiation. Both patients were treated for malignancy before the diagnosis of NBS was established (K. Chrzanowska, unpublished observation).

Most malignancies develop before the age of 20 years (median age, 9 years; range, 1–34 years), and in about 20 to 30 percent of patients cancer appears prior to the diagnosis of NBS (Varon et al., 2000). On the basis of available records, an approximately 50-fold risk of early onset of cancer and a more than 1,000-fold risk of lymphoma are estimated for patients with NBS.

The precise mechanisms leading to the increased cancer prevalence in NBS remain unclear. Thus it is an open question as to whether the *NBS1* gene has a general function as a tumor-suppressor gene. Molecular investigation of the frequency of the most common *NBS1* mutation, 657del5, in two NHL cohorts with 109 and 62 German children, respectively, failed to detect this mutation in the *NBS1* gene (Rischewski et al., 2000; Stanulla et al., 2000). Furthermore, a fluorescence in situ hybridization (FISH) analysis of tumor samples from 16 German NHL patients detected no deletions of the *NBS1* gene (Stumm et al., 2001b). Sequencing studies on 20 Japanese lymphomas (Hama et al., 2000) and tumor samples from 91 NHL patients in the United States (Cerosaletti et al., 2002) provided no evidence that *NBS1* mutations play a major role in the development of NHL. These studies demonstrate that neither a NBS heterozygote status nor mutations or deletions of the *NBS1* gene in the tumor itself are frequent events in patients with B- and T-cell lymphomas. However, a Polish study of 456 children with lymphoid malignancies (208 with NHL and 248 with ALL) revealed five heterozygous carriers of a germline 657del5 mutation, in contrast to the expected incidence of 2.75 (Chrzanowska et al., 2004). This study has

been expanded, showing similar results and suggesting that *NBS1* gene heterozygosity is not a major factor in lymphoid malignancies in childhood and adolescence (Chrzanowska et al., 2006).

In contrast to NHL, Varon et al. (2001) detected mutations in *NBS1* in 15 percent of cases of childhood ALL, whereas none was observed in controls, a finding indicating a possible involvement of the *NBS1* gene in the development of ALL. There is evidence that heterozygotes for NBS also show a significantly increased rate of malignancies (Seemanová et al., 1990). Recently performed studies on 1,683 nonselected Polish patients with malignant tumors detected increased germline mutation frequencies for the 657del5 mutation and increased frequencies for the R215W amino acid exchange variant, indicating that heterozygous carriers of NBS mutations may indeed have an increased risk of developing tumors, especially in breast cancer and melanoma (Steffen et al., 2004). These data have been corroborated by increased translocation frequencies in NBS heterozygotes (Stumm et al., 2001a; see Cytogenetics, below). More recently Shimada et al. (2004) reported the first case of aplastic anemia with a homozygous missense mutation in the *NBS1* gene (I171V) and hypothesized that the *NBS1* gene may play an important role in the pathogenesis of this complication. A major analysis of cancer occurrence in NBS families has recently unequivocally demonstrated an increased cancer risk for heterozygotes with the Slavic mutation (Seemanova et al., 2007).

PATHOLOGICAL FINDINGS

Of more than 70 NBS patients whose deaths have been ascertained, less than 10 died from infections that led to fatal respiratory failure, and two from renal insufficiency due to amyloidosis. Two others died as a result of bone marrow aplasia (Resnick et al., 2002), a hallmark of another chromosomal instability syndrome, FA. All remaining patients died from malignancies. The oldest survivors with the Slavic 657del 5 mutation were a 33-year-old Polish patient and a 31-year-old Dutch patient, both men. A patient with a homozygous dinucleotide insertion in exon 7 was alive at 55 years of age without having developed a malignancy (Maraschio et al., 1986; Varon et al., 2006). The mutation in this patient leads to an alternatively spliced mRNA and a truncated protein product with an internal deletion that, presumably, upholds the functions of the full-length protein (Varon et al., 2006).

Autopsies performed on several NBS patients showed a brain weight that was more than 50 percent reduced in all patients examined and internal hydrocephalus in some (Muschke et al., 2004; Seemanová et al., 1985; van de Kaa et al., 1994). A clear neuropathological difference from A-T has been demonstrated in NBS with a cerebellum of normal size and development (van de Kaa et al., 1994).

A simplified gyral pattern, especially in the frontal lobes, with a severely diminished number of neocortical neurons has been documented (Lammens et al., 2003). Marked hypoplasia or absence of the thymus, or thymus replacement by fibrous tissues was reported in several cases (Muschke et al., 2004; Seemanová et al., 1985; van de Kaa et al., 1994).

Suspicion of a lymphoproliferative disorder is the most frequent indication for lymph node biopsy, but only a few reports have appeared on the histological and immunophenotypic features of lymphomas (Elenitoba-Johnson and Jaffe, 1997; Paulli et al., 2000; van de Kaa et al., 1994). A detailed description of 10 cases of NHL and 1 of Hodgkin's disease revealed morphological and immunotypic diversity of these NBS-linked lymphomas, ranging from immature, precursor-type lymphoid malignancies to mature T-cell lymphomas to immunoglobulin-producing, diffuse large B-cell lymphomas (DLBCL), a spectrum that appears to be more characteristic for adult rather than pediatric patients (Gladkowska-Dura et al., 2000, 2002, 2008). Further immunophenotypic and rearrangement studies have revealed clonal *IgH* gene rearrangements in all but one DLBCL case, clonal *IgK* gene rearrangements in all cases, and *IgL* gene rearrangements in two (Gladkowska-Dura et al., 2002, 2008). None of the cases showed a Bcl-2/IgH translocation.

LABORATORY FINDINGS

Laboratory tests helpful in the diagnosis of NBS include evaluation of humoral and cellular immunity, quantitation of serum α-fetoprotein (AFP) levels, karyotyping, and radiosensitivity assays. Molecular analysis is possible in most cases (see Genetics, below).

Immunological Data

The immune deficiency in NBS patients is very heterogenic and affects the humoral and cellular immune systems (Table 48.4). A longitudinal follow-up study of 40 NBS patients, diagnosed and monitored at a single medical center, the Children's Memorial Health Institute (CMHI) in Warsaw, offered a unique opportunity to gather clinical and laboratory data on a large series of patients (Gregorek et al., 2002). This study extends and supplements data collected earlier to assess the immune system in individuals with NBS (Chrzanowska et al., 1995b; International Nijmegen Breakage Syndrome Study Group, 2000).

Table 48.4 **IMMUNE DEFECTS IN PATIENTS WITH ATAXIA-TELANGIECTASIA VARIANT OR NIJMEGEN BREAKAGE SYNDROME**

Lymphopenia, T and B cells
Humoral immunity
Absent or low serum levels of IgA, IgG, IgM, or IgE
Abnormal IgG subclass distribution (deficient in IgG2, IgG4)
Cellular immunity
Low numbers of CD4+ subset
Decreased CD4+/CD8+ ratio
High number of NK cells
Impaired proliferative response to mitogens in vitro

The most important observation is the considerable variability in immunodeficiency seen among different patients and in the same individual over the course of time (Gregorek et al., 2002). At diagnosis, severe hypogammaglobulinemia with IgG concentrations below 2.0 g/L, low or undetectable IgA, and decreased IgM was observed in 21 percent of patients, while an additional 20 percent had normal concentrations of all three major immunoglobulin classes. The most common finding was a combined deficit of IgG and IgA (31 percent), followed by isolated IgG deficiency (28 percent). IgG subclass distribution was abnormal in most patients, affecting predominantly IgG4 (74 percent), followed by IgG2 (66 percent) and IgG1 (63 percent). In about 37 percent of NBS patients, normal levels of total serum IgG can mask deficiency of IgG subclasses. This phenomenon points to the importance of determining IgG subclasses, especially in NBS patients who suffer from frequent infections. The concentrations of IgM and IgG3 are rarely affected; in fact, IgM levels may be elevated (Chrzanowska et al., 1995b; Gregorek et al., 2002; Wegner et al., 1988). These observations suggest that the process of class switching to C_H genes downstream of γ3 (γ1, α1, γ2, γ4, ε, and α2) is frequently blocked in NBS. Recently, Pan et al. (2002) provided the first evidence linking ATM and nibrin to class-switch recombination (CSR). Lahdesmaki et al. (2004) have suggested that MRE11, nibrin, and ATM might play both common and independent roles in CSR.

Similar to A-T patients, both normal (Der Kaloustian et al., 1996; Green et al., 1995) and disturbed (Weemaes et al., 1991; Wegner et al., 1988) antibody responses to diphtheria and tetanus vaccination have been reported. One NBS patient failed to mount a primary antibody response to *Helix pomatia* hemocyanin (Weemaes et al., 1991). Naturally acquired IgG-specific antibodies to most invasive pneumococcal polysaccharides (e.g., serotypes 3, 19, 23) were not detectable or were found in very low titers in 75 percent of patients investigated at CMHI. Moreover, only 25 percent of patients vaccinated against hepatitis B virus developed antibodies to hepatitis B surface antigen of the protective IgG isotype, which are restricted to two IgG subclasses: IgG1 (present in all positive samples) and IgG3 (found in one patient only). In 65 percent of the individuals, only IgM antibodies to hepatitis B surface antigens were found; in the remaining 10 percent, no specific antibodies were detectable, despite normal or only moderately decreased levels of total IgG (Gregorek et al., 2002). Systematic longitudinal observations of 17 available NBS patients at CMHI showed a progressive deterioration of the immune system in 9 of 17 patients (53 percent). There was no correlation between immunodeficiency profile (or its severity) and duration of the disease or the age or gender of the patients studied.

T-cell immunity is abnormal in most tested patients. The most consistent defects are reduced numbers of $CD3^+$ T cells observed in 93 percent, a reduced number of $CD4^+$ T cells in 95 percent, and a reduction in $CD8^+$ T cells in 80 percent. A decreased CD4/CD8 ratio is also a characteristic feature of this syndrome (Chrzanowska et al., 1995b; International Nijmegen Breakage Syndrome Study Group, 2000; van der Burgt et al., 1996). The number of B cells is reduced in most patients (≈75 percent) but may also be normal or even elevated in some patients despite marked deficiency of serum immunoglobulins, suggesting an intrinsic B-cell defect affecting CSR (Gregorek et al., 2002). Detailed characteristics of natural killer (NK) and T-lymphocyte surface receptors have been reported in a large group (n = 42) of NBS patients (Michalkiewicz et al., 2003).

A deficiency of $CD4^+$, $CD45RA^+$ (naïve) cells and an excess of $CD4^+$, $CD45RO^+$ (memory) T cells has been observed in all patients tested (Chrzanowska et al., 1995b). A relatively high number of NK cells was noted in the majority of NBS patients (Der Kaloustian et al., 1996; Green et al., 1995). In vitro lymphocyte proliferation in response to mitogens is defective in most patients (Conley et al., 1986; Chrzanowska et al., 1995b; Der Kaloustian et al., 1986; International Nijmegen Breakage Syndrome Study Group, 2000; Seemanová et al., 1985; Weemaes et al., 1981; Wegner et al., 1988). In one case lymphocyte proliferation in the presence of specific antigens (tetanus, tuberculin, candidin) was absent despite a normal response to PHA (Stoppa-Lyonnet et al., 1992). Recall antigens (Merieux) given intradermally produced no delayed-type hypersensitivity reactions (Wegner et al., 1988).

α-Fetoprotein Level

Serum AFP concentration is within the normal range in NBS (van der Burgt et al., 1996), in contrast to A-T, where elevated levels are found in more than 90 percent of patients (Woods and Taylor, 1992).

Cytogenetics

In most cases, the diagnosis of NBS is entertained on clinical findings and confirmed by cytogenetic and/or molecular analysis of the *NBS1* gene. T lymphocytes of NBS patients often show a poor response to mitogens; consequently, cultures exhibit a low mitotic index. This limitation to cytogenetic characterization of patient's cells, particularly when testing for mutagenic sensitivity, can be overcome in most cases by using EBV-transformed lymphoblastoid cell lines.

NBS cells express the typical cytogenetic features of a chromosomal instability syndrome (Table 48.5). In general, NBS patients have a normal karyotype, but chromosomal instability, as in A-T patients, is a consistent finding. One of the most striking features of NBS is the high level of chromosome rearrangements in cultured T lymphocytes involving chromosomes 7 and 14. Most of these rearrangements occur in chromosome bands 7p13, 7q35, 14q11, and 14q32 (as in A-T), which are the location of the human immunoglobulin and T-cell–receptor genes (Aurias et al., 1980; Aurias and Dutrillaux, 1986). Generally, translocations are detectable in 10 to 35 percent of NBS cells and in 5 to 10 percent of A-T cells (van der Burgt et al., 1996). The most frequently detected aberration in T lymphocytes is inv(7)(p13q35), followed by other rearrangements such as t(7; 14)(p13; q11), t(7; 14)(q35; q11), t(7; 7)(p13; q35), and t(14; 14)(q11; q32) (van der Burgt et al., 1996). Other less frequently reported NBS

Table 48.5 CYTOGENETIC AND CELLULAR FEATURES OF NIJMEGEN BREAKAGE SYNDROME CELLS

Normal constitutive karyotype
Increased spontaneous chromosomal instability
Open chromatid and chromosome breaks
Rearrangements of chromosomes 7 and 14
Telomere fusions
Radioresistant DNA synthesis
Hypersensitivity to ionizing radiation and radiomimetic agents
Increased sensitivity to alkylating agents

breakpoints, for example t(X;14)(q27–28; q11–13) , have also been found in A-T cells (Wegner, 1991).

Open chromosomal aberrations, such as chromatid breaks, chromosome breaks, and centric fragments, as well as marker chromosomes and unspecific chromatid exchanges have been frequently found in lymphocytes and fibroblasts of NBS patients (Barbi et al., 1991; Chrzanowska et al., 1995a, 2001; Conley et al., 1986; Demas et al., 1981; Der Kaloustian et al., 1996; Kleier et al., 2000; Maraschio et al., 2001; Pérez-Vera et al, 1997; Seemanová et al., 1985; Stoppa-Lyonnet et al., 1992; Taalmann et al., 1989; Tupler et al., 1997; Wegner et al., 1988). In contrast, chromosomal instability has not been observed in NBS bone marrow cells (Weemaes et al., 1981). An additional uncommon chromosomal abnormality has been described in a 5-year-old NBS patient who showed, in addition to the typical 7/14 translocations, monosomies of nearly all chromosomes in 64 percent of the analyzed lymphocyte metaphases (Der Kaloustian et al., 1996). This finding points to deficiencies in the fidelity of mitotic chromosome separation. Whether nibrin, the product of *NBS1,* is involved in chromosome segregations remains unclear. An elevated rate of spontaneous chromosomal instability has been observed in EBV-positive immortalized B lymphoblasts from many NBS patients (Conley et al., 1986; Maraschio et al., 2001; Tupler et al., 1997).

However, some NBS cell lines have a low frequency of chromosomal aberrations or no chromosomal instability at all (Chrzanowska et al., 2001; Stumm et al., 1997; Wegner, 1991). In contrast to primary T lymphocytes, the spontaneous instability in lymphoblastoid cell lines (LCLs) is expressed as unspecific chromosomal aberrations, including a tendency of chromosomes to form telomeric associations resulting in dicentric chromosomes. Molecular and cellular data collected from NBS patients suggest that this cytogenetic phenomenon is a direct consequence of a functional deficiency of nibrin, a protein found at telomeres, where it associates with the telomeric repeat binding factor TRF2 (Lombard and Guarente, 2000; Zhu et al., 2000). Chromosomes from NBS patients have shortened telomeres that can be corrected by reintroduction of nibrin into patient fibroblasts (Ranganathan et al., 2001). Thus, the absence of nibrin might interfere with telomere metabolism, resulting in illegitimate fusion of telomeres between different chromosomes. Siwicki et al. (2003) have provided evidence that telomere length maintenance is intact in T lymphocytes in the absence of full-length nibrin, presumably because of an alternatively spliced NBS protein of 70 kDa.

All of the cytogenetic aberrations discussed above were obtained by standard microscopic analysis of Giemsa-stained and/or GTG-banded chromosomes. More distinct insight into the chromosomal instability of NBS cells was obtained by use of FISH with a three-color whole-chromosome painting assay (WCP 1, 2, 4) (Color Plate 48.I). Through use of this technique, an increased frequency of spontaneous translocations was detected (Stumm et al., 2001a). The presence of chromosomal aberrations, which might escape detection by conventional cytogenetic techniques, demonstrates that the degree of spontaneous genomic instability in NBS might be even higher than previously thought and may be an important risk factor for tumor development. The WCP 1, 2, 4 assay is also suitable for the detection of radiation-induced chromosomal instability in NBS and A-T patients (Neubauer et al., 2002).

Sister chromatid exchange (SCE) frequencies were found to be normal in lymphocytes (Barbi et al., 1991; Conley et al., 1986; Der Kaloustian et al., 1996; Weemaes et al., 1981; Wegner et al., 1988), fibroblasts, and LCLs (Conley et al., 1986) from all NBS patients investigated to date. The induction of chromosomal breakage in NBS lymphocytes and fibroblasts by irradiation proves a strong hypersensitivity to ionizing radiation (IR) as well as to radiomimetic agents such as bleomycin (Green et al., 1995; Taalman et al., 1989; Wegner et al., 1988). These characteristics clearly separate NBS cells from normal cells (Fig. 48.4) and have been used in our laboratories to confirm the diagnosis. A metaphase with a typical spectrum of lesions is shown in Figure 48.5. Increased radiosensitivity of NBS cells is also apparent from a decrease in colony-forming

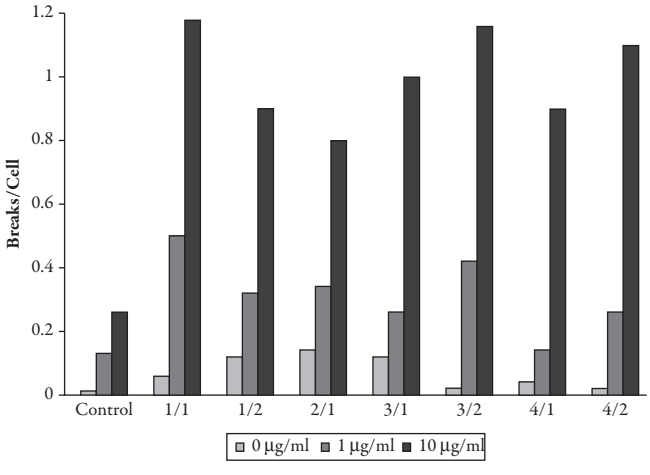

Figure 48.4 Spontaneous and bleomycin-induced chromosomal breakage rates in lymphoblastoid cell line metaphases from Nijmegen breakage syndrome (NBS) patients and a control, respectively. Bleomycin was added 1 hour before harvesting: 50 cells/column were counted in each situation. Note that there is an unequivocal discrimination between affected and control individuals at the higher bleomycin concentration. Patients are identified by family number (first digit) and individual number (second digit).

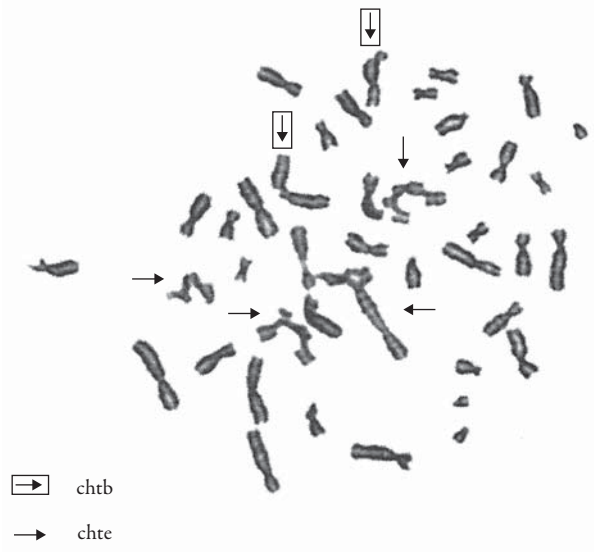

Figure 48.5 Lymphoblastoid cell line metaphase of a bleomycin-treated Nijmegen breakage syndrome cell showing chromatid breaks (chtb) and chromatid exchanges (chte).

ability following exposure to IR (Jaspers et al., 1988a; Taalman et al., 1983). Controversial results have been published concerning the hypersensitivity of NBS cells to alkylating agents. Seemanová et al. (1985) found weak evidence for increased chromosomal sensitivity to the bifunctional alkylating agent diepoxybutane (DEB) in one of two analyzed patients; Der Kaloustian et al. (1996) found normal DEB sensitivity in a third NBS patient. However, a clearly increased response to Trenimon was reported in siblings with NBS as early as 1991 (Wegner, 1991). Results obtained from these patients, now proven to carry the typical Slavic mutation 657del5, are shown in Figure 48.6. The speculation that the functionally deficient nibrin plays a central role in the aberrant repair processes of different types of DNA damage in NBS cells has been proven correct. Nakanishi et al. (2002) provided evidence for cooperation between the FA gene product FANCD2 and nibrin in the DNA cross-linking response (see Fanconi Anemia, above, and Molecular Interactions Between Nibrin and Other Proteins, below). Extensive studies of a cohort of NBS and a group of typical A-T patients corroborated the finding of marked sensitivity to the trifunctional alkylating agent Trenimon (Wegner et al., 1994). At doses of $10{\sim}^{8}$ M Trenimon, the chromosomal breakage rates of some NBS cell lines exceeded the control rate by more than 10 times (Stumm et al., 1997; Wegner, 1991; Wegner et al., 1994) (Fig. 48.6). A moderate sensitivity to MMC has been observed in one NBS patient (Chrzanowska et al., 2001). This moderate sensitivity to MMC is lower than in FA patients but has also been found in cell lines from other NBS patients (Kraakman-van der Zwet et al., 1999; Nakanishi et al., 2002; M. Stumm and R. Wegner, unpublished observation). These findings are of significance with respect to chemotherapy for NBS patients: the intensity of the treatment should be adjusted to the patient's individual risk factors and tolerance (Seidemann et al., 2000). Therefore, testing cells for their response to cytostatic agents should be considered and might reduce the risk of therapeutic side effects in sensitive patients.

Cell Cycle

Although the function of nibrin in cell-cycle control is far from fully understood, its involvement in cell-cycle checkpoints is supported by cellular, molecular, and cytogenetic data. Unlike in normal cells, DNA synthesis after IR or bleomycin treatment is not inhibited in NBS cells (Chrzanowska et al., 1995a; Jaspers et al., 1988a; Wegner et al., 1988). This feature, called *radioresistant DNA synthesis* (RDS), was initially described in A-T cells (Cramer and Painter, 1981; de Wit et al., 1981). RDS in NBS cells seems to be linked to a pathway involving the interaction of nibrin and SMC1. The inhibition of DNA synthesis after IR seems to depend on

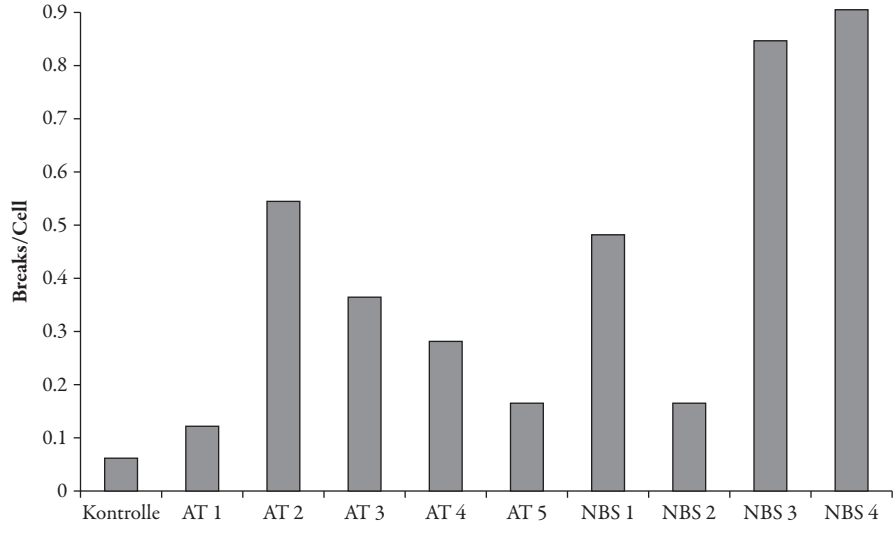

Figure 48.6 Trenimon-induced chromosomal breakage in lymphoblastoid cell line metaphases from Nijmegen breakage syndrome (NBS) and ataxia-telangiectasia (AT) patients. Trenimon exposure (10−8 M) lasted 24 hours. At least 50 cells/column were analyzed.

phosphorylation of SMC1, a member of the cohesion proteins. Efficient phosphorylation of SMC1 by ATM requires nibrin (reviewed by Digweed and Sperling, 2004). In addition to this highly characteristic defect in an S-phase–dependent cell-cycle checkpoint, there are further disturbances in cell-cycle progression in some NBS cell lines. The role of *NBS1* in G1/S checkpoint control is controversial, because the extent of p53 accumulation and strength of expression of G1/S arrest after irradiation differ substantially in individual NBS cell lines (Antoccia et al., 1999; Girard et al., 2000; Jongmans et al., 1997; Matsuura et al., 1998; Sullivan et al., 1997; Yamazaki et al., 1998). An explanation for these variations might be dose-dependent differences in the response, as Girard et al. (2002) showed G1/S arrest in NBS cells at 1 Gy that was abolished at 5 Gy. Irrespective of differences in p53 induction and G1/S checkpoint control, NBS and A-T cells show comparable chromosome aberrations, both in quantity and in quality. This means that there is no simple correlation between checkpoint control and radiation-induced chromosomal instability. Therefore, factors other than those related directly to G1/S cell-cycle checkpoint control seem to be involved mainly in radiation sensitivity and chromosomal instability in NBS cells (Antoccia et al., 1999, 2002). The role of NBS 1 in G2 checkpoint control is also controversial, because the G2/M-phase transition appears to be extremely variable among different NBS cell lines. Some NBS cells, like A-T cells, fail to stop entry into mitosis after irradiation, a finding suggesting that NBS1 deficiency may disturb the G2/M checkpoint (Buscemi et al., 2001; Maraschio et al., 2001; Pincheira et al., 1998). In contrast, other NBS cells show a normal G2/M transition (Antoccia et al., 1997, 2002; Girard et al., 2000; Yamazaki et al., 1998). Because recent reports suggest an impaired ability of NBS cell lines to phosphorylate checkpoint kinase 2 (CHK2) (Buscemi et al., 2001; Girard et al., 2002), it is reasonable to expect effects of nibrin mutations on G2/M checkpoint control (see Molecular Interactions Between Nibrin and Other Proteins, below).

The expression of checkpoint impairment in irradiated NBS cells appears to vary considerably and be dose-dependent. Therefore, checkpoint disturbance is likely not the main reason for the strong radiation sensitivity in these cells over a broad range of doses.

GENETICS

Identification of the *NBS1* Gene

Despite clear differences in the clinical characteristics of NBS and A-T, cells from patients with these diseases express nearly identical cytogenetic and cellular features. This phenomenon led to the suggestion that NBS and A-T are two disorders due to allelic mutations (Curry et al., 1989). In contrast to this proposal, linkage analysis in six NBS families, formerly called ataxia-telangiectasia variant (AT-V) families, with at least two affected siblings proved unequivocally that the underlying *NBS* gene was not localized in the *ATM* region at 11q23.1 (Stumm et al., 1995). In agreement with this linkage exclusion, chromosome 11 could not complement the NBS phenotype on the cellular level in chromosome transfer studies (Komatsu et al., 1996). In 1988 it was postulated that NBS is a heterogeneous disease and that NBS patients fall into two complementation groups, AT-V1 (Nijmegen breakage syndrome) and AT-V2 (Berlin breakage syndrome) (Jaspers et al., 1988a, 1988b; Wegner et al., 1988). This conclusion was based on complementation studies using differentially labeled parental fibroblast cell lines in fusion experiments and comparing the rate of DNA synthesis in homokaryons with that in heterokaryons after irradiation or bleomycin treatment. Doubts about the reliability of this assay came with the report that A-T patients assigned to four complementation groups by employing the same assay actually all carried allelic mutations in the same gene, the *ATM* gene (Savitsky et al., 1995). Subsequent cell-fusion studies between AT-V1 and AT-V2 LCLs failed to achieve complementation, although there was clear normalization in the rate of chromosomal aberrations after fusion with normal cells (Stumm et al., 1997).

Finally, mapping of the *NBS* gene was initiated using two approaches. One was a whole-genome scan by polymerase chain reaction (PCR)-based micro satellite markers; the other followed the concept of unmasking heterozygosity. The latter study involved linkage studies in NBS families with markers spanning the potential gene loci at the breakpoints of a constitutional translocation t(3; 7)(q12; q31.3) in a NBS patient, where the derivative chromosomes were transmitted from the unaffected father to the affected daughter. Both linkage and haplotype analysis with markers spanning both translocation breakpoints on chromosomes 3 and 7 in 12 NBS families allowed the clear exclusion of an AT-V gene from the translocation breakpoints (Chrzanowska et al., 1997) but failed to identify the gene location. In contrast, the whole-genome scan was successful in localizing the gene. The analysis of 20 NBS patients from 14 families proved linkage to a 1 cM interval between markers D8S171 and D8S170 on chromosome 8q21 in all families. Furthermore, these results indicate that there is only one single *NBS* gene (Saar et al., 1997).

The *NBS 1* Gene

The gene underlying NBS, designated *NBS1,* was identified independently by two groups. Varon et al. (1998) employed the positional cloning strategy, whereas Carney et al. (1998) studied the hMre11/hRad50 double-strand repair complex and identified a third member of this complex, p95, as being the product of the *NBS1* gene, now called *nibrin.* As shown in Figure 48.7, the *NBS* gene spans about 50 kb of genomic DNA, has 16 exons, codes for a protein with 754 amino acids, and has a calculated molecular weight of 85 kDa. The mRNA is polyadenylated at two alternative sites, leading to mRNAs of 4.4 and 2.4 kb in all tissues examined thus far. Altogether, at least nine different mutations have been identified so far in NBS patients (Digweed and Sperling, 2004; Maraschio et al., 2001; Resnick et al., 2002; Varon et al., 1998; P. J. Concannon and R. A. Gatti, www.geneclinics.org). The 657del5 mutation is the most widespread Slavic founder mutation, which results in a frameshift causing the largest truncation of nibrin. Seven additional truncation mutations were identified in exons 6, 7,

8, and 10, all downstream of the forkhead-associated (FHA) and breast cancer carboxy-terminal (BRCT) protein domains (Fig. 48.7). Therefore, all NBS patients studied to date have large sequence losses in the C-terminal portion of the protein. Nevertheless, all patients express a truncated protein containing the N-terminal domains, a finding suggesting that these sequences may be essential during embryonic development and that *NBS1* null mutants would result in fetal death. In 2001, Maser et al. reported that NBS cells with the common 657del5 mutation produce a 70 kDa protein fragment ($NBS1p^{70}$) lacking the native N terminus, which associates with the hRAD50/hMRE11 complex. This NBS $1p^{70}$ fragment is produced by internal translation initiation within the *NBS1* mRNA using an open reading frame generated by the 657del5 frameshift. Therefore, the common *NBS1* 657del5 mutation seems to be a hypomorphic mutation, encoding a partially functional protein that diminishes the severity of the NBS phenotype. This hypomorphic mutation might be essential for fetal development in humans and other mammals, because null mutations have not been found in humans, and mouse null mutants are embryonic lethal (Dumon-Jones et al., 2003; Zhu et al., 2001). Interestingly, null mutations in *MRE11* and *RAD50* are also lethal in mammals (Luo et al., 1999; Xiao and Weaver, 1997). Although the amino acid sequence of nibrin shows no global homology to other known proteins, there are two domains within the N-terminal 200 residues that can be found in other proteins: a BRCT domain, first described in the *BRCA1* gene, and an FHA domain, named after the transcription factor family in which it was initially found (Fig. 48.7). Both of these domains are expected to be involved in protein–protein interaction. Two members of the NHEJ repair pathway of DNA DSBs, hMRE11 and hRAD50, were identified as molecular partners of nibrin (Carney et al., 1998). Nibrin shows a weak similarity (46 percent) to the yeast protein XRS2, restricted only to the first 115 amino acids. In contrast, the entire amino acid sequences of the MRE11 and RAD50 proteins are widely conserved from yeast to mammals.

MOLECULAR BIOLOGY OF NIBRIN

Nibrin appears to exert multifunctional activity. The identification of nibrin as a member of the human NHEJ repair complex of DSB suggests that defective DSB repair may be the central problem in NBS. The impasse involving p53 activation and cell-cycle arrest indicate that nibrin may also be involved in signal transduction. Another possible role of nibrin involves its interaction with histone γ-H2AX, forming a complex that associates with irradiation-induced DSBs (Kobayashi et al., 2002). However, nibrin seems to also have an important role in the direct processing of DSB. Within 30 minutes of irradiation, discrete nuclear foci can be visualized in the irradiated nuclei of cells by staining with antibodies to the repair proteins hMRE11 or hRAD50. Staining with antibodies to nibrin produces exactly the same pattern, demonstrating that nibrin remains in the nuclei for more than 8 hours after irradiation. The formation of nuclear foci is fully abrogated in NBS cells (Color Plate 48.II). Even the diffuse nuclear staining found in unirradiated normal cells is lacking

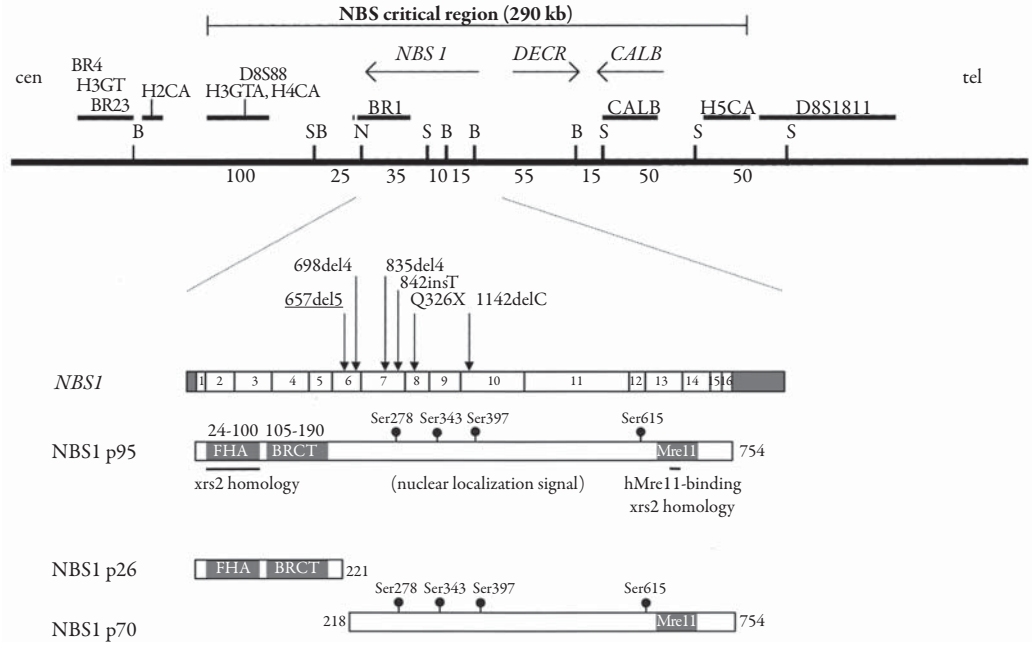

Figure 48.7 The *NBS1* gene and protein(s). Shown here is a physical map of the NBS1 region as defined by haplotype analyses of Nijmegen breakage syndrome (NBS) patients of Slavic origin. The positions of genes and genetic markers are indicated. The numbers below the line representing the DNA indicate the distances in kb between restriction enzyme sites (S, SalI; N, NotI; B, BamHI). Below the physical map, the exon structure of the *NBS1* gene is shown expanded. The position of mutations and the location of forkhead-associated (FHA) and breast cancer carboxy- terminal (BRCT) protein domains within the 754 residue p95 sequence are indicated. Serine residues that are phosphorylation targets are shown together with regions demonstrating similarity to yeast Xrs2 or implicated in binding to MRE11. Two protein fragments, p26 and p70, are found in NBS patient cells carrying the 657del5 mutation because of premature termination of translation and alternative translation, respectively.

in NBS cells, and considerable proportions of hRAD50 and hMRE11 are localized in the cytoplasm rather than in the nucleus. Since hRAD50 and hMRE11 are still found as a complex in NBS cells, a functional nibrin is clearly responsible for the location of these repair enzymes to the sites of DNA damage (Carney et al., 1998; Ito et al., 1999). In addition, nibrin is essential for the phosphorylation of hMRE11 after DNA damage (Dong et al., 1999), and it potentiates the ATP-driven DNA unwinding and endonuclease activity by the hRAD50/hMRE11 complex (Paull and Gellert, 1999). The hRAD50/hMRE11/nibrin complex has manganese-dependent, single-stranded DNA endonuclease and 3′ to 5′ exonculease activities; thus, it may be directly responsible for preparation of DNA ends for rejoining (Trujillo et al., 1998). Taken together, these findings indicate that nibrin plays an important regulatory role in the hRAD50/hMRE11/nibrin complex that responds to irradiation-induced DNA damage. The whole complex may act as a key factor in signaling and processing of DSB to initiate NHEJ and possibly homologous recombination as well.

Molecular Interactions Between Nibrin and Other Proteins

Considering the strong similarities in the cellular phenotypes of A-T and NBS, an important finding was the discovery that ATM and the hRAD50/hMRE11/nibrin complex function in the same network. Four laboratories reported that ATM modifies the hRAD50/hMRE11/nibrin complex by phosphorylation of nibrin (Gatei et al., 2000; Lim et al., 2000; Wu et al., 2000; Zhao et al., 2000). Following exposure to IR, rapid phosphorylation of at least two serine residues of nibrin occurs. It is possible that the phosphorylation of distinct residues could modify the hRAD50/hMRE11/nibrin complex in different ways and therefore play a concerted regulatory role. This function is disturbed in NBS cells, because cells expressing mutant nibrin cannot be phosphorylated by ATM. ATM-dependent activation of CHK2, a key protein in cell-cycle control in response to DNA damage, requires functional nibrin (Buscemi et al., 2001). In addition to a role downstream of ATM, it is also now abundantly clear that the trimeric nibrin complex is involved in the effective activation of ATM itself. After DNA damage, ATM dimers dissociate and are autophosphorylated, for which the trimeric complex is required (Lee and Paull, 2004). Thus, apart from the function in DSB repair, the hRAD50/hMRE11/nibrin complex appears to be specifically required to activate checkpoint control pathways following the formation of DSBs (reviewed in D'Amours and Jackson, 2002).

Nibrin physically interacts with histone by direct binding to γ-H2AX, which is phosphorylated in response to the introduction of DSB and may therefore act as a very early responder to the DNA repair machinery. The FHA/BRCT domain of nibrin is essential for physical interaction with γ-H2AX and seems to play a crucial role in the binding to histone and in localization of the hMRE11/hRAD50 repair complex to damaged DNA (Kobayashi et al., 2002). The interaction may, however, be indirect since recent studies suggest binding of nibrin to the protein MDC1 via its FHA domain, with γ-H2AX then actually binding to MDC1 (Spycher et al., 2008). Additionally, as Nakanishi et al. (2002) were able to show, nibrin and the FA subtype D2 protein (FANCD2) cooperate in two distinct cellular functions, one involved in the response to DNA cross-links and another involved in the S-phase checkpoint control. Therefore, nibrin functions at the intersection of two main signaling pathways. In response to the DNA cross-linking agent MMC, nibrin assembles in subnuclear foci with hMRE11/hRAD50 and FANCD2. IR activates an S-phase checkpoint through the ATM- and NBS1-dependent phosphorylation of FANCD2. Thus, the involvement of nibrin in the pathway of DNA cross-linking repair, as shown by molecular and cellular analysis, fits with earlier cytogenetic results of a significant increase in chromosomal aberrations above normal levels in NBS cells exposed to Trenimon (Stumm et al., 1997; Wegner, 1991) or other cross-linkers as discussed above (in Cytogenetics).

Moreover, there is evidence that the hMRE complex also plays an important role in prevention of DSB formation during the normal replicative process. It has been shown that certain helicases, for example proteins mutated in Werner syndrome (Cheng et al., 2004) and in BS (Franchitto and Pichierri, 2002a, 2002b), associate with the hMRE complex via binding to NBS1 in vitro, and in vivo after IR or MMC exposure, preventing the accumulation of DSB during chromosomal DNA replication (Costanzo et al., 2001). These observations provide convincing evidence for a functional link of multiple proteins that are mutated in many of the known chromosomal instability syndromes, including FA, NBS, BS, Werner syndrome, and A-T (see Chapter 47).

HETEROGENEITY OF NBS

Some patients indistinguishable from NBS by clinical and cellular criteria do not carry mutations in the *NBS1* gene (Cerosaletti et al., 1998; Hiel et al., 2001, Maraschio et al., 2003). These observations strongly suggest mutations in one or more other genes that may cause NBS-like phenotypes. Indeed, a novel nonhomologous end-joining factor, NHEJ1, also called Cernunnos protein, has recently been identified and found to be mutated in patients with an NBS-like phenotype characterized by microcephaly, SCID, and chromosomal instability (Ahnesorg et al., 2006; Buck et al., 2006) (see Chapter 13).

PRENATAL DIAGNOSIS

Prenatal diagnosis of NBS is based on molecular methods whenever the underlying gene mutations in the index patient or parents are known. When no informative molecular data are available, RDS analysis in cultured chorionic villi or amniotic fluid cells is a reliable method for identifying NBS in a fetus (Der Kaloustian at al., 1996; Jaspers et al., 1990; Kleijer et al., 1994). Heterozygotes cannot be diagnosed by cytogenetic means (Wegner, 1991). Detailed protocols for cytogenetic analysis of NBS and other chromosomal instability syndromes are provided by Wegner and Stumm (1999).

TREATMENT AND PROGNOSIS

Traditionally, NBS patients are treated symptomatically. Intravenous administration of immunoglobulin (IVIG) and antibiotic prophylaxis may be an effective treatment in patients with significant immune deficiency and recurrent infections. One should also keep in mind that immunodeficiency mandates avoidance of live vaccines. Because cellular susceptibility to radiation and chemotherapy is increased in NBS patients, as in those with A-T, diagnostic irradiation should be reduced as much as possible and management of cancer therapy must be modified (Barth et al., 2003; Busch, 1994; Hart et al., 1987; Seidemann et al., 2000). NBS females presenting with hypergonadotropic hypogonadism require hormonal replacement therapy to induce and complete puberty and to avoid osteoporosis (Pozo and Argente, 2003). With symptomatic therapy alone, the overall prognosis for patients with NBS is unfavorable as compared to normal individuals, with premature death occurring due to either overwhelming infection or malignancies. A recent report describing the European experience with hematopoietic stem cell transplantation (HSCT) has reduced earlier concerns about increased toxicity of chemotherapy in NBS patients. Of the six patients transplanted for malignancy (n = 4) or severe immune deficiency (n = 2), five were alive and well after a median follow-up of 2.2 years (range: 1.7–8.1 years), with restored immunity. Donors included matched siblings (n = 2), matched unrelated donors (n = 2), and matched or mismatched family donors. The only fatality, due to sepsis, was a 16-year-old boy who was the only patient receiving myeloablative conditioning (Albert et al., 2010).

BLOOM SYNDROME

BS (MIM 210900) is an autosomal recessive chromosomal instability syndrome. The most consistent physical feature of BS is a strikingly small but well-proportioned body size and predisposition to the early development of a variety of cancers (German, 1993; German and Ellis, 2002). BS is the consequence of either homozygosity or compound heterozygosity of mutations in *BLM,* a gene that encodes the phylogenetically highly conserved nuclear RECQL2-helicase.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

BS was first recognized as a clinical entity by a dermatologist (Bloom, 1954). The most striking clinical feature, besides the small body size, is a sun-sensitive erythematous "butterfly" skin lesion of the face, a feature that diagnostically sets the smallness of BS apart from other growth deficiencies (Color Plate 48.III). The full spectrum of BS has been defined by collecting clinical data through the Bloom Syndrome Registry (German and Passarge, 1989), in which a cohort of 169 patients diagnosed before 1991 has been enrolled and a second cohort of 60 additional cases added after January 1991. The clinical features and complications that constitute the phenotype BS, based on the registry data, are summarized in Table 48.6 (German 1993; German and Ellis, 2002; unpublished registry data). Following Bloom's original report of a sun-sensitive "telangiectatic erythema resembling lupus erythematosus in dwarfs," additional classic features of BS were reported: (1) a striking sparsity of adipose tissue throughout infancy and childhood, (2) serious gastrointestinal problems during infancy, (3) susceptibility to respiratory tract and middle ear infections, and (4) sub- or infertility and an unusually early menopause. Nevertheless, at least five women with BS have become pregnant (Chisholm et al., 2001). Major complications of BS, subsequently observed and confirmed by findings from the registry, include chronic lung disease, which developed in at

Table 48.6 CLINICAL PHENOTYPE, IMMUNODEFICIENCY, AND CHROMOSOMAL ABNORMALITIES OF BLOOM SYNDROME

Growth and Development
Abnormally small body size
Sparseness of subcutaneous fat
Slightly disproportional microcephaly
Characteristic facial and head configuration
Minor anatomical malformations
Skin Lesions
Sun-sensitive erythema limited almost exclusively to the face and dorsa of hands and forearms
Non–sun-sensitive hyper- and hypopigmented areas
Gastrointestinal Symptoms
Most consistent during infancy
Gastroesophageal reflux, vomiting
Anorexia
Diarrhea
Infertility
Lack of sperm production
Premature menopause
Complications
Chronic lung disease
Diabetes mellitus, type II
Neoplasia
Immunodeficiency
Hypogammaglobulinemia
Depressed delayed type hypersensitivity
Susceptibility to infections, mostly bacterial
Upper and lower respiratory tract
Otitis media
Genomic Instability in Somatic Cells
Aberrant DNA replication
Increased chromosomal interchanges
Sister chromatid exchange
Quadriradials, telomeric association

least 9 of the 169 individuals from cohort I, causing premature death in 5 at a mean age of 24.6 years. Although considered to be a consequence of recurrent lung infections, an alternative etiology, gastroesophageal reflux, has been proposed as cause of the chronic lung pathology. Diabetes mellitus, diagnosed at a mean age of 25.7 years, and resembling adult-onset diabetes, developed in 31 individuals of cohort I. A total of 143 episodes of cancer have been diagnosed in 90 of the 169 patients with BS. This remarkable predisposition to the early development of cancer is a hallmark of BS (German et al., 1997) and of the other chromosomal instability syndromes described in this chapter and in Chapter 47. By age 25, approximately half of the patients with BS will have developed a malignancy, many of them more than one type. In the first two decades of life, the predominant types are leukemia and NHL. Later, carcinomas affecting predominantly the colon, skin, and breast are common. An increased risk of colorectal cancer in BLM heterozygosity has been observed in one study of Ashkenazi Jews (Gruber et al., 2002), but not in another (Cleary et al., 2003).

LABORATORY FINDINGS

Cytogenetics

Once BS is suspected, the diagnosis can be confirmed by karyotyping: the chromosomes of PHA-stimulated lymphocytes of an individual with BS exhibit an excessive number of SCEs (Fig. 48.8), a finding uniquely characteristic of BS (German et al., 1977).

In addition to the high numbers of SCEs, cultured B and T lymphocytes and skin fibroblasts from individuals with BS exhibit enhanced chromosome instability—"breakage"—as indicated by an increased number of chromatid gaps and breaks and structurally rearranged chromosomes. Approximately 1 percent of cultured lymphocytes in metaphase display a symmetrical four-armed configuration, designated as *quadriradial* (QR), composed of two homologous chromosomes. Opposite arms of the QR are of equal length, and the centromeres are positioned opposite one another (Fig. 48.8; see also Cytogenetics of FA, above; Fig. 48.1). A QR of the type characteristic of BS is cytogenetic evidence that during the preceding S phase an interchange took place between chromatids of the members of a homologous chromosome pair, and the point of exchange apparently was at homologous sites. Historically, QRs constituted the first evidence that homologous recombination can occur in mammalian somatic cells in the form of somatic crossing over.

Somatic Cell Mutability

Neither the SCEs nor the homologous chromatid interchanges exemplified by the QRs are necessarily mutagenic, although the interchanges would give rise to recombined chromosomes in half of the progeny of affected cells. However, the many gaps and breaks observed in metaphases do suggest that the excessive chromatid-exchange mechanism in BS cells is error-prone. Direct evidence of increased spontaneous mutability of

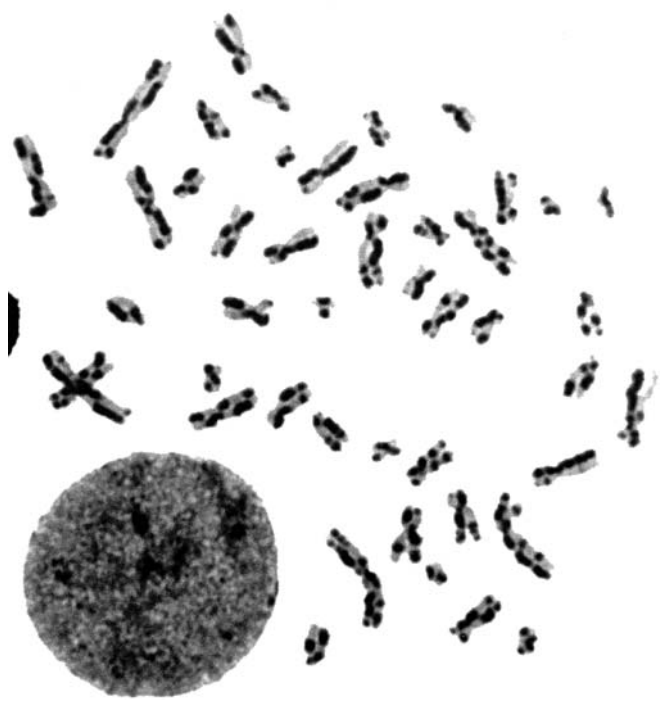

Figure 48.8 The characteristic and diagnostic elevation in number of sister chromatid exchanges (SCEs) in a cultured Bloom syndrome cell exposed to bromodeoxyuridine (BrdU) for two cell division cycles. Differentiation of the sister chromatids, dark or light, is accomplished by exposure of the BrdU-substituted chromosomes to the Hoechst dye 33258, then to light, and finally to Giemsa stain. The approximately 135 SCEs in this cell contrast with the fewer than 10 SCEs seen in similarly treated normal cells. A quadriradial chromosome is visible in the left field.

BS cells in vivo comes from studies that estimate the frequency of mutations affecting specific loci in human tissues. Coding loci that have been examined cytogenetically (but not at the molecular level) include the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) located on the X chromosome, the MN blood type (the glycophorin A locus on chromosome 4), and the major histocompatibility complex (on chromosome 6). For all three loci studied, the frequency of mutations in BS cells is greatly increased—for example, up to eight-fold for HGPRT (Vijayalaxmi et al., 1983) and 50- to 100-fold for the glycophorin A locus (Langlois et al., 1989). Finally, noncoding repetitive loci examined by molecular techniques were found to be hypermutatable, and molecular evidence confirming the cytogenetic evidence for excessive somatic recombination has been obtained in proliferating cells from a patient with BS (Groden et al., 1990). Thus, BS has to be considered a "mutator phenotype" (German, 1992) with mutations of many types, arising from nucleotide substitutions, deletions, and homologous recombination, and presumably affecting any part of the genome, accumulating excessively in proliferating cells both in vivo and in vitro.

Hematological Studies

Standard hematological parameters are normal except in patients who have developed leukemia or preleukemia.

Persistent anemia, usually mild and asymptomatic, is present in a subgroup of individuals with BS. Data submitted to the BS registry indicated that a myelodysplastic syndrome developed in 11 patients following cancer chemotherapy and spontaneously in one young-adult BS patient.

Endrocrine Studies

Ten individuals with BS, 9 months to 28 years of age, underwent endocrine evaluation; three nondiabetic children were found to have glucose intolerance and insulin resistance; two young adults had unsuspected diabetes or prediabetes. Growth hormone production was normal in all 10 patients studied (M. I. New, unpublished results).

Semen from approximately a dozen men with BS lacked spermatozoa completely with one exception, an adolescent who had sperm of abnormal morphology (J. German, unpublished results). Men heterozygous for a BS-causing mutation (fathers of BS patients) produced an increased number of spermatozoa with multiple breaks and rearrangements (Martin et al., 1994), suggesting that the infertility in men with BS is the consequence of a disturbance in meiosis. Supporting this summation is the finding that in normal mouse testes the BS protein (BSM) (vide infra) colocalizes with the replication protein A in the meiotic bivalent at the time of crossing over (Walpita et al., 1999).

Immunological Studies

Abnormal immune function, a common finding in BS patients, is highly variable and usually not severe (Etzioni et al., 1989; Hutteroth et al., 1975; Kondo et al., 1992a, 1992b; Taniguchi et al., 1982; Van Kerckhove et al., 1988; Weemaes et al., 1979, 1991). Hypogammaglobulinemia has been present in 87 percent of patients entered in the BS registry and involves one or more serum immunoglobulin classes (IgM, IgA, and, less commonly, IgG). Although most BS patients have decreased serum immunoglobulin levels, the majority have normal in vivo antibody responses to vaccines. Delayed-type hypersensitivity skin tests are generally negative, but skin reactivity to DNCB has been induced. Absolute lymphocyte counts and percentages of $CD4^+$ and $CD8^+$ T cells, B cells, and NK cells are normal, and most BS patients have normal in vitro lymphocyte proliferation to mitogens. Abnormal NK-cell function has been reported (Ueno et al., 1985).

It is unclear if the increased rate of infection is a direct consequence of usually mild and variable immune deficiency. Data from the BS registry indicate that 86 percent of individuals who develop serious infections have a deficiency of one or more serum immunoglobulin isotypes, but in 14 percent immunoglobulin concentrations are normal. Of those patients without a history of infections, however, 28 percent have abnormally low immunoglobulin levels. V(D)J recombination (Hsieh et al., 1993) and somatic hypermutation of immunoglobulin genes (Sack et al., 1998) are normal and in agreement with the observation that most patients with BS respond normally to vaccinations.

GENETICS AND MOLECULAR BASIS OF BS

BS had been recognized throughout the world as a very rare genetic disease, with the exception of the Ashkenazi Jewish population, in which approximately 1 in 110 individuals is a carrier of BS. Genetic analysis is consistent with autosomal recessive transmission: parents of BS patients are clinically unaffected; both sexes are equally affected; the ratio of affected to nonaffected siblings among those born after the index case are approximately 1:4; and, in non-Ashkenazi families, parental consanguinity is over 25 percent. The high parental consanguinity rate among non-Ashkenazi families with BS combined with the hypermutability of BS cells allowed for homozygosity mapping to localize the gene to chromosome band 15q26.1 (German et al., 1994). The same group showed that 96 percent of patients whose parents were related were homozygous for a polymorphic marker in the pro-oncogene *FES,* strongly suggesting that the *BLM* gene is tightly linked to FES (Ellis et al., 1994). Ellis et al. (1995) observed that in some BS patients a minority of blood lymphocytes had normal SCE rates. Using lymphoblastoid cells established from patients with low SCE rates in peripheral blood lymphocytes, it was shown that polymorphic loci distal to the gene localization on 15q became homozygous, whereas markers proximal to the gene remained heterozygous. These findings were interpreted that low-SCE lymphocytes arose by recombination in patients who had inherited alleles from their (nonconsanguineous) parents that were mutated in different sites and thus had generated a functionally wild-type gene. On the basis of polymorphic markers used, the recombination must have occurred between the polymorphic loci D15S1108 and D15S127, a 250 kb region. Following the construction of a physical map of this region (Straughen et al., 1996), a candidate gene, designated *BLM,* was identified within this cDNA region (Ellis et al., 1995), and sequence analysis of this gene when using DNA from BS patients revealed nonsense and missense mutations. The BLM cDNA consists of 4,437 nucleotides and encodes a 1,417-amino acid protein with homology to the RecQ family of helicases in *Escherichia coli.* The finding that the high SCE rate observed in BS cells could be reduced to control values if a normal *BLM* gene was transfected into cells obtained from BS patients further confirmed that *BLM* was indeed the gene responsible for BS. BLM, therefore, is a member of the same subfamily of helicases that includes the Sgs1 protein of *Saccharomyces cerevisiae* and the human proteins WRN and RECQ4, mutated, respectively, in Werner syndrome and some cases of Rothmund-Thomson syndrome. The fact that *BLM* is most closely related to the yeast proteins Rghlp and Sgs (Kusano et al., 1999) is of interest because *BLM* has been demonstrated to suppress premature aging and increased homologous recombination caused by mutations of the *Sgs1* gene (Heo et al., 1999). Studies of mutants for *Dmblm*, the *Drosophila* homolog of human *BLM*, suggests that this gene functions in DSB repair (Adams et al., 2003; Kusano et al., 1999, 2001). BLM has been identified as a DNA binding protein with preference for DNA structures that resemble the presumed initial intermediate formed during homologous recombination; it can bind to and unwind such substrates in vitro, including holiday junctions and D loops (Van Brabant et al., 2000). These

observations, together with the high rate of QR and SCE formation, support the hypothesis that *BLM* plays an antirecombinogenic function and that cells from BS patients, in which *BLM* function is lacking, are hyperrecombinogenic.

Western blot analysis and immunofluorescence microscopy demonstrate that cultured lymphoblastoid cells from most BS patients lack BLM. In normal cells, BLM protein is localized within the nucleus, where its total amount, distribution, and colocalization with other nuclear proteins vary at different phases of the cell division cycle (Sanz et al., 2000).

BLM has been identified as a member of a group of proteins that associate with BRCA1 to form a large complex that has been named *BASC* (BRCA1-associated genome surveillance complex). This complex consists of tumor suppressors and DNA damage repair proteins including MSH2, MSH6, MLH1, ATM, BLM, and the RAD50/MRE11/NBS1 protein complex (Wang et al., 2000). These proteins colocalize to large nuclear foci when cells are treated with agents that interfere with DNA synthesis. All members of this complex play roles in the recognition of abnormal DNA structures or damaged DNA, suggesting that BASC may serve as a sensor for DNA damage. Thus, BLM is part of a protein complex that coordinates the activities required for maintenance and genome integrity during the process of DNA replication, activities suggesting a central role for BLM as well as NBS1 in DNA repair.

Transfection of a normal *BLM* gene into cultured SV40-transformed BS fibroblasts results in nuclear transfer of the BLM protein and reduction of the SCE rate, indicating that the helicase activity of BLM is required for its function (Ellis et al., 1999; Neff et al., 1999). The most common mutation of BLM is a 6 bp deletion/7 bp insertion in exon 10, which is the homozygous mutation causing BS in Ashkenazi Jews (Ellis et al., 1995). More than 60 unique mutations in the *BLM* gene have been identified in families with at least one affected individual. Homozygosity for a given BS mutation is found in most BS patients whose parents are known to be cousins. In non-Ashkenazi families, in which the parents are not related, compound heterozygosity is most common. There is no obvious genotype–phenotype correlation.

BLM is part of an evolutionarily conserved protein complex together with topoisomerase IIIα and other factors, including RMI1 and RMI2 (BTR complex). This BTR complex localizes to anaphase bridges during mitosis, and BS cells show excessive anaphase bridging. Some particularly fine bridges contained FANCD2 and FANCI and were enriched at fragile sites, where gaps, breaks, and chromosomal rearrangements cluster after replication inhibition. These findings suggest that incomplete replication at such sites require dissolution by the BTR complex during mitosis (Chan et al., 2009).

Other human genes in the RecQ family include *RECQ4,* mutated in Rothmund-Thomson syndrome (Lindor et al., 2000); *RECQ3* (WRN), mutated in Werner syndrome (Yu et al., 1996); and *RECQL/RecQ1* and *RECQ5*, for which no syndromes have yet been identified.

CARRIER DETECTION AND PRENATAL DIAGNOSIS

Carrier females can be identified by DNA analysis if the mutation affecting the index case is known. A rapid method for detection of the Ashkenazi Jewish mutation is available (Straughen et al., 1998). Prenatal diagnosis of BS has been achieved by identifying a high rate of SCE in chorionic villi (Howell and Davies, 1994). Mutation analysis of fetal DNA is, however, the most reliable technique to establish the status of a fetus.

TREATMENT AND PROGNOSIS

Adequate nutrition is a common problem in infants and young children with BS, who typically show little interest in eating. This is compounded by frequent episodes of vomiting and diarrhea that may lead to life-threatening episodes of dehydration requiring hospitalization and may ultimately lead to the need for gastrostomy tube feeding. Infections require prompt diagnosis and adequate treatment with antibiotics. If hypogammaglobulinemia is documented and antibody deficiency demonstrated, the use of IVIG is recommended. In BS, as in patients with A-T, the extent of immune deficiency varies greatly.

Steps should be taken to protect the face of BS patients from sun exposure, especially during the early years of life. The diabetes mellitus observed in individuals with BS is not well characterized but resembles that of the adult-onset (type 2) condition, although it generally occurs earlier, usually in the 20s and 30s. Importantly, patients and their families should be informed about the high risk of developing cancer so that appropriate surveillance mechanisms can be put into place. Because individuals with BS are hypersensitive to chemotherapeutic agents, use of these compounds may have to be adjusted. Interestingly, the tumors of BS patients seem to be more sensitive to these therapeutic agents and cures have been reported using approximately half the dose of standard protocols.

Measures to increase height in patients, including growth hormone administration, have been largely unsuccessful. It has been postulated that the absence of BLM from somatic cells places a restriction on cell number and size, possibly through the deregulation of the p53 tumor suppressor pathway, which may not be limited to malignant cells (Garkavtsev et al., 2001).

ANIMAL MODELS

Disrupting *Blm* gene function in mice has created useful models for BS. Depending on the defect created by a targeted mutation of *Blm,* homozygous mutant animals may exhibit embryonic lethality, while in other mice homozygosity may yield viable and fertile animals with a cancer predisposition. In one model, a site upstream of the Blm helicase homology domain was targeted for disruption by use of homologous recombination. Whereas heterozygous mice appear normal and are phenotypically identical to wild-type littermates, mouse embryos homozygous for this mutation appear developmentally delayed and die by embryonic day 13.5 (Chester et al., 1998). $Blm^{-/-}$ littermates were smaller in size by 50 percent at 9.5 days postconception and remained smaller until death at 13.5 days postconception. Interestingly, the $Blm^{-/-}$ embryos were normal in their own body proportion and without structural abnormalities.

This BS knockout mouse model recapitulates many aspects of the human disease, including small size of the embryos, increased numbers of micronuclei in embryo blood cells, slow growth of cultured embryo fibroblasts, and, finally, a high number of SCE in cultured embryo fibroblasts, characteristically also seen in cells from Bloom patients. These data suggest that mutation of *BLM* in humans is sufficient to cause most aspects of the human disorder.

In addition, studies of mouse embryos clearly demonstrate increased programmed cell death, an observation not previously described in BS patients. There was also a marked reduction of the blood volume and the number of circulating red blood cells beginning at 9.5 days postconception; the affected embryos had only 5 or 10 percent as much blood as their wild-type littermates. Furthermore, an increased number of macrocytes and an increased presence of nuclear fragments were present in mutant versus wild-type erythrocytes (Chester et al., 1998).

Another knockout mouse model with a hypomorphic Blm protein produced a diminished quantity of normal mRNA and protein. These animals were viable and showed an inverse correlation between the quantity of Blm protein and the level of chromosome instability and a similar genotypic relationship for tumor predisposition, suggesting that Blm protein is rate-limiting for maintaining genome stability and the avoidance of tumors (McDaniel et al., 2003). These viable knockout mice had an 18-fold increase in the rate of somatic loss of heterozygosity (LOH), indicating a marked elevation of the mitotic recombination rate in mutated cells (Luo et al., 2000). Cell lines from these mice show elevations in the rate of mitotic recombination. These mice are also prone to a wide variety of cancers.

A unique mouse model was generated using gene targeting by homologous recombination to disrupt the mouse *Blm* gene to simulate BLM^{Ash}, a BS-causing mutant allele of BLM carried by approximately 1 percent of Ashkenazi Jews (Li et al., 1998). This mutation causes a frameshift in exon 10 that results in premature translation termination. Homozygous disruption of Blm by this method resulted in embryonic lethality. Cell lysates from heterozygous animals ($Blm^{+/-}$) had an approximately 50 percent reduction in Blm compared to wild type. There was a twofold increase in the number of micronuclei in BrdU-treated cultures of heterozygous deficient cells, a result suggesting that heterozygous cells have a subtle increase in genomic instability, presumably related to the reduced BLM level. There was a slight acceleration in the development of murine leukemia virus-induced metastatic T-cell lymphoma and an increased incidence of intestinal adenomas in mice heterozygous for this Blm mutation (Goss et al., 2002). These results demonstrate that Blm haploinsufficiency is sufficient to affect tumor formation in susceptible mice and probably to alter genome stability. This increased susceptibility to cancer in heterozygous mice supports the finding in human carriers for BS that they have an increased risk of colorectal cancer (Gruber et al., 2002).

Rare Syndromes with Chromosomal Instability

Patients with the clinical and cytogenetic features of chromosomal instability syndromes, in particular NBS and AT, but without mutations in the respective genes are of particular interest because they may disclose clues about unknown gene products involved in the network of genome integrity surveillance. Ligase I (LIG1) deficiency (MIM 126391) was described in one female patient with typical features of a chromosomal instability syndrome—growth retardation, telangiectasia, immunodeficiency, and lymphoma—at the age of 19 years (Webster et al., 1992). Hypersensitivity to UV light, alkylating agents, and IR was observed at the clinical and cellular levels. Molecular analysis identified two missense mutations in the *LIG1* gene of this patient (Barnes et al., 1992). A link to the NHEJ repair network was suggested by the finding of a physical association of LIG1 with MRE11 (Petrini et al., 1995). Only one patient with LIG1 deficiency has been described thus far. This low number might be explained by the minor role of LIG1 in NHEJ compared to that of ligase IV (LIG4) (see below), which can be substituted more easily. Another explanation might be the presence of undetected mutations in another gene involved in NHEJ.

More recently, mutations in the *LIG4* gene were shown to cause an NBS-like syndrome in four patients (O'Driscoll et al., 2001) (Table 48.1, see Chapter 13). On the cellular level, cell lines from LIG4-deficient patients show pronounced radiosensitivity similar to that in NBS. In contrast to NBS cells, LIG4-deficient cells show normal cell-cycle checkpoint responses but impaired DSB rejoining. Since V(D)J recombination is also affected, immunodeficiency is part of the clinical phenotype. Thus, LIG4, if mutated, is responsible for the defective DSB repair, resulting in a novel combined immunodeficiency syndrome (LIG4 deficiency syndrome, MIM *606593). By targeted disruption of both *LIG4* alleles in a human pre-B-cell line studied for radiosensitivity, Grawunder et al. (1998) showed that LIG4 activity is responsible for the ligation step in nonhomologous DNA end-joining and in V(D)J recombination.

It has been demonstrated that LIG4 forms a tight complex with the protein XRCC4 (Grawunder et al. 1998) to repair DSB by the NHEJ pathway. However, it took 8 more years to identify the third partner of this complex, which was suspected by Dai et al. (2003) while studying a patient with T-B-SCID whose cells showed dramatic radiosensitivity, decreased DSB rejoining, and reduced fidelity in signal and coding joint formation during V(D)J recombination. This patient (2BN), while sharing several characteristics of NBS and of LIG4 deficiency, did not have mutations in the respective genes (Dai et al., 2003). Two groups recently reported independently mutations in a hitherto unknown gene through cDNA functional complementation cloning (Buck et al., 2006) and yeast two-hybrid screening for *XRCC4* interactors (Ahnesorg et al., 2006), respectively. This novel protein has been named Cernunnos (Buck et al., 2006) or XLF (Ahnesorg et al., 2006) and was officially designated as nonhomologous end-joining factor 1 (NHEJ1). Mutations in this gene are responsible for the clinical phenotype mentioned above, including microcephaly, and for defective NHEJ and V(D)J recombination (MIM 611291) resulting in severe combined immune deficiency (Buck et al., 2006) (see Chapter 13).

Waltes et al. described a patient with a disorder resembling NBS who harbored different hypomorphic mutations,

one in each allele of the *RAD50* gene (Waltes et al., 2009). The girl, originally described in 1991 by Barbi et al., presented with many clinical characteristics of NBS, but not with immunodeficiency (Table 48.1). The Rad50 deficiency (MIM *604040) resulted in increased spontaneous chromosomal instability, radiosensitivity, RDS, impaired nibrin phosphorylation, and impaired nuclear foci formation after irradiation. Since hRAD50 is one of the three partners of the hMRE11/hRAD50/nibrin complex, it is not surprising to find the NBS phenotype in a compound heterozygous individual. The link between RAD50 deficiency and increased radiosensitivity points to the importance of a fully functional hMRE11/hRAD50/nibrin complex for reliable NHEJ.

More surprising is the clinical picture of patients carrying mutations in the *hMRE11* gene (Stewart et al., 1999) (Table 48.1). Because these patients show many similarities to A-T, although with a milder phenotype and without mutations in the *ATM* gene, this syndrome has been called ataxia-telangiectasia–like disorder (A-TLD) (MIM 604391). The protein hMRE11 is engaged in forming the hMRE11/hRAD50/nibrin complex, which plays an early role in a signal transduction pathway responding to DSB induced by IR and radiomimetic chemicals (Taylor et al., 2004). Both these events activate DNA repair as well as cell-cycle checkpoint controls. All *hMRE11* mutations observed in this recessive disorder result in the expression of proteins with some residual function that may be necessary for the survival of affected patients. Typically, this residual function results from a hypomorphic mutation of at least one *hMRE11* allele.

A recently described DNA repair defect, Riddle syndrome (MIM 611943), characterized by mild motor control and learning difficulties, facial dysmorphism, short stature, immunodeficiency and radiosensitivity, is caused by mutations in RNF168, a ubiquitin ligase. RNF168 is recruited to the site of DNA damage by binding to ubiquitylated histone H2A, resulting in chromatin modification and accumulation of 53BP1 and BRACA1 to DNA lesions (Stewart et al., 2009).

Immunodeficiency with centromere instability and facial anomalies (ICF syndrome) (MIM 242860) is reported in Chapter 49.

CONCLUDING REMARKS

The descriptive level of chromosomal instability syndromes of only one decade ago has been complemented by the discovery that the chromosomal instability syndromes not only form subgroups based on their descriptive features but are actually linked together at the molecular level. Most if not all genes mutated in the syndromes described in this chapter (including *ATM,* see Chapter 47) take part in the complex network of DSB sensing, signal transduction, and DNA repair. Although much more has to be done to determine specific functional aspects, the facts known to date allow a first glimpse into the complex network of genomic stability maintenance. A very simplified schema of this network is shown in Figure 48.9, which lists only those gene products mutated in the chromosomal instability syndromes presented in this chapter. Their physiological functions have been demonstrated by the analysis of gene mutations in relevant patients. The identification and investigation of additional pathological conditions

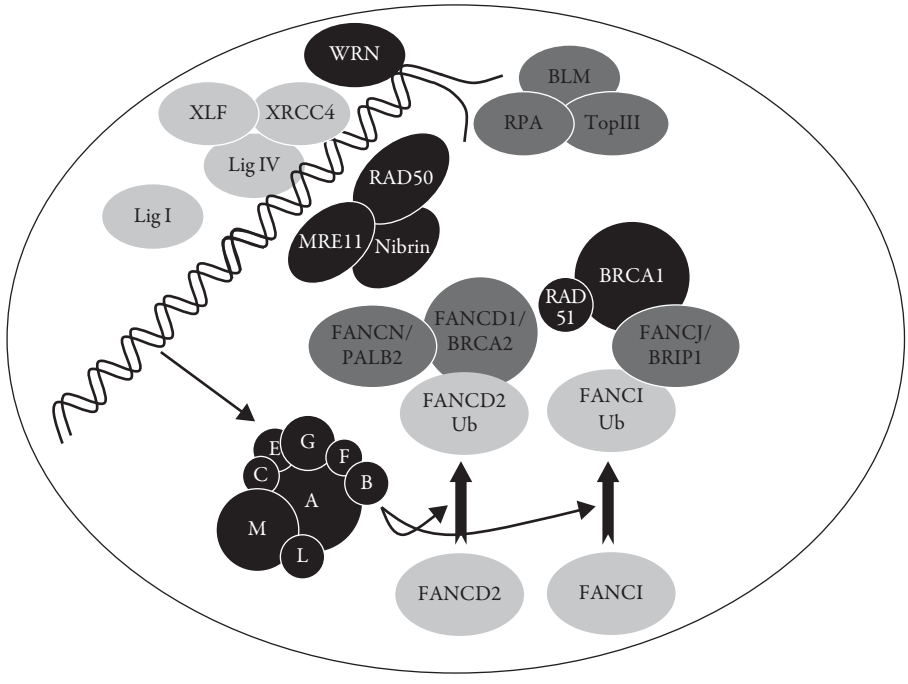

Figure 48.9 The network of proteins mutated in chromosomal instability syndromes. This highly simplified schematic drawing shows the proteins acting in the DSB repair network. Only proteins mutated in the chromosomal instability syndromes discussed in this chapter are shown. Several protein complexes can be identified: the FA core complex, the MRE11/RAD50/nibrin complex, the LIG4 complex, the BLM complex, and the complex consisting of BRCA1/BRAC2/RAD51/FANCD2/FANCI. The BASC complex (Wang et al., 2000) includes BRCA1, BLM, and RAD50/MRE11/nibrin. Lig, ligase; WRN, Werner syndrome; XLF, XLF/NHEJ1/Cernunnos protein.

are essential to a better understanding of these crucial cellular processes; for the benefit of our patients, it is even more important to generate new ideas that lead to more effective treatments of these devastating genetic disorders.

IMMUNODEFICIENCY WITH CENTROMERE INSTABILITY AND FACIAL ANOMALIES (ICF SYNDROME)

R. Scott Hansen, Corry M. R. Weemaes, and Silvère M. van der Maarel

Immunodeficiency with centromeric instability and facial anomalies (ICF syndrome) (MIM #242860) is a rare autosomal recessive disease characterized by immunodeficiency of variable extent, mild facial anomalies, and chromosome instability involving the pericentromeric regions of chromosomes 1, 9, and 16. Two groups independently reported the disease in the late 1970s (Hultén, 1978; Tiepolo et al., 1978, 1979). A patient described earlier by Østergaard (1973) also appears to have had ICF syndrome based on the clinical symptoms and the chromosomal abnormalities reported. The acronym ICF was suggested in accordance with the characteristic features of the syndrome: *I*mmunodeficiency, *C*entromeric instability, and *F*acial anomalies (Maraschio et al., 1988). Only about 50 ICF patients have been described in the literature thus far, but underdiagnosis of the syndrome is quite possible because of phenotypic variability and infrequent testing for the diagnostic chromosome anomalies. Here we summarize the common clinical features of this limited set of patients as well as the molecular defects associated with ICF.

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Although ICF patients have been found all over the world, they are concentrated in the Mediterranean area (de Greef et al., 2011; Hagleitner et al., 2008). Inheritance is autosomal recessive and consanguinity has been found in several ICF families. At least 20 of the known patients have died, most of them before the age of 12 years. The predominant cause of death was severe respiratory tract infections, sepsis, and malignancy (Hagleitner et al., 2008).

As described below, two genes known to be mutated in ICF are *DNMT3B* (ICF1) and *ZBTB24* (ICF2). ICF1 and ICF2 patients have a similar phenotypes (Hagleitner et al., 2008), including the same facial anomalies, lower respiratory tract infections, opportunistic infections, and immunodeficiency.

FACIAL ANOMALIES

Mild facial dysmorphic features are found in most ICF patients (Table 49.1). Hultén, in 1978, described a boy with a peculiar facial appearance characterized by bilateral epicanthus and slight protrusion of the right external ear (Hultén, 1978). The patient described by Tiepolo et al. had an epicanthus and low nasal bridge (Maraschio et al., 1988; Tiepolo et al., 1978, 1979). Several other dysmorphisms have been described subsequently, including macroglossia (Fryns et al., 1981), micrognathia (Howard et al., 1985), and hypertelorism (Carpenter et al., 1988).

Phenotypic characteristics currently considered part of ICF syndrome may include a round face with epicanthus, telecanthus, flat nasal bridge, hypertelorism, upturned nose, macroglossia, micrognathia, and low-set ears. Hypertelorism, flat nasal bridge, epicanthic folds, and low-set ears were most frequent. Many of these features become more prominent during later childhood; however, dysmorphic features are not always present in adult ICF patients. Thus, patients with agammaglobulinemia in whom B cells are present should be considered for cytogenetic analysis to preclude ICF syndrome.

Facial anomalies may or may not be present immediately after birth. For example, the brother of the patient described by Smeets et al. (1994) did not show dysmorphic features until the age of 1 year, when he presented with a round face and telecanthus (Color Plate 49.I).

GROWTH AND DEVELOPMENT AND NEUROLOGICAL PROBLEMS

Although some ICF patients were significantly smaller than normal at birth, most show normal birth weight. Growth

Table 49.1 CLINICAL FEATURES AND GENE MUTATIONS IN ICF SYNDROME

	TOTAL	*DNMT3B* MUTATION	*ZBTB24* MUTATION

Selective IgA deficiency	1	1	
IgG2 subclass deficiency	1		
CD4 cells decreased	7/41	3/18	1/7
Lymphocyte stimulation in vitro decreased	5/30	2/14	

retardation occurred in some patients because of failure to thrive following infections or gastrointestinal problems. The majority of ICF patients have shown a delay in walking, as well as in initial speech. Additionally, hypotonia was demonstrated in several patients (Carpenter et al., 1988; Petit et al., 1997; Schuffenhauer et al., 1995). Some ICF children needed physiotherapy and/or speech therapy to learn to walk or talk.

The intelligence of ICF patients is quite variable. A few patients were moderately or severely mentally retarded (Gimelli et al. 1993; Howard et al. 1985; Schuffenhauer et al. 1995 Tiepolo et al. 1979). The initial cytogenetic analysis for some of these patients, however, was performed because they presented with mental retardation and dysmorphisms rather than immunodeficiency. One child was reported as doing exceptionally well in high school, showing that the disorder can exist without retardation. Children with ICF frequently have difficulty with speech and gross motor skills. Physiotherapeutic support and speech therapy often have a positive influence on their development. Hagleitner described five patients with cortical atrophy, two of whom developed generalized tonic-clonic seizures within their first 2 years of life. Two other patients had a progressive deterioration of cognitive functions at the age of 10 years (Hagleitner et al., 2008).

Because many patients succumb to infections at an early age, little is known about sexual development in ICF

individuals. Puberty generally appears to be normal in the few cases followed. A pregnancy has been reported, for example, in one adult female patient, although her older affected brother is azoospermic (G. Gimelli, personal communication).

The most common malformations found are inguinal hernia and hypospadias, cleft palate, and syndactyly (Hagleitner et al., 2008). Cardiac anomalies were reported in two patients and included ventricular septal defect and atrial septal defect. Congenital hypothyroidism was found in one patient. Cerebral malformations were reported in individual patients and include focal cortical heterotopy, corpus callosum hypoplasia, and hydrocephalus.

INFECTIONS

Infections are a prominent clinical feature in ICF syndrome, especially respiratory tract infections, which occur in nearly all cases (Table 49.1). Pneumonia, often caused by *Haemophilus influenzae* or *Streptococcus pneumoniae* (Howard et al., 1985; Østergaard, 1973) is a common affliction. Bacterial sepsis occurred in several patients due to infection with *Klebsiella*, *Pseudomonas*, or *Staphylococcus aureus*. In addition, opportunistic infections such as *Pneumocystis carinii (jiroveci)* pneumonia (PCP) (Bauld et al., 1991), cytomegalovirus (Fasth et al,. 1990), and *Candida albicans* (Fasth et al., 1990; Valkova et al., 1987) also frequently occur in ICF patients. One patient with selective IgM deficiency developed a progressive multifocal leukoencephalopathy due to JC virus at the age of 35 years; she concurrently had agammaglobulinemia (Colucci et al., 2004). Infections with JC virus, *P. jiroveci*, and *Candida* suggest that a subtle defect of T-cell function must be present, apart from the hypogammaglobulinemia. In some ICF patients a T-cell defect has been demonstrated (Table 49.1); however, one of the patients presenting with PCP seemed to have had only a B-cell deficiency (Bauld et al., 1991).

Despite substitution therapy with immunoglobulins, many ICF patients have died from infection at a very young age. Allogeneic stem cell transplantation has been performed successfully in four patients (Gennery et al., 2007).

GASTROINTESTINAL PROBLEMS

Protruding abdomen has been described in several ICF patients (Fryns et al., 1981; Smeets et al., 1994; Turleau et al., 1989). Failure to thrive is common. Many patients suffer diarrhea (Fasth et al., 1990; Maraschio et al., 1988; Smeets et al., 1994; Turleau et al., 1989; Valkova et al., 1987), and extended total parenteral feeding was necessary in several children (Turleau et al., 1989; Valkova et al., 1987). Microorganisms such as *Cryptosporidium* or *Giardia lamblia* were not found in cultures from these patients. Malabsorption was reported in several patients (Fryns et al., 1981; Petit et al., 1997; Smeets et al., 1994; Turleau et al., 1989), and villous atrophy has been demonstrated in some patients (Carpenter et al., 1988; Fryns et al., 1981; Turleau et al., 1989).

MALIGNANCIES AND HEMATOLOGICAL ABNORMALITIES

Aplastic anemia has been reported in ICF (Hagleitner et al., 2008). Acquired leukocytopenia and thrombocytopenia of unknown origin were documented in several patients. In two patients, cortical atrophy evolved at the same time without evidence for an infectious origin.

The observed progressive deterioration and/or thrombocytopenia and leukocytopenia in combination with cerebral atrophy is similar to the pathology of neurological manifestations in systemic lupus erythematosus, another disease linked to DNA hypomethylation (Sekigawa et al., 2006). Development of hematological abnormalities such as aplastic anemia or thrombocytopenia and leukocytopenia, hepatosplenomegaly, and arthritis may be caused by autoimmune mechanisms. Autoimmunity in the absence of antibodies suggests activation of autoreactive T cells by T-cell receptor or by innate activating receptors directly.

Hematological malignancies were reported in two patients and included one ICF2 patient who developed a classical Hodgkin's lymphoma (Schuetz et al., 2007) and one ICF1 patient who acquired a common pre-B leukemia. Additionally, a second ICF1 patient died from angiosarcoma (van den Brand et al., 2011).

A predisposition to cancer is frequently associated with immunodeficiency. Various types of cancer share with ICF syndrome cells the characteristic of hypomethylated satellite 2 DNA, which is known to be associated with chromosomal instability and is believed to promote tumor frequency and malignancy (Ueda et al., 2006).

LABORATORY FINDINGS

IMMUNOLOGICAL FINDINGS

One of the characteristic findings in the ICF syndrome is immunodeficiency (Table 49.1), which can be quite variable, ranging from severe immunodeficiency to a near-normal immune system. Agammaglobulinemia with normal B cells is the most common finding in ICF patients. Some patients have decreased levels of all immunoglobulins, and four patients were reported with selective IgA, IgM, or IgG2 subclass deficiency. One patient had only a slightly decreased number of CD4-positive cells (Gimelli et al., 1993). Selective IgM deficiency and failure to produce antibodies to polysaccharide antigens, but a normal response to protein antigens such as tetanus toxoid, was observed in a patient with ICF who was subsequently found to have normal IgM levels and normal isohemagglutinin titers; antibodies to *H. influenzae*, however, remained absent (Østergaard, 1973, 1977).

Normal percentages of T cells were observed in most patients tested, and CD4-positive cells were decreased (<10th percentile) only in some patients (Hagleitner et al., 2008). A limited number of patients underwent assessment of T-cell function in vitro. Five of 30 patients tested showed decreased or absent cell proliferation when stimulated with the mitogen PHA.

CYTOGENETIC ABNORMALITIES

Aberrations of chromosomes 1 and/or 16 involving their heterochromatic pericentromeric DNA sequences can be observed at high frequency in regular lymphocyte cultures of peripheral blood samples from ICF patients. These aberrations can be recognized as gaps, breaks, deletions, isochromosomes, multiradial figures, interchanges between pericentromeric regions, and multiradial configurations (Fig. 49.1). Two short arms of chromosomes 1 and 16 are present in all aberrant cells, with a varying number of long arms, suggesting that breaks occurred just below the centromere within the heterochromatic region on the proximal long arm (Haas, 1990). Similar aberrations involving chromosome 9 (Fryns et al., 1981; Tiepolo et al., 1979; Valkova et al., 1987) and, rarely, chromosomes 2 (Valkova et al., 1987) and 10 (Turleau et al., 1989) have also been reported.

The overall frequency of ICF cells with chromosomal aberrations often increases with culture time (Maraschio et al., 1988; Smeets et al., 1994; Tiepolo et al., 1979), although the opposite has also been reported (Turleau et al., 1989). Moreover, aberrations can also become more complex with increasing time in culture (Howard et al., 1985; Hultén, 1978; Smeets et al., 1994; Tiepolo et al., 1979). Interphase nuclei consistently show an increased number of micronuclei and/or nuclear protrusions (Fasth et al., 1990; Maraschio et al., 1992). Fluorescence in situ hybridization studies have clearly demonstrated that portions of chromosomes 1 and 16 are present in these micronuclei (Maraschio et al., 1992; Smeets et al., 1994). Cultured peripheral blood lymphocytes always display numerous aberrations, whereas other tissues, such as cultured fibroblasts, Epstein-Barr-virus–transformed B cells, and bone marrow cells, usually show many fewer, if any, aberrant cells. When aberrations are present in such cells, they are usually reduced in complexity compared to those seen in lymphocytes (Fasth et al., 1990; Gimelli et al., 1993; Howard et al., 1985; Maraschio et al., 1989; Turleau et al., 1989).

STRATEGIES FOR DIAGNOSIS

Without chromosome studies, most patients with ICF syndrome would be classified as suffering from common variable immunodeficiency (CVID) according to the WHO classification for primary immunodeficiencies (see Chapter 28). ICF syndrome should be considered, therefore, for all patients with B-cell–positive agammaglobulinemia or CVID without a known gene defect, even when facial anomalies are absent. A history of delayed milestones, such as walking and speech, is also suggestive for ICF syndrome. Diagnosis of ICF syndrome can be made by cytogenetic analysis and Southern blot analysis of satellite DNA methylation.

PRENATAL DIAGNOSIS

Prenatal diagnosis of ICF syndrome by mutation detection has been performed successfully in ICF1 patients (Rigolet et al., 2007). Now that the molecular defect for a large proportion of ICF2 patients has been identified as mutations in *ZBTB24* (as discussed below) (de Greef et al., 2011), prenatal diagnosis can be extended to include both genes *DNMT3B* and *ZBTB24*.

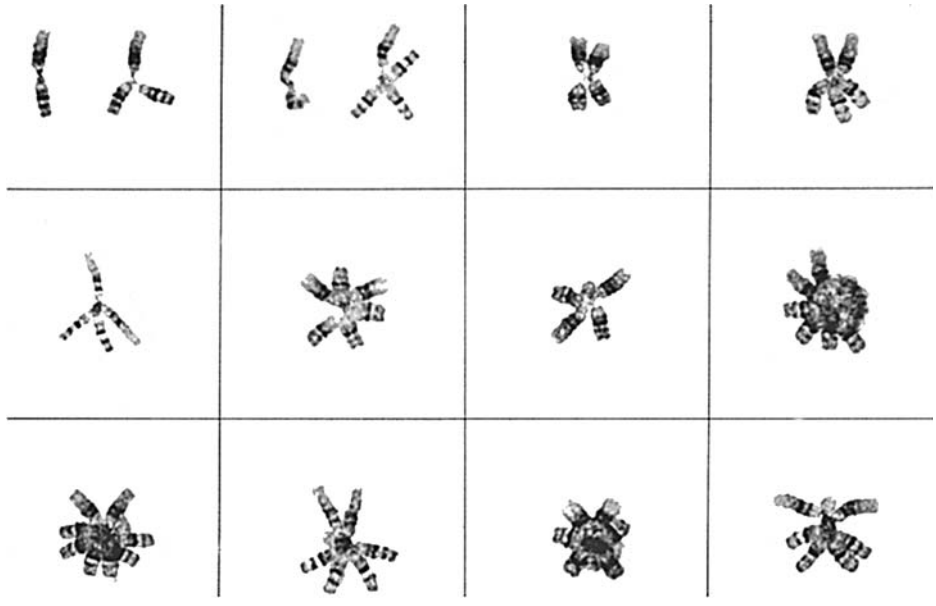

Figure 49.1 Top row: chromosome 1 abnormalities. A, Chromosome 1 with two long arms (down). B, One normal chromosome 1 and one chromosome 1 with three long arms. C, Two chromosomes 1 fused in the paracentric heterochromatin. D, Two chromosomes 1 fused with two short arms (up) and three long arms (down). Row 2: E, Two chromosomes 1 fused in the paracentric heterochromatin, F, Two chromosomes 1 fused with two short arms (left and right upwards) and four long arms. G, Two chromosomes 1 and a piece of chromosome 16 fused in the paracentric heterochromatin. H, A complex rearrangement of both chromosomes 1 and 16 with multiple long arms of both chromosomes. Row 3: I, A complex rearrangement of both chromosomes 1 and 16 with multiple long arms of both chromosomes; J. two short arms of chromosome 1 (up) and 4 long arms of chromosome 1 (down) with a piece of chromosome 16 centrally. K, A complex rearrangement of both chromosomes 1 and 16 with multiple long arms of both chromosomes. L, Two short arms of chromosome 1 (up) and 4 long arms of chromosome 1 (down) with a piece of chromosome 16 centrally.

TREATMENT AND PROGNOSIS

Nearly all ICF patients receive regular infusions of intravenous immunoglobulin (IVIG). This treatment reduces the severity and frequency of infections in most patients. Despite IVIG treatment, however, at least 15 patients died in infancy or in childhood because of infections (Fasth et al., 1990; Fryns et al., 1981; Valkova et al., 1987; C. Weemaes, unpublished observations). Most of these patients suffered from agammaglobulinemia with some T-cell defects, but a patient with only IgA deficiency also died at a young age (11 years) (Tiepolo et al., 1979).

Opportunistic infections with *P. jiroveci* resulting in interstitial pneumonia (PCP), cytomegalovirus, and *Candida* have been described (Bauld et al., 1991; Fasth et al., 1990; Valkova et al., 1987). Prophylactic use of trimethoprim-sulfamethoxazole to prevent PCP seems to be indicated, even when a T-cell defect has not been demonstrated.

Hematopoietic stem cell transplantation should be considered in patients suffering from infections and failure to thrive. It was successful in three such patients (Gennery et al., 2007). Because B cells are defective in ICF syndrome (Blanco-Betancourt et al., 2004), it is important to consider a myeloablative regimen in order to achieve reconstitution of both T and B lymphocytes. Further investigation using mouse models should help to evaluate the efficacy of potential therapies.

MOLECULAR BASIS: MUTATIONS IN *DNMT3B* AND *ZBTB24*

The extremely rare occurrence of the ICF syndrome and the existence of affected consanguineous individuals strongly suggested an autosomal recessive transmission and made the localization of the ICF gene a suitable target for homozygosity mapping. Wijmenga (Wijmenga et al., 1998) performed homozygosity mapping in three consanguineous ICF families: one of Dutch ancestry and two of Turkish ethnicity. This study identified a 9 cM region on chromosome 20q11-q13 that was homozygous in all affected inbred individuals.

Although the etiology of ICF syndrome was not clear at that time, the hypomethylation that is observed in ICF patients suggested a role for DNA methylation in this disorder (Jeanpierre et al., 1993). This hypothesis was further substantiated by the observation that the cytogenetic abnormalities in ICF syndrome could be complemented by fusion of ICF cells to normal cells (Schuffenhauer et al., 1995). Cell fusion also led to a partial restoration of the de novo methylation of ICF satellite 2 and 3 sequences (Hansen et al., 1999), presumably through the activity of a functional de novo DNA methyltransferase from the non-ICF cell. A search of the raw sequence data from human chromosome 20 for the presence of a DNA methyltransferase gene led to the identification of a gene highly homologous to murine *Dnmt3b*. The *DNMT3B* gene was localized to 20q11 within the 9 cM region to which the ICF gene was localized previously. Mutations of this gene in ICF patients confirmed that *DNMT3B* was indeed a gene responsible for ICF syndrome (Hansen et al., 1999; Okano et al., 1999; Xu et al., 1999).

As not all cases of ICF syndrome could be explained by mutations in *DNMT3B*, the search for ICF genes continued. Different from ICF1 patients, with mutations in *DNMT3B*, these *DNMT3B* mutation-negative patients, or ICF2 cases, all show hypomethylation of α-satellite repeat DNA on chromosome 9 in addition to those regions previously shown to be hypomethylated in ICF1 patients (Miniou et al., 1997). By combining homozygosity mapping in consanguineous ICF2 families with exome sequencing, loss-of-function mutations in *ZBTB24* were identified as the underlying cause of 60 to 70 percent of ICF2 patients (de Greef et al., 2011). As one consanguineous ICF patient was excluded for both loci, it is likely that there is at least one more locus involved in the development of ICF syndrome.

DNMT3B GENE STRUCTURE AND MUTATIONAL ANALYSIS

The *DNMT3B* gene spans a region of about 50 kb and encodes a transcript of 4.3 kb representing 23 exons, 22 of which are coding (Xie et al., 1999). Alternative splicing of the gene leads to at least five isoforms: *DNMT3B1*, *DNMT3B2*, *DNMT3B3*, *DNMT3B4*, and *DNMT3B5* (Hansen et al., 1999; Robertson et al., 1999). *DNMT3B* expression can be detected in several tissues but occurs at much higher levels in testis and thymus. The C-terminal region of the corresponding protein (MT3β) contains five highly conserved DNA methyltransferase motifs (I, IV, VI, IX, and X) (Xie et al., 1999) and a motif (VIII) with a much weaker similarity (Hansen et al., 1999). Functions for these motifs in the transmethylation reaction, such as cofactor binding, are inferred from crystallography data for other methyltransferases. The N-terminal region of MT3β contains a cysteine-rich domain that shows homology to the zinc-finger helicase region found in the ATRX protein (Picketts et al., 1996) that might mediate protein–protein or protein–DNA interactions. Closer to the N-terminus of MT3β is a PWWP domain that may also be involved in protein–protein interactions (Stec et al., 2000) but has recently been shown to bind DNA (Qiu et al., 2002).

More than 30 different ICF patients have been subjected to *DNMT3B* mutation analysis and at least 23 different mutations have been discovered (Fig. 49.2a) (reviewed by Hagleitner et al., 2008). ICF mutations in *DNMT3B* can be divided into three classes: (1) nonsense mutations that occur early in the transcript, (2) missense and splice-site mutations in the methyltransferase catalytic domain, and (3) a missense mutation near the PWWP domain. While the nonsense mutations are expected not to result in protein, the second class of mutations lead to proteins with compromised catalytic activity (Gowher and Jeltsch, 2002; Xu et al., 1999). A reported missense mutation near the PWWP domain in a Japanese ICF patient suggests an important role for this motif in MT3β function (Shirohzu et al., 2002). Studies in mice (Okano et al., 1999) have shown that complete MT3β deficiency is embryonic lethal; such lethality might also apply to humans. Consistent with the retention of some essential MT3β activity

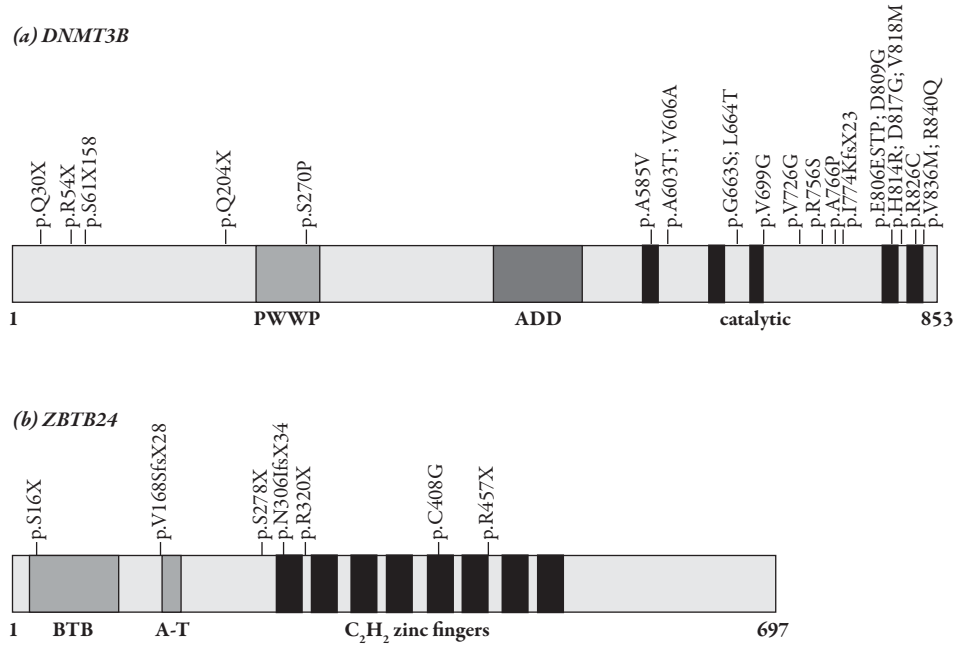

Figure 49.2 ICF mutations in *DNMT3B* (a) and *ZBTB24* (b). Codon numbers for mutations in *DNMT3B* refer to the 3B1 isoform (GenBank accession no. AF156488) (Hagleitner et al., 2008; Hansen et al., 1999). Gene structure and mutation data for *ZBTB24* are described in de Greef et al. (2011).

in ICF patients, all three predicted null mutations described so far are accompanied by a missense mutation in the other allele (Wijmenga et al., 2000; Xu et al., 1999). Bisulfite methylation studies of ICF cells also support residual methyltransferase activity for missense mutant enzymes (Hassan et al., 2001). Furthermore, some of the missense mutations have been shown to produce proteins with significant methyltransferase activity in vitro (Gowher & Jeltsch, 2002). Residual MT3β activity was also observed in mouse models in which specific point mutations observed in ICF patients were introduced in *Dnmt3b* (Ueda et al., 2006).

Based on the rarity of the disease and the finding of consanguinity in some ICF families, the early prediction was that most ICF cases would involve homozygous mutations derived from a limited number of founders. Only 8 of 17 ICF patients were found to have homozygous mutations, however, and all differed from each other; the majority of *DNMT3B* mutations, therefore, appear to have arisen from several unique events. Alternatively, it is possible that the number of gene carriers—and in turn the number of potential ICF patients—is much larger than expected; some mutations may be incompatible with life in certain heterozygous combinations, while others may lead to extremely mild phenotypes that have not been connected to ICF syndrome. Phenotype–genotype relationships have yet to be confidently uncovered because of the limited set of patients with known mutations, many of whom are compound heterozygotes. Additionally, phenotypic variability is likely for any given mutation because the corresponding molecular defects are predicted to derive from epigenetic abnormalities that are intrinsically variable.

DNMT3B FUNCTION

The primary defects leading to phenotypic consequences in ICF are predicted to result from abnormal escape from transcriptional silencing due to lack of methylation by MT3β. Hypomethylation and escape from silencing in ICF cells has been demonstrated for certain genes on the inactive X chromosome (Gartler & Hansen, 2002; Hansen et al., 2000; Tao et al., 2002), the Y chromosome (Hansen et al., 2000), an autosomal repetitive element (Kondo et al., 2000), and an autosomal cancer-testis gene (Tao et al., 2002). Hypomethylation in the promoter region is not sufficient for escape to occur in many cases because silencing is maintained unless accompanied by advanced replication (Hansen et al., 2000). Although it is not clear how these particular genes could be responsible for the ICF phenotype, it is likely that a similar mechanism is responsible for genes that do play key roles in facial development and the immune system.

Abnormal gene regulation could also result from hypomethylation at pericentromeric regions or other repetitive, CpG-rich regions by a mechanism similar to the phenomenon of position-effect variegation found in yeast, *Drosophila*, and mammalian systems (Kleinjan & van Heyningen, 1998; Wakimoto, 1998). Genes of this type would be affected in *cis* because they are within or near repetitive regions that are normally hypermethylated and late replicating. In addition to transcriptional regulation abnormalities, immunoglobulin deficiency in ICF could potentially result from a failure to achieve productive germline rearrangements critical to B- and T-cell development because of hypomethylation within the rearrangement loci (Engler et al., 1993; Mostoslavsky et al.,

1998; Whitehurst et al., 2000). This could lead to defective B-cell differentiation, lack of memory B cells, and impaired B-cell negative selection (Blanco-Betancourt et al., 2004).

In the immune system alone, the list of potential candidate genes for dysregulation with ICF-like consequences is quite long. One hope for finding key genes involved in ICF was the cDNA microarray approach for large-scale studies of gene expression in normal and ICF cells. Such data were expected to help identify key pathways affected in ICF that might be targeted for therapeutic intervention. Several attempts have been made to identify genes that are specifically deregulated in ICF syndrome (Ehrlich et al., 2001, 2008; Jin et al., 2008). Genes involved in diverse functions such as development, chromatin structure and transcriptional activity, signaling, immunity, and defense were identified as transcriptionally deregulated, and many of them could contribute to the primary phenotype of ICF syndrome. Interestingly, in only a few of the genes that were transcriptionally upregulated, subtle demethylation of their promoter regions could be detected. Promoters of some upregulated genes showed clear changes in histone modifications, including loss of repressive chromatin marks such as histone H3 lysine 27 trimethylation and the polycomb repressive complex PRC2 and gain of the active histone H3 lysine 9 acetylation marker (Jin et al., 2008).

Some of these transcriptionally deregulated genes show altered nuclear distribution in ICF LCLs. Some genes in the pseudoautosomal region 2 (PAR2) of human chromosomes X and Y showed an abnormal localization within the chromosome territory when differentially expressed (Matarazzo et al., 2007). In addition, a recent report also indicates that subtelomeric regions are hypomethylated in ICF syndrome, which is associated with abnormally short telomeres and enhanced expression of telomeric-repeat-containing RNA (Yehezkel et al. 2008). Collectively, these results indicate that defects in *DNMT3B* have a much wider genomic implication than previous anticipated from the first observations of pericentromeric defects.

MT3β appears to have several interacting partners (Geiman et al., 2004a, 2004b; Gopalakrishnan et al., 2009; Kim et al., 2002), including other DNA methyltransferases (MT1 and MT3α), histone deacetylases (HDAC1 and HDAC2), heterochromatin protein 1 alpha, components of a condensin complex (hCAP-C, hCAP-E, and hCAP-G), a chromatin remodeling protein (hSNF2H), a centromere protein (CENP-C), and a chromokinesin homolog (KIF4A). These interactions, however, are typically mapped to the N-terminal portion of the protein, whereas most ICF mutations occur in the C-terminal catalytic domains, indicating that the relevance of these interactions for ICF pathology needs further exploration. Interactions with the DNMT3L protein, however, do have clear relevance with respect to ICF mutations. DNMT3L is a DNMT3 family member that, although catalytically inactive itself, stimulates MT3β activity through interaction with the C-terminus. Two reported ICF mutations decrease the affinity between both proteins and strongly decrease the stimulation of MT3β by DNMT3L (Xie et al., 2006).

Also relevant to ICF mutations is the finding that MT3β is SUMOlyated and normally helps localize the protein to chromatin; the S270P ICF mutation in the N-terminal PWWP domain results in an abnormal diffuse nuclear localization and constitutive activation of nuclear factor kappa-B (Park et al., 2008).

ZBTB24 GENE STRUCTURE AND MUTATIONAL ANALYSIS

The *ZBTB24* gene contains 7 exons that span a region of about 22 kb on chromosome 6. It encodes a transcript of 5.5 kb. *ZBTB24* is ubiquitously expressed, but the highest levels of expression can be detected naïve B cells (de Greef et al., 2011). The ZBTB24 protein contains a BTB protein–protein interaction domain (bric-a-bric, tram-track, broad complex), a DNA-binding A-T hook domain, and eight C2H2 zinc-finger domains (Fig. 49.2a). BTB domains can be found at the N-terminus of other zinc-finger proteins, where they are involved in homomeric or heteromeric dimerization (Bardwell & Treisman, 1994) and transcriptional repression (Deweindt et al., 1995). A-T hook domains and C2H2 zinc-finger domains are DNA-binding motifs.

Seven of 11 ICF2 patients, mostly unrelated, were found to have mutations in *ZBTB24*. These mutations create premature stop codons in all but one patient. The remaining mutation replaces a conserved cysteine for a glycine in one of the conserved C2H2 zinc-finger domains of ZBTB24. This strongly suggests that loss-of-function mutations in *ZBTB24* underlie the ICF2 syndrome.

ZBTB24 FUNCTION

Although ZBTB24 has not been studied in detail, it is a member of a family of more than 40 human ZBTB proteins, some of which have been shown to be involved in hematological differentiation (Stogios et al., 2005). Perhaps the most studied ZBTB protein in the context of hematological differentiation is BCL6 (ZBTB27). BCL6 was identified as being deregulated in certain B-cell lymphomas through chromosomal translocations (Ye et al., 1995) and is required for germinal center formation (Dent et al., 1997). Other ZBTB proteins that have been mechanistically linked to hematological development and malignancy are BCL6B (ZBTB28), PATZ1 (ZBTB19), ZBTB7B, and ZBTB32 (Bilic et al., 2006; He et al., 2005; Kang et al., 2005; Manders et al., 2005; Piazza et al., 2004; Sun et al., 2005; Takamori et al., 2004). Future functional studies of ZBTB24 are, therefore, likely to further our understanding of the pathophysiology of ICF syndrome.

ANIMAL MODEL

Additional evidence that MT3α and MT3β do, indeed, have de novo methyltransferase activity came from studies in mice, in which both genes were inactivated by homologous recombination (Okano et al., 1999). The expression levels of *Dnmt3a* and *Dnmt3b* are extremely high in undifferentiated embryonic stem cells but are rapidly downregulated after differentiation such that much lower levels are found in adult somatic tissues. Both *Dnmt3a* and *Dnmt3b* appear to be essential for

mouse development, as the *Dnmt*3b$^{-/-}$ mice die before post-conception day 11.5 and the *Dnmt3a*$^{-/-}$ mice die perinatally. The *Dnmt3a* and *Dnmt3b* genes exhibited some overlapping methylation target sites, but *Dnmt3b* deficiency specifically decreased methylation at pericentromeric minor satellite repeats, similar to the hypomethylation seen in ICF syndrome patients at analogous satellite repeats.

More recently, ICF knock-in mice were generated by introducing two ICF mutations into the murine *Dnmt3b* gene by homologous recombination and the catalytic domain of MT3β was also deleted as part of the study (Ueda et al., 2006). While the deletion model resulted in embryonic lethality similar to the *Dnmt3b* knockout alleles, mice homozygous for the ICF mutations developed to term and had phenotypes comparable with ICF syndrome, including hypomethylation of repetitive DNA, craniofacial anomalies, and T-cell death by apoptosis. Remarkable differences were also noted: while ICF patients typically show severely reduced immunoglobulin counts, these mice show mainly defects in the T-cell lineage (Ueda et al., 2006). In ICF syndrome, T-cell defects are rarely described. Nevertheless, these mice will likely prove useful for further studies of the pathogenic mechanisms underlying this disorder; presumably, mouse models of ZBTB24 deficiency will also contribute to our understanding.

CONCLUDING REMARKS

On the basis of our current knowledge, it is likely that a compromised MT3β methyltransferase leads to hypomethylation of specific chromosomal loci, deheterochromatinization, advanced replication, and transcriptional activation of key genes whose dysregulation affects facial development and the immune system. A compromised ZBTB24 protein presumably affects overlapping genes and/or pathways to bring about the phenotypes shared by ICF1 and ICF2 patients. Discovery of such genes should further our understanding of these phenotypes and of the normal role of these proteins in methylation-dependent transcriptional regulation. Examination of the molecular properties of these proteins and their interacting partners will help explain the apparent specificity for hypomethylation defects and provide candidate genes that might be mutated in ICF patients who were not found to have mutations in either of the two known genes. Although the syndrome appears to be quite rare, increased ascertainment may develop as awareness of ICF increases and diagnosis of immunodeficiency includes more cytogenetic and methylation studies. The ICF syndrome provides one of the first examples of a human disease whose major defect alters the epigenetic structure and regulation of the genome, thus providing us with excellent model systems for study. Because proper epigenetic regulation is crucial for development and differentiation, explication of the epigenetic alterations in ICF and their functional consequences should have implications for a large spectrum of human disease.

50.

INTRODUCTION TO GRANULOCYTE DISORDERS

Karl Welte, Cornelia Zeidler, and David C. Dale

Neutrophils play a major role in orchestrating the inflammatory response, in the resolution of inflammation, and in wound healing, in addition to simply killing microorganisms (Borregaard et al., 2007; Dale et al., 2008). The bone marrow of healthy individuals produces 1 million neutrophils/kg/minute. This is a highly regulated and dynamic process that requires specific hematopoietic growth factors and a functional bone marrow microenvironment. Hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and interleukin-3 (IL-3) stimulate receptor-dependent intracellular signaling pathways that lead to activation of lineage-specific transcription factors (Tenen et al., 1997). In steady state, differentiation depends on the transcription factors LEF-1 and C/EBP alpha (Skokowa et al., 2006), whereas C/EBP epsilon is required for terminal differentiation and expression of secondary granule proteins (Gombart et al., 2005). With stress or infections, C/EBP beta is also required (Hirai et al., 2006).

The entry and exit of neutrophil into and from the bloodstream is also a highly regulated process. Receptor ligand pairs such as VLA-4 binding to VCAM-1 or fibronectin and SDF-1/CXCL 12 (Eash et al., 2009) binding to CXCR-4 retain neutrophils and their progenitors in the marrow. Several chemokines regulate the movement of these cells from the marrow to the blood.

Once released from the marrow, the neutrophil half-life in the blood is only 6 to 10 hours. The cells in the vascular compartment are approximately equally distributed between the circulating and marginal pools. Neutrophils exit from the marginal pool and enter the tissues by first attaching to the vascular endothelial cells and then squeezing out between them. Integrins and selectins expressed on the surface of neutrophils direct these functions. In the tissues neutrophils ingest and kill invading microorganisms through the generation of H_2O_2 and oxygen radicals and the actions of a variety of enzymes stored in the neutrophils' primary and secondary granules. Immunoglobulins and complement proteins facilitate the process of ingestion and killing, which depends primarily on an intact system for generating oxygen radicals. Neutrophils also secrete cytokines and chemokines, such as IL-1, IL-8, TNF, VEGF, and CXCL2, that support resolution of inflammation and healing of damaged tissue (Borregaard et al., 2007; Dale et al., 2008).

This chapter focuses on recognizing neutrophil disorders, both of numbers and functions. Subsequent chapters (51–53) deal in greater detail with the clinical features, pathophysiology, and treatment of these conditions.

NEUTROPENIA

Normally the circulation blood neutrophil count is between 1,800 and 7,000/uL both in children and adults. Neutropenia (neutrophil count <1,800/uL) is easily detected by a routine complete blood count. Severe neutropenia is defined as an absolute decrease in the number of circulating neutrophils in blood to levels below 500/uL (Welte & Boxer, 1997). In most disorders affecting neutrophil numbers, neutropenia is chronic and often severe. The hallmark of severe chronic neutropenia is increased susceptibility to bacterial infections of the oropharynx (particularly the periodontal tissues), the respiratory tract, and the skin. The most common manifestations are mouth ulcers, gingivitis, sinusitis, pharyngitis, cellulitis, and cutaneous abscesses. When neutropenia is very severe and the patient cannot generate neutrophils in response to the stress of infection, abscesses of the lung and liver, other deep tissue infections, and bacteremia may occur.

Neutropenic colitis with invasion by anaerobic pathogens such as *Clostridium* species is a severe and often fatal complication. Bacteremia is otherwise uncommon, unless there is concomitant monocytopenia or other defects in host defenses. The most commonly isolated bacteria from neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria. Fungal infections usually follow periods of antibiotic treatment.

CONGENITAL NEUTROPENIA

Congenital neutropenia (CN) comprises a heterogeneous group of bone marrow failure syndromes characterized by a maturation arrest of myelopoiesis at the level of the promyelocyte/myelocyte stage, with peripheral blood absolute neutrophil counts (ANC) below 0.5×10^9/L. CN is usually recognized when a complete blood count with differential is performed in an infant or young child with recurrent fever and signs and symptoms of recurrent infections (Dale et al., 1993; Welte & Dale, 1996; Welte et al., 2006). In this setting, the differential diagnosis includes alloimmune, autoimmune, or drug-induced neutropenia and viral infections. The most useful assessments are a careful medical history and thorough examination of the patient, review of previous blood counts, if available, and a bone marrow examination. As noted above, in an infant or young child with several days or weeks of severe chronic neutropenia, the finding of "maturation arrest" in the marrow is highly suggestive of the diagnosis of congenital neutropenia (see Chapter 51).

Recent research has permitted a genetic approach to classifying CN (Table 50.1) and has also shed light on the molecular mechanisms controlling the development and function of neutrophils. From a clinical point of view, two major groups of inherited neutropenia disorders can be distinguished: CN without major additional organ system manifestations, and CN occurring as part of multisystem disease. CN is also classified by the pattern of inheritance. For example, autosomal dominant CN is attributable to neutrophil elastase gene (*ELA2*) mutations and represents approximately 50 to 60 percent of all cases of CN (Dale et al., 2000). Because the *ELA2* gene is expressed solely in myeloid tissues, neutrophils are the only tissue affected with mutations of this gene.

Autosomal recessive CN is less common, representing up to 30 percent of patients with CN, depending on the ethnic makeup of the population. The genes associated with autosomal recessive severe CN—for example, *HAX1* (Klein et al., 2007) and *G6PC3* (Boztug et al., 2009)—are widely expressed, and patients with these mutations may have other congenital abnormalities. From a pathophysiological perspective, ineffective production of neutrophils due to cell loss or apoptosis during development is a common feature of these diseases (Dale et al., 2009). Table 50.1 lists genetic mutations associated with CN.

Both autosomal dominant and autosomal recessive CN are now considered as a preleukemic condition, with a cumulative incidence for leukemia estimated as high as 25 percent after 20 years of observation (Rosenberg et al., 2006). The individual risk for each genetic subtype and the genotype–phenotype associations are not yet clear because the number of patients tested for an underlying genetic defect is still limited. Both groups of patients, HAX1-CN and ELA2-CN, develop leukemia in a similar frequency. Acquired G-CSF receptor (*CSF3R*) mutations are detected in approximately 80 percent of CN patients who developed acute myeloid leukemia, suggesting that these mutations are involved in leukemogenesis (Ancliff et al., 2003; Dong et al., 1995; Germeshausen et al., 2007).

CYCLIC NEUTROPENIA

Cyclic neutropenia is a unique form of CN. It is an autosomal dominant disorder characterized by regular oscillations of blood neutrophil counts (between 0 and 2,000/uL), with a usual period length of 21 days. Fever, mouth ulcers, and infections, sometime fatal, are common during the neutropenic periods. More than 80 percent of well-documented cases of cyclic neutropenia are attributable to mutations in the neutrophil elastase (*ELA2*) gene (Horwitz et al., 2007) (Chapter 51).

CONGENITAL NEUTROPENIA ASSOCIATED WITH SYNDROMAL FEATURES

A number of immune deficiency syndromes are associated with neutropenia. Usually, the neutropenia is a secondary and variable feature of the syndrome. In brief, some key features for recognition of these conditions are as follows.

NEUTROPENIA ASSOCIATED WITH LYMPHOID CELL DYSFUNCTION

Reticular dysgenesis is caused by mutations in the adenylate kinase (*AK2*) gene and is characterized by early differentiation arrest in the myeloid lineage associated with severe combined immunodeficiency and sensorineural hearing loss. It is characterized by neutropenia and lymphopenia and defective humoral immunity (Lagresle-Peyrou et al., 2009; Pannicke et al., 2009) (Chapter 18).

Wiskott-Aldrich syndrome is caused by mutations in the *WAS* gene (Chapter 43). In rare cases, neutropenia is associated with activating mutations in the WAS protein and may be the presenting or sole manifestation (Ancliff et al., 2006; Devriendt et al., 2001).

Warts, Hypogammaglobulinemia, Immune deficiency, Myelokathexis (WHIM) syndrome is defined as dysgranulopoiesis associated with hypogammaglobulinemia and dermal papillomavirus infections (warts) (Gorlin et al., 2000). WHIM is caused by mutations in the chemokine receptor gene *CXCR4*, the receptor for SDF-1 (Hernandez et al., 2003). The neutrophils show vacuoles, prominent granules, and nuclear hypersegmentation with pyknotic-appearing nuclear lobes (Chapter 40).

X-linked hyper-IgM syndrome is caused by mutations in the *CD40L* gene that, in addition to neutropenia, cause defects in switching from IgM to IgG, IgA, and IgE (Etzioni et al., 2004) (Chapter 26).

Table 50.1 CAUSES FOR CHRONIC NEUTROPENIA

	GENETIC DEFECT	RECESSIVE (R-CN)	DOMINANT (D-CN)	NEUTROPENIA PLUS
ELA2 CN	*ELA2*	-	+	Preleukemic syndrome
HAX1 CN	*HAX1*	+	-	Preleukemic syndrome
Neutropenia with *WASP* mutation	*WASP*	X-linked	-	Monocytopenia, platelets normal
Neutropenia associated with metabolic syndrome				
Shwachman-Diamond syndrome	*SBDS*	+	-	Exocrine pancreas insufficiency, short stature, bone anomalies, anemia, thrombocytopenia, leukemic transformation
Barth syndrome	*Taz 1*	X-linked	-	Dilated cardiomyopathy, skeletal myopathy, short stature, 3-Methylglutaconic aciduria
GSD 1b*	Glucose-6-phosphate-translocase	+	-	Hypoglycemia, lactic acidosis
G6PC3 CN	*G6PC3*	+	-	Short stature, cardiac or urogenital anomalies, visibility of subcutaneous veins
Neutropenia with lymphoid cell dysfunction				
Congenital neutropenia with *GFI-1* mutation	*GFI-1*	-	+	B-/T-cell deficiency
WHIM syndrome	*CXCR4*	-	+	Myelokathexis, IgG deficiency, warts
Hyper-IgM syndrome	*CD40-L*	X-linked	-	IgG, IgA, IgE deficiency
Reticular dysgenesis	*AK2*	+	-	Severe combined immunodeficiency, sensorineural hearing loss
Neutropenia with pigmentation defects				
Griscelli syndrome	*Rab27a*	+	-	Partial albinism, IgG deficiency despite normal lymphocyte numbers, hemophagocytosis
Chediak-Higashi syndrome	*CHS* gene	+	-	Albinism, T/NK + chemotaxis defect
Hermansky-Pudlack syndrome	*AP3B1*	+	-	Partial albinism, short stature, IgG deficiency, hemorrhagic diathesis
Hermansky-Pudlack-like syndrome	*p14*	+	-	Partial albinism, short stature, IgG deficiency

CN= chronic neutropenia; GSD 1b = glycogen storage disease type 1b

NEUTROPENIA ASSOCIATED WITH PIGMENTATION DEFECTS

Chediak-Higashi syndrome (CHS) (Chediak et al., 1952; Higashi et al., 1954) and Griscelli syndrome (Menasche et al., 2000) have variable degrees of neutropenia and susceptibility to infections. CHS is characterized by oculocutaneous albinism, giant lysosomes in neutrophils, and neuropathy. Hermansky-Pudlak syndrome type 2 (HPS2) is also characterized by decreased numbers of NK cells, and p14 deficiency is characterized by persistently reduced peripheral blood neutrophil counts. In contrast to CN with myeloid maturation arrest, CHS, HPS2, and p14 deficiency show presence of neutrophils in the bone marrow. CHS is caused by mutations in the *CHS* gene; HPS2 by mutations in the *AP3B1* gene (Jung et al., 2006), which encodes an adapter protein involved in shuttling granule proteins; and p14 deficiency by a mutation in the *p14* gene (Bohn et al., 2007), also encoding for an endosomal adaptor protein (Chapter 51).

NEUTROPENIA ASSOCIATED WITH METABOLIC ABNORMALITIES

Glycogen storage disease type Ib (GSD1) is caused by mutations in the glucose-phosphate-translocase gene. GSD1 patients show typical features of glycogen storage disease (hypoglycemia, lactic acidosis, hepatomegaly) (Melis et al., 2005). In contrast, patients with *G6PC3* deficiency caused by mutations in the *glucose-6-phosphatase subunit 3* gene (Boztug et al., 2009) do not develop symptoms of glycogen storage. However, they show increased visibility of superficial veins and developmental defects of the cardiovascular and urogenital systems. The pathophysiological mechanism of neutropenia may be due to endoplasmic reticulum stress and increased apoptosis of myeloid cells (Chapter 51).

EXOCRINE PANCREAS INSUFFICIENCY (SHWACHMAN-DIAMOND SYNDROME)

Patients with Shwachman-Diamond syndrome (SDS) suffer from exocrine pancreas insufficiency, short stature,

chondrodysplasia, and severe neutropenia (Shimamura et al., 2006; Shwachman et al., 1964). SDS is caused by mutations in the *SBDS* gene (Boocock et al., 2003), which leads to defective ribosomal maturation and defective protein synthesis. Patients with SDS are at high risk for developing leukemia (Dror et al., 2002).

DISORDERS OF NEUTROPHIL FUNCTION

Inherited disorders of neutrophil function are attributable to mutations in the many specific components of the neutrophil that are responsible for the formation of granules and granule proteins, the internal and cell surface proteins and energy components necessary for neutrophil trafficking, and the enzymes essential for the metabolic burst and generation of oxygen radical and hypochlorous acid for microbial killing (Chapter 52). Some disorders affect both neutrophil production and function.

Identification of specific defects in neutrophil function is complex. It begins with a complete history and physical examination because many common conditions, such as diabetes, renal and vascular diseases, and conditions causing chronic edema, predispose patients to infections by affecting neutrophil trafficking and function. A history of bacteremia and the specific organisms isolated are useful. Bacteremia with an encapsulated organism is a clue that the patient may have a phagocytic defect, most commonly a defect in immunoglobulins or complement proteins, or in the clearance function of the spleen. It is very important to obtain complete blood counts when the patient is in good health and during illness. Some patients with functional defects, for example CHS, are neutropenic and fail to develop neutrophilia in the face of severe infection. Others, for example patients with leukocyte adhesion deficiency syndrome, have extreme neutrophilia with their recurrent infections. It is critical to perform a careful examination of the blood cells by light microscopy, looking at the presence and size of the granules. Tests of the metabolic burst associated with phagocytosis, as well as screening tests for chronic granulomatous disease, are now widely available, but further cellular and biochemical testing generally requires referral to a research laboratory. Genetic analysis is best performed after consultation with a specialist.

DEFECTS IN FORMATION OF GRANULES AND GRANULE PROTEINS

There are a number of defects in the formation of neutrophil granule and granule proteins. CHS is an autosomal recessive disorder affecting many organ systems, identified readily by the giant granules in neutrophils. In the specific granule deficiency syndrome, an autosomal recessive disorder, the secondary granules and all of their constituents are missing, i.e., lactoferrin, alkaline phosphatase and defensins. The defect can be seen with light microscopy on Wright-stained blood smears. In myeloperoxidase deficiency, standard histochemical staining readily reveals the abnormality.

DEFECTS IN NEUTROPHIL TRAFFICKING

Leukocyte adhesion deficiency syndrome (LAD) (Chapter 53) should be suspected in a child with recurrent high fevers, leukocytosis and neutrophilia, and recurrent soft tissue infections (Arnaout, 1990; Crowley et al., 1980). Characteristically there is evidence of soft tissue inflammation but delay in the formation of pus. LAD I is an autosomal recessive disorder in which neutrophil adhesion, chemotaxis, and ingestion of opsonized microbes are impaired because of mutations in the gene for CD18, ß subunit of the ß2 integrins (Dana et al., 1984). Diagnosis is established by flow cytometry to detect expression of CD18. LAD II is a clinically similar syndrome caused by defective selectin-mediated adhesion due to deficient sialyl-Lewis X ligand, and LADIII is caused by mutations in *Kindlin 3*, which is crucial for β2 integrin adhesiveness (Chapter 53).

In WHIM syndrome, mutations in *CXCR4* result in abnormal trafficking of neutrophils and lymphocytes, resulting in severe neutropenia and lymphopenia, with predominantly apoptotic neutrophils seen in the circulation (Chapter 40).

DEFECTS IN THE METABOLIC BURST AND MICROBIAL KILLING

Patients with defects in the metabolic burst and microbicidal mechanisms usually present with recurrent fevers and pulmonary, gastrointestinal, and cutaneous infections. The hallmark of these disorders is the development of chronic inflammatory granulomas widely distributed in the body. The identity of the organisms causing the infections is helpful in making this diagnosis. For example, in chronic granulomatous disease, infections by fungi, such as *Aspergillus* species as well as *S. aureus* and other catalase-positive microorganisms, are common (Chapter 52).

Several molecular and genetic defects cause a similar syndrome: defects in the components of NADPH-oxidase, G6PD, MPO, glutathione reductase, and glutathione synthetase. Chronic granulomatous disease is an inherited disorder of neutrophil function in which generation of superoxide by the respiratory burst oxidase is absent or markedly deficient (Malech et al., 2007). Definition of the specific defect is important for the prognosis and care of these patients (Chapter 52).

EVALUATION OF PATIENTS WITH DISORDERS OF GRANULOPOIESIS

Many of the phagocyte disorders have similar clinical manifestations, which can even overlap with disorders of lymphocyte function. Patients with an unusual frequency of bacterial infections or with infections with exceptional severity should be evaluated for disorders of granulopoiesis. The first test to consider is a peripheral blood neutrophil count. If the number is sufficient or even elevated, phagocyte function assays should be performed, such as the nitroblue-tetrazolium test, or flow-based assays for superoxide generation or the expression of CD18 surface glycoprotein.

If neutrophil counts are below 500/uL, a neutropenia workup is indicated, starting with a search for antineutrophil

antibodies. If there are no antibodies detectable, bone marrow aspiration should be performed to search for maturation arrest, typical for congenital neutropenias. In addition, genetic testing for mutations in the genes for *ELA2*, *HAX1*, and others should be performed. Cyclic neutropenia is diagnosed by the cyclic pattern of serial blood neutrophil counts. In neutropenias associated with specific syndromes, skeletal anomalies, or skin anomalies (e.g., pigmentation defects), workup for heart or metabolic anomalies should be performed.

51.

SEVERE CONGENITAL NEUTROPENIA

Christoph Klein

CLINICAL FINDINGS

In 1950, the Swedish pediatrician Rolf Kostmann described eight children suffering from lethal bacterial infections due to almost complete absence of mature neutrophil granulocytes (Kostmann, 1950, 1956). The disease was transmitted as an autosomal recessive trait and was characterized by a block in myeloid cell maturation at the stage of promyelocytes (Fig. 51.1a). Historically, this report represents the first description of a human primary immunodeficiency disorder. Affected patients are prone to severe and recurrent bacterial infections such as otitis media, bronchitis, pneumonia, osteomyelitis, or cellulitis (Fig. 51.1b). During long periods of persistent neutropenia (i.e., in untreated conditions), patients are at risk for fungal infections (Al-Kindi et al., 2008; Alvarez-Moya et al., 2009). A characteristic feature of infected sites is the absence of pus. Many patients suffer from chronic gingivitis and tooth decay. In addition, decreased bone mineral density, leading to osteopenia or osteoporosis and an increased propensity to fractures, is a common clinical problem (Borzutzky et al., 2006; Yakisan et al., 1997).

Congenital neutropenia may be an isolated finding or may be seen in association with other syndromal features, such as hypopigmentation, neurocognitive delay, pancreatic insufficiency, cardiac or urogenital malformations, or deficiency of adaptive immunity (Table 51.1). Therefore, a comprehensive clinical examination is mandatory. The identification of genetic defects has started to illuminate the pathophysiology of severe congenital neutropenia (SCN) syndromes and specific risk factors for long-term complications (Klein, 2011). Recent insights into the function of SCN genes have also been made possible by in vivo studies in animal models.

MOLECULAR GENETICS

NEUTROPENIA WITHOUT SYNDROMAL FEATURES

SCN and Mutations in ELA2/ELANE

The team of Marshall Horwitz and David Dale was the first to identify a molecular defect in patients with cyclic neutropenia (Horwitz et al., 1999) and SCN (Dale et al., 2000). Using a genome-wide linkage analysis approach in 13 families with cyclic neutropenia, these investigators identified heterozygous mutations in the gene encoding neutrophil elastase (ELANE—ELA2-neutrophil expressed). ELANE is a serine protease exclusively expressed in myeloid cells and is found as a constitutive protein in azurophilic granules in neutrophil granulocytes. Upon stimulation of granulocytes, ELANE is released and performs a variety of functions. By cleaving bacterial proteins, ELANE serves as a defense mechanism. In addition, ELANE may bind to and cleave host proteins such as N2N, a member of the Notch family of proteins (Duan et al., 2004), G-CSF and G-CSF receptor (Hunter et al., 2003), coagulation factors, and extracellular matrix proteins (Faurschou & Borregaard, 2003). ELANE also displays enzymatic activity inside the cells. Processing of PML-RAR alpha may directly affect the differentiation control of myeloid cells (Lane & Ley, 2003).

So far, more than 50 mutations in *ELANE* have been identified in patients with SCN or cyclic neutropenia (Fig. 51.2) (Horwitz et al., 2007). Mutated ELANE in patients with SCN acts as a dominant-negative factor. *ELANE* mutations can be acquired or transmitted in an autosomal dominant mode(Boxer et al., 2006). A number of families with somatic mosaicism have also been reported (Ancliff et al., 2002; Germeshausen et al., 2001b).

Myeloid cells with mutated ELANE are prone to premature apoptosis (Aprikyan et al., 2003; Grenda et al., 2007; Massullo et al., 2005), yet the mechanisms of increased cell death remain incompletely resolved. Three nonmutually exclusive hypotheses have been raised: (1) disruption of proteolytic activity of ELANE, (2) mislocalization of the mutated protein, and (3) induction of the "unfolded protein response" due to misfolding of the mutated protein (Horwitz et al., 2007; Xia & Link, 2008). The "unfolded protein response" has evolved to protect cells against damaging effects of improperly folded proteins.

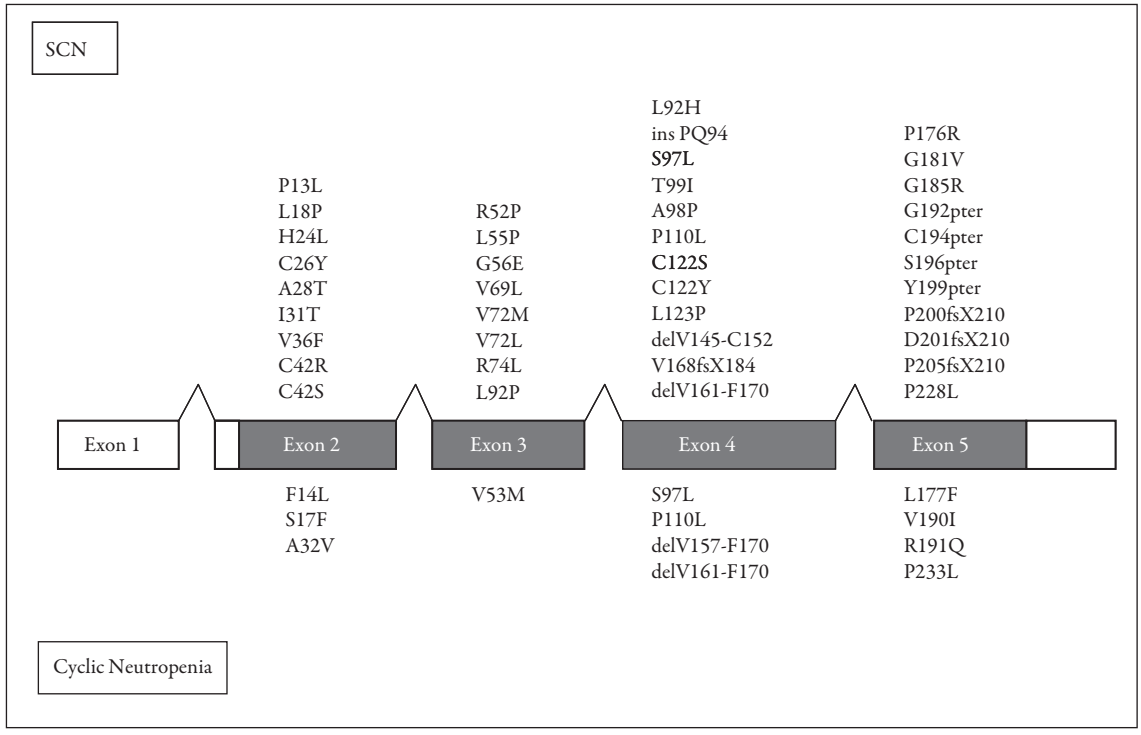

Figure 51.2 Synopsis of known mutations in ELANE.

Nascent proteins destined for secretory vesicles are directed to the endoplasmic reticulum (ER), where protein folding takes place (Ron & Walter, 2007). The unfolded protein response signal cascade is initiated by three ER-localized protein sensors: IRE1 alpha (inositol-requiring 1alpha), PERK (double-stranded RNA-dependent protein kinase [PKR])

-like ER kinase, and activating transcription factor 6 (ATF6). In case of ER stress, these sensors are activated and trigger a complex series of events destined to maintain the homeostasis of the ER and to promote protein folding, maturation, secretion, and ER-associated protein degradation. If these rescue mechanisms fail, the unfolded protein response will initiate apoptosis to protect cells and the organism from dysfunctional or toxic proteins (Zhang & Kaufman, 2008). Both myeloid cell lines engineered to express mutant ELA2 proteins and primary human cells from SCN-ELANE^{mut} patients showed increased biochemical signs of ER stress such as upregulation of Bip and cleavage of XBP-1 (Grenda et al., 2007; Kollner et al., 2006), strongly suggesting that the unfolded protein response is at least partially involved in the pathophysiological mechanisms explaining increased apoptosis in myeloid progenitor cells. Consistent with this hypothesis, neutrophils from patients expressing SCN-ELANE^{mut} show decreased transcription and translation of multiple granule-associated proteins, such as myeloperoxidase, lactoferrin, cathepsin G, and human neutrophil peptide (Donini et al., 2007), the bactericidal protein LL37 (Putsep et al., 2002), and neutrophil elastase itself (Skokowa et al., 2009a).

Despite these insights, many questions remain. For example, why do ELANE^{mut} alleles cause cyclic neutropenia in some patients and SCN in others? Why do some patients respond to G-CSF whereas others are considered nonresponders? Why do ELANE^{mut} alleles predispose to leukemogenesis? These clinically relevant questions must be addressed by future studies.

SCN and Mutations in HAX1

In his seminal paper, Rolf Kostmann noted that SCN was transmitted in an autosomal recessive mode of inheritance (Kostmann, 1950, 1956)—clearly distinct from the autosomal dominant inheritance pattern in ELANE^{mut} patients. This clinical observation was the first clue that SCN must comprise heterogeneous genetic defects. To investigate the molecular etiology of autosomal recessive SCN, we initiated a genome-wide linkage analysis in three consanguineous Turkish families and discovered homozygous mutations in HAX1 (HCLS1-associated protein X-1). Subsequently, biallelic mutations in HAX1 were identified in many SCN patients of various ethnic backgrounds, including the historic Swedish patients described by Kostmann (Fig. 51.3).

HAX1, a ubiquitously expressed antiapoptotic protein, was originally identified as a binding partner of HS1, a protein kinase involved in BCR-mediated signaling (Suzuki et al., 1997). In light of its distant sequence homology to members of the BCL2 family of antiapoptotic molecules and its predominant mitochondrial localization, the hypothesis has been raised that HAX1 might display an antiapoptotic function. In fact, a number of functional studies have confirmed a role for HAX1 in the maintenance of cellular viability (Sharp et al., 2002; Yedavalli et al., 2005). HAX1 regulates the inner mitochondrial membrane potential ($\Delta\Psi_m$), which is maintained by

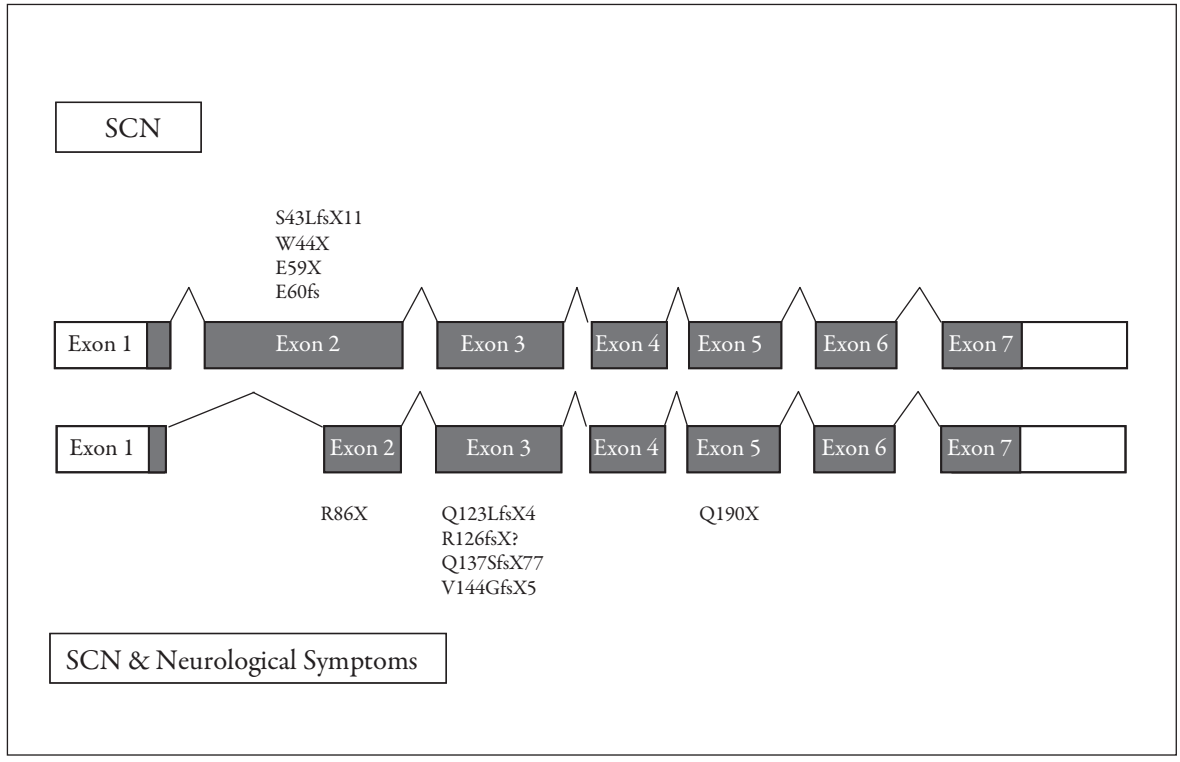

Figure 51.3 Synopsis of known mutations in HAX1.

an active ion gradient. HAX1-deficient cells display a lower threshold to dissipate their inner mitochondrial membrane potential, defining a point of no return for the apoptotic pathway. Loss of $\Delta\Psi_m$ triggers activation of Bax, release of cytochrome c, and activation of death-inducing caspases. In addition to its role in controlling the mitochondrial membrane potential, HAX1 interacts with a great variety of cytosolic proteins, such as cortactin and the polycystic kidney disease protein PKD2 (Gallagher et al., 2000), G alpha13 (Radhika et al., 2004), IL1 alpha (Kawaguchi et al., 2006), and integrin alphavbeta6 (Ramsay et al., 2007), suggesting that HAX1 may also coordinate signaling pathways in the cytosol. A number of viral proteins has also been shown to interact with HAX1—findings that have supported the hypothesis that viruses may have hijacked some of the endogenous functions of HAX1 to escape apoptosis (reviewed in Klein, 2011).

Important insights into the biology of HAX1 came from a murine model system (Chao et al., 2008). Murine hax1 controls parl-dependent conformational changes in htra2/omi, suggesting that hax1 plays a role in presenting htra2 to a proteolytic processing machinery. In contrast to human patients, hax1-deficient mice die shortly after reaching adolescence of neuronal degeneration. This observation has triggered a series of neurological investigations in human HAX1-deficient patients. Of note, Swedish patients originating from the families described by Kostmann suffer from cognitive disorders (Carlsson & Fasth, 2001). Neurological impairment, from mild developmental delay to severe epilepsy and devastating neurodegeneration, has been described in several SCN patients (Ishikawa et al., 2008; Matsubara et al., 2007; Rezaei et al., 2007). Further studies revealed a surprising genotype–phenotype correlation (Germeshausen et al., 2008). Two human HAX1 splice variants are known, giving rise to isoform A and isoform B. Isoform B is characterized by a splice event removing part of exon 2 and is preferentially expressed in neuronal cells. Mutations affecting only isoform 1 (i.e., mutations in exon 2) cause a phenotype restricted to congenital neutropenia, while mutations affecting both isoform 1 and isoform 2 lead to SCN associated with variable degrees of neurological impairment (Carlsson et al., 2008; Germeshausen et al., 2008).

Congenital Neutropenia and Mutations in GFI1

GFI1 (growth factor independent 1) is a zinc-finger transcription factor controlling differentiation of multiple hematopoietic and nonhematopoietic cells. Originally identified as a transcriptional repressor in T cells (Zweidler-Mckay et al., 1996), Gfi1 has become a key regulator of hematopoietic stem cell differentiation, as evidenced by defective myelopoiesis (Hock et al., 2003; Karsunky et al., 2002) and reduced stem cell self-renewal (Hock & Orkin, 2005) in Gfi1-knockout mice. In addition, Gfi1 is necessary to control intestinal endocrine cell differentiation and viability of neuronal cells (Shroyer et al., 2005; Tsuda et al., 2005).

Person et al. described two patients with heterozygous mutations in GFI1 (GFI1N382S), affecting the DNA-interacting domain of GFI1 (Person et al., 2003). Affected patients showed a myeloid maturation arrest, a paucity of mature neutrophils, and a propensity to develop recurrent infections. Recently, a murine model of the $GFI1^{N382S}$ mutant has been studied in greater detail, confirming a dominant-negative

block in granulopoiesis associated with dysregulation of CSF1 and its receptor (Zarebski et al., 2008).

Acting as a transcriptional repressor, GFI1 controls multiple target genes and regulatory micro-RNAs (Hock et al., 2003; Hock & Orkin, 2005; Karsunky et al., 2002; Velu et al., 2009). Several downstream targets of GFI1, such as ELA2 and CEBPe, have an established role in controlling hematopoiesis (Duan & Horwitz, 2003; Zhuang et al., 2006). In addition, Gfi1 controls transcription of the regulatory micro-RNAS miR-21 and miR-196B (Velu et al., 2009), as well as HoxA9, Pbx1, and Meis1 during normal myelopoiesis (Horman et al., 2009). Studies in Gfi1-deficient mice have demonstrated a role in TH2 (Zhu et al., 2002) and TH17 T cells (Zhu et al., 2009). Furthermore, Gfi1 has been implicated in B-cell differentiation (Rathinam & Klein, 2007) and control of autoimmunity (Rathinam et al., 2008). In light of these complex regulatory functions, multiple aberrant pathways may contribute to the phenotype of congenital neutropenia in patients with GFI1 mutations.

Congenital Neutropenia and Mutations in WAS

Loss-of-function WASp mutations cause Wiskott-Aldrich syndrome (Chapter 43). In contrast, gain-of-function mutations in WAS have been associated with a variant of congenital neutropenia (Devriendt et al., 2001). Affected patients carry mutations that affect the autoinhibitory structure of WASp, leading to conformational changes that induce increased actin polymerization. In addition to neutropenia, patients showed variable degrees of lymphopenia, reduced lymphocyte proliferation, and abrogated phagocyte activity (Ancliff et al., 2006). A large pedigree with multiple affected members has highlighted the clinical variability of patients harboring the same mutation (Beel et al., 2009). Interestingly, activating WASP mutations may also lead to myelodysplasia and overt leukemia (Ancliff et al., 2006; Beel & Vandenberghe, 2009). A similar phenotype could be reproduced in vitro using retroviral gene transfer of the mutant WASp (I294T) allele into hematopoietic stem cells (Moulding et al., 2007). This caused enhanced and delocalized actin polymerization throughout the cell, decreased proliferation, and increased apoptosis. Cells became binucleated, suggesting a failure of cytokinesis, and micronuclei were formed, indicative of genomic instability (Moulding et al., 2007). These elegant studies provided an interesting link between WASP as a regulator of the cytoskeleton and the control of cell division.

SCN WITH SYNDROMAL FEATURES

SCN with Lymphoid Deficiency and Inner Ear Hearing Loss—Reticular Dysgenesis

Reticular dysgenesis is an autosomal recessive form of early differentiation arrest in the myeloid lineage associated with severe combined immunodeficiency due to impaired lymphoid development (de Vall & Seynhaeve, 1959). In addition, affected patients suffer from sensorineural hearing loss (Small et al., 1999). Congenital neutropenia in reticular dysgenesis is not responsive to G-CSF (Bujan et al., 1993). Using a genome linkage analysis and candidate gene sequencing approach, mutations in adenylate kinase 2 (*AK2*) have been identified by two independent groups (Lagresle-Peyrou et al., 2009; Pannicke et al., 2009). AK2 is localized in the mitochondrial intermembrane space and may be important in mitochondrial energy metabolism and control of apoptosis via FADD and caspase 10 (Lee et al., 2007). The myeloid phenotype of AK2-deficient patients, in particular with respect to dissipation of the mitochondrial membrane potential, is very similar to HAX1-deficient patients, yet a link between HAX1 and AK2 remains unknown.

Disorders of Glycogen Metabolism

Two distinct but related disorders of neutrophil differentiation and viability have been linked to glucose metabolism. Glycogen storage disease type 1 is a well-known metabolic disorder leading to glycogen storage and hypoglycemia due to mutations in glucose-6-phosphatase (G6PC1). Patients with a related disease, glycogen storage disease type 1b, have metabolic features of glycogen storage disease type 1 and show in addition a phenotype of congenital neutropenia. Glycogenosis type 1b is caused by a mutations in *SLC37A4*, the gene encoding glucose-6-phosphate translocase (G6PT) (Gerin et al., 1997). Systemic complications such as liver adenomas, nephropathy, bone mineral density defect, polycystic ovaries, short stature, and Crohn's-like inflammatory bowel disease are also seen in this disorder, yet clear genotype–phenotype correlations could not be established (Melis et al., 2005). Patients with GSD-1b also show an increased prevalence of thyroid autoimmunity and hypothyroidism (Melis et al., 2007). A mouse model of G6PT deficiency has shed light on the pathophysiology. Murine GSD-Ib neutrophils exhibited increased production of ER chaperones and oxidative stress, leading to increased mitochondria-dependent apoptosis (Kim et al., 2008).

Recently, a novel genetic defect in the glucose-6-phosphate pathway has been discovered, caused by mutations in *G6PC3* (Boztug et al., 2009). In contrast to G6PC1 deficiency and G6PT deficiency, patients with G6PC3 deficiency present with congenital neutropenia and variable developmental disorders affecting the cardiovascular and/or urogenital system, such as atrial septum defect type II, cor triatriatum, or cryptorchidism and ureteral fistulas, respectively. Many patients show a characteristic visibility of subcutaneous veins, potentially due to decreased subcutaneous fat tissue.

G6PC3 is a ubiquitously expressed phosphatase located in the endoplasmic reticulum. In G6PC3-deficient cells, increased ER stress leads to the activation of the "unfolded protein response" and an increased susceptibility to apoptosis via decreased enzymatic activity of GSK3 beta (Boztug et al., 2009). Although functionally linked, G6PC3 deficiency and G6PT deficiency not only have distinct clinical phenotypes but are also different with respect to neutrophil function, suggesting that *G6PC3* and *SLC37A4* have nonredundant functions in their control of glucose metabolism in the ER.

Barth Syndrome

Barth syndrome is an X-linked dominant syndrome characterized by dilated cardiomyopathy, skeletal myopathy, growth deficiency, neutropenia, and 3-methylglutaconic aciduria (Barth et al., 1983; Kelley et al., 1991). The most common clinical presentation is cardiomyopathy in infancy. Bacterial infections secondary to neutropenia may be the first symptom, yet not all patients consistently show decreased neutrophil counts (Spencer et al., 2006).

The disease is caused by mutations in the ubiquitously expressed gene *TAZ*, which encodes tafazzin, a mitochondrial acyltransferase involved in cardiolipin metabolism (Bione et al., 1996). During cardiolipin maturation, phospholipase A removes one saturated acyl chain to generate monolyso-CL (MLCL), while tafazzin replaces it with an unsaturated acyl chain taken from phosphatidylcholine (PC), a process repeated until remodeling is complete (Xu et al., 2006). As a consequence, tafazzin-deficient cells show reduced mature cardiolipin levels and increased levels of monolysocardiolipin. Cardiolipin has been shown to participate in mitochondria-dependent apoptotic steps by serving as a "docking site" for tBid on the mitochondrial membrane (Lutter et al., 2000) and is required for Bax activation and mitochondrial outer membrane permeabilization (Kuwana et al., 2002).

Cardiolipin has been shown to participate in mitochondria-dependent apoptotic steps by serving as a "docking site" for tBid on the mitochondrial membrane and by anchoring caspase-8 for translocation into the mitochondrial membrane (Gonzalvez et al., 2008). Cardiolipin deficiency may therefore lead to decreased sensitivity to apoptosis, and tafazzin knockdown results in increased resistance to apoptosis. In neutrophils, a disassembly of protein complexes at the inner mitochondrial membrane is associated with exposure of phosphatidyl serine on the cell surface (Kuijpers et al., 2003).

Although phosphatidyl serine exposure is usually considered to be a marker for apoptosis, tafazzin-deficient neutrophils show no other apoptotic features and function normally, suggesting that neutropenia may not be caused by increased apoptosis of myeloid precursors or mature neutrophils. Since externalization of phophatidylserine enhances the recognition and engulfment of stressed cells by macrophages (Jitkaew et al., 2009), neutropenia in tafazzin deficiency may result from increased clearance of neutrophils by tissue macrophages (van Raam & Kuijpers, 2009). Thus, tafazzin deficiency, in contrast to HAX1 deficiency, may represent an interesting model system to study extrinsic mechanisms of neutrophil decay.

Congenital Neutropenia and Poikiloderma

A unique genodermatosis associating poikiloderma and neutropenia was reported by Clericuzio et al. in Navajo kindreds (Erickson, 1999). Two additional pedigrees have been published (Mostefai et al., 2008; Van Hove et al., 2005). This autosomal recessive syndrome is characterized by onset of a papular erythematous rash, pigment anomalies, telangiectasia, pachyonychia, hyperkeratosis, and variable degrees of congenital neutropenia. The molecular etiology remains unknown.

Congenital Neutropenia and Peripheral Neuropathy (Charcot-Marie-Tooth 2)

Charcot-Marie-Tooth (CMT) disease is a heterogeneous peripheral neuropathy disorder. CMT2, caused by monoallelic mutations in dynamin-2 (DNM2), has been associated with congenital neutropenia (Bitoun et al., 2008; Zuchner et al., 2005). DNM2 belongs to the family of large GTPases and is part of the cellular fusion-fission apparatus. DNM2 mutant proteins exhibit an altered conformation of the pleckstrin homology domain, thus affecting altered membrane dynamics. It remains to be shown how these aberrations lead to neutropenia.

Cohen Syndrome

Cohen et al. described an autosomal recessive syndrome including obesity, hypotonia, mental deficiency, craniofacial anomalies, and limb and spinal anomalies (Cohen et al., 1973). In the majority of Finnish patients the phenotype also included chorioretinal dystrophy and congenital neutropenia (Chandler et al., 2003; Norio et al., 1984).

Despite the phenotypic heterogeneity, Cohen syndrome is genetically homogeneous—all patients reported have a double mutation of *VPS13B* (*COH1*) (Kolehmainen et al., 2003). The human protein VPS13B is homologous to a yeast protein VPS13, which has a function in protein sorting and intracellular trafficking. However, there is no detailed explanation of how VPS13B deficiency causes the symptoms of Cohen syndrome, including neutropenia. Similar to other congenital neutropenia syndromes caused by aberrant vesicular trafficking (such as CHS, AP3 deficiency, p14 deficiency), Cohen syndrome is not associated with myeloid maturation arrest in the bone marrow.

NEUTROPENIA AND DISORDERS INVOLVING RIBOSOMAL PROTEINS

Infectious complications secondary to congenital neutropenia may be the first clinical presentation of a multisystem disorder characterized by defective ribosomal proteins: Shwachman-Diamond syndrome and cartilage-hair hypoplasia.

SHWACHMANN DIAMOND SYNDROME

Shwachmann-Diamond syndrome (SDS) was initially recognized as a complex syndrome associating exocrine pancreatic insufficiency and bone marrow dysfunction (Bodian et al., 1964; Shwachman et al., 1964). Clinically, most patients present with steatorrhea and failure to thrive. Neutropenia is the most common hematological feature, but anemia and thrombocytopenia may be seen as well. Myeloid cell development is characterized by increased sensitivity to apoptosis (Dror & Freedman, 2001). SDS predisposes to myelodysplasia and leukemia (Dror, 2005; Shimamura, 2006). SDS patients may also present with skeletal problems such as delayed growth and osteopenia (Makitie et al., 2004). Ninety percent of patients

with SDS show biallelic mutations in *SBDS*, a gene localized on chromosome 7q11 encoding a highly conserved protein with poorly defined functions (Boocock et al., 2003). Human SBDS localizes to the nucleolus in a cell-cycle–dependent manner (Austin et al., 2005) and is associated with ribosomal RNA (Ganapathi et al., 2007). Studies in the yeast SBDS ortholog Sdo1 revealed its importance for the release and recycling of the nucleolar shuttling factor Tif6 from pre-60S ribosomes, a key step in 60S maturation and translational activation of ribosomes (Menne et al., 2007). The detailed mechanism underlying the phenotype of neutropenia in SBDS-deficient cells remains enigmatic.

CARTILAGE-HAIR HYPOPLASIA

Cartilage-hair hypoplasia (CHH; McKusick et al., 1965) is a pleiotropic syndrome associating skeletal dysplasia, hypoplastic hair, gastrointestinal dysfunction, neutropenia, and lymphoid immunodeficiency (Lux et al., 1970). The syndrome was first described in the Amish community but is also prevalent in the Finnish population. Like SDS, CHH patients have a predisposition to bone marrow failure and cancer, in particular non-Hodgkin's lymphoma and basal cell carcinoma (Makitie et al., 1999; Taskinen et al., 2008; Thiel et al., 2007). CHH is caused by mutations in *RMRP*, encoding the RNA component of the endoribonuclease RNase MRP. RMRP has an important role in cleavage of RNA in mitochondrial DNA synthesis as well as in nucleolar cleavage of pre-rRNA (Ridanpaa et al., 2001). In view of the marked clinical variability, RMRP mutations should be considered when evaluating patients with combined immune deficiency, regardless of the presence of other manifestations (Kavadas et al., 2008).

Syndromes that Combine SCN or Neutrophil Dysfunction with Hypopigmentation

Some of the granules in neutrophils also belong to a more general class of lysosome-related organelles, sometimes called "secretory lysosomes" (Stinchcombe et al., 2004). Secretory lysosomes serve to sequester, transport, and secrete substances such as pigment and microbicidal peptides. Defects in secretory lysosomes may result in clinical phenotypes associating hypopigmentation and immunodeficiency. Four autosomal recessive traits have been described: Hermansky-Pudlak syndrome (HPS) type 2, Griscelli syndrome (GS) type 2, Chediak-Higashi syndrome (CHS), and p14 (MAPBPIP/ROBLD3) deficiency. Congenital neutropenia is consistently seen in HPS type 2 and p14 deficiency, whereas in GS type 2 and CHS (both discussed in Chapter 53), neutropenia may be absent or intermittent. The original syndrome described by Hermansky and Pudlak (1959) includes primarily hypopigmentation and prolonged bleeding times due to defective platelet granules. There are eight known human genes each of which is mutated in a different recessive form of HPS. Only HPS2, which is caused by a mutation in the gene *AP3B1*, includes a neutrophil dysfunction (Dell'Angelica et al., 1999). The AP3B1 protein is part of the heterotetrameric AP3 complex, which serves as an adaptor for endosomal transport networks. The cargo composition of AP3 in neutrophils is unknown, but Benson et al. suggested that AP3 may be a carrier for ELANE in both dogs and humans (Benson et al., 2003).

In addition to neutrophils, other cells of the immune system, such as NK cells (Enders et al., 2006; Fontana et al., 2006), NKT cells (Jung et al., 2006), and dendritic cells (Sugita et al., 2002), also appear to be affected in AP3-deficient patients.

Recently, a rare syndrome combining neutropenia, lymphoid immunodeficiency, and hypopigmentation was characterized in a single family with four affected children (Bohn et al., 2007). This syndrome is caused by a homozygous point mutation in the 3′ untranslated region of the gene that encodes p14 (MAPBPIP/ROBLD3) (Bohn et al., 2007). Residual p14/ROBLD3 protein likely explains why they can live, while p14-knockout mice are not viable (Teis et al., 2006). Other symptoms of p14/ROBLD3 deficiency include short stature, hypogammaglobulinemia (in particular low IgM serum levels), reduced numbers of B-cell subsets, and defective function of cytotoxic T cells, which may contribute to a general state of immunodeficiency. p14/ROBLD3-deficient neutrophils are defective in bacterial killing (Bohn et al., 2007). p14/ROBLD3 is an endosomal adaptor protein that acts as a scaffold when binding to MP1, enabling MP1 to participate in the ERK signaling cascade (Teis et al., 2002; Wunderlich et al., 2001).

Studies in AP3-deficient and p14/ROBDL3-deficient neutrophils illuminated the critical role of membrane trafficking for neutrophil homeostasis. However, further studies are required to explain the pathophysiology of neutropenia in these rare patients.

THERAPY OF SCN

The most important therapeutic goal in patients with congenital neutropenia is the reconstitution of adequate antibacterial host defense by neutrophil granulocytes. Recombinant human G-CSF (rh-G-CSF) is the first-line therapy of patients with SCN (Bonilla et al., 1989) G-CSF induces differentiation of neutrophil granulocytes and reduces apoptosis via multiple molecular effectors, including nicotinamide phosphoribosyltransferase (NAMPT) and NAD(+)-dependent sirtuin-1 activation (Skokowa et al., 2009b). Since the individual response to rh-G-CSF is quite variable, the dose should be titrated to achieve a protective neutrophil count of more than 1,000 neutrophils/microliter. Most patients respond to subcutaneous administration of rh-G-CSF, using starting doses of 5 microgram/kg/d. Patients who do not respond to even high-dose rh-G-CSF therapy (up to 50 to 100 microgram/kg) are considered poor responders. These individuals are candidates for allogeneic hematopoietic stem cell transplantation (HSCT) as a curative therapeutic strategy. Furthermore, patients developing myelodysplastic syndromes or leukemia should be candidates for allogeneic HSCT.

While allogeneic HSCT is currently the only curative therapy, there is hope that the molecular identification of underlying genetic defects may open horizons for specific

therapeutic approaches using transplantation of genetically modified autologous hematopoietic stem cells in the future.

CONGENITAL NEUTROPENIA AND PREDISPOSITION TO LEUKEMIA

Similar to several other inherited bone marrow failure syndromes, many subtypes of severe congenital neutropenia constitute premalignant conditions with an increased risk of clonal hematopoietic diseases such as myelodysplastic syndrome (MDS) and leukemia (Donadieu et al., 2005; Rosenberg et al., 2006, 2008). Most commonly, acute myeloid leukemia is seen, but patients with onset of acute lymphoid leukemia (Germeshausen et al., 2001a; Yetgin et al., 2008) or chronic myelomonocytic leukemia (Germeshausen et al., 2005) have also been described. The cumulative incidence for malignant transformation in congenital neutropenia after 10 years of G-CSF was 21 percent (Rosenberg et al., 2006). Recent data suggest that there may be no difference in leukemogenic risk for patients with mutations in HAX1 and ELA2 (Zeidler et al., 2009). In contrast, in certain subtypes of congenital neutropenia (e.g., G6PC3 deficiency, p14/ROBLD3 deficiency, AP3 deficiency), leukemic transformation has never been observed to date. Future studies will have to show whether the risk of clonal hematopoietic disorders depends on the genetic subtype.

Various acquired somatic mutations have been identified in hematopoietic cells of patients with SCN. Monoallelic mutations in the G-CSF receptor, encoded by the gene *CSF3R*, appear to play a key role in driving myelopoiesis. Nonsense mutations in *CSF3R*, truncating the distal cytoplasmic portion of the G-CSF receptor, are present in up to 40 percent of SCN patients and are strongly associated with the development of MDS/AML (Germeshausen et al., 2007). Of note, mutations in *CSF3R* may also be present prior to therapy with rh-G-CSF. The molecular pathophysiology of *CSF3R* mutations are under active investigation. Truncated mutants of the G-CSF receptor lack responsiveness to negative feedback loops (Hermans et al., 1999; van de Geijn et al., 2004). For example, deficient binding of SOCS3 may lead to misrouting of the G-CSF receptor and consecutively increased activation of STAT3/STAT5 (Irandoust et al., 2007; van de Geijn et al., 2004). Furthermore, deficient negative signaling via SHIP and cytokine-inducible Src homology 2 protein (CIS) (Hunter et al., 2004) may contribute to increased signaling via the G-CSF receptor. Using single-cell analysis of human bone marrow samples, Germeshausen et al. documented that CSF3R mutations are acquired in multipotent hematopoietic progenitor cells in congenital neutropenia patients and confer a survival advantage in myeloid progenitor cells (Germeshausen et al., 2009). Similar results were seen in a murine model system in which hematopoietic stem cells were transduced with vectors encoding a truncated G-CSF receptor. In competitive repopulation experiments, G-CSF-R^{mut} stem cells outgrew normal stem cells in a G-CSF–dependent manner (Liu et al., 2008). These studies document the pathogenic role of mutated G-CSF receptors as one critical event in the complex pathway of leukemogenesis. However, *CSF3R* mutations are not sufficient for driving leukemogenesis. This is illustrated by a recent report describing a large multigeneration pedigree in which an activating mutation in *CSF3R* has been found (Plo et al., 2009). Twelve of 16 members showed a point mutation in the G-CSF receptor (T617N), leading to chronic neutrophilia secondary to constitutive signaling via the G-CSF receptor. Only one patient developed an atypical myelodysplastic syndrome, suggesting that continuous activation via the G-CSF receptor may only represent a weak predisposing factor for clonal outgrowth.

Considering the risk of leukemogenesis in SCN patients, it has become clinical routine to screen for the onset of *CSF3R* mutations regularly (at yearly intervals). Mutations in *CSF3R* may be a first molecular signature preceding the development of a clonal disorder but do not justify the clinical diagnosis of MDS/AML. Additional molecular and cytogenetic aberrations commonly involve partial or complete losses of chromosome 7, activating RAS mutations, or abnormalities of chromosome 21 (Freedman et al., 2000). More comprehensive mutational profiling in 14 patients with AML/MDS on the basis of SCN revealed that the common mutations occurring in de novo AML (involving *FLT3, KIT, JAK2* genes) are not seen in leukemia cells arising in patients with SCN (Link et al., 2007). These findings suggest that the mechanisms governing leukemogenesis in SCN patients may be distinct from those molecular mechanisms controlling leukemogenesis in non-SCN patients.

CONCLUSIONS AND PERSPECTIVE

Despite the great progress that has been made in the field, many questions remain. First, patients with congenital neutropenia continue to suffer from severe and long-term complications, such as acute and chronic infections and subsequent organ damage. Of great clinical relevance, many patients are prone to develop myelodysplasia or leukemia. Second, in many patients the molecular etiology cannot yet be identified and the specific implications of defined genetic defects remain mysterious. At present, many published studies are Eurocentric and tend to neglect non-Caucasian ethnic groups, in whom other genetic defects may prevail. Third, the molecular pathophysiology of congenital neutropenia is far from being resolved—in particular, the epistatic relationships between defined genetic defects remain enigmatic. Finally, the only curative therapeutic approach consists of allogeneic HSCT, a procedure associated with severe morbidity and mortality. Novel gene-based therapies are only starting to be investigated in preclinical systems. Thus, a concerted global effort is needed to improve the diagnosis and therapy of patients with congenital neutropenia.

ACKNOWLEDGMENT

I am indebted to many physicians and scientists around the world contributing to the concerted effort to elucidate the genetic and pathophysiological aspects of congenital

neutropenia, including the members of the European and American branches of the International SCN Registry. I apologize for not citing many important references due to space constraints. This work was sponsored by the Deutsche Forschungsgemeinschaft (Gottfried-Wilhelm-Leibniz program) and the Bundesministerium für Bildung und Forschung (German PIDNET).

52.

CHRONIC GRANULOMATOUS DISEASE

Dirk Roos, Steven M. Holland, and Taco W. Kuijpers

Chronic granulomatous disease (CGD) is an uncommon congenital immunodeficiency seen in approximately 1 in 250,000 individuals. It is caused by a profound defect in a burst of oxygen consumption that normally accompanies phagocytosis in all myeloid cells (neutrophils, eosinophils, monocytes, and macrophages). This "respiratory burst" involves the catalytic conversion of molecular oxygen to the oxygen free-radical superoxide (O_2^-), which in turn gives rise to hydrogen peroxide (H_2O_2), hypochlorous acid (HOCl), and hydroxyl radical (•OH). These oxygen derivatives play a critical role in the killing of pathogenic bacteria and fungi. As a result of the failure to activate the respiratory burst in their phagocytes, the majority of CGD patients suffer from severe recurrent infections, the most common of which are pneumonia, lymphadenitis, cutaneous and hepatic abscesses, osteomyelitis, and septicemia. These severe infections usually become apparent during the first year of life and are caused predominantly by *Staphylococcus aureus*, *Aspergillus* species, enteric gram-negative bacteria, *Serratia marcescens*, *Burkholderia* (*Pseudomonas*) *cepacia* complex, or bacillus Calmette-Guérin (BCG). In addition, CGD patients have diffuse granulomas (presumably caused by microbes) that can become large enough to cause obstructive or painful symptoms in the esophagus, stomach, or biliary, urogenital, or pulmonary system.

While all CGD patients share the severe defect in the respiratory burst, there is substantial heterogeneity in the molecular mechanisms responsible. The enzyme that catalyzes the respiratory burst, NADPH oxidase, consists of at least five subunits (designated *phox* for phagocyte oxidase): gp91^{phox} and p22^{phox} (the two membrane-bound subunits of a low-potential flavocytochrome *b*, termed flavocytochrome b_{558}, that is the redox center of the oxidase) as well as three cytosolic oxidase components, p40^{phox}, p47^{phox}, and p67^{phox}. CGD is caused by a defect in any one of these five components. Mutations in the gp91^{phox} gene (*CYBB* on chromosome Xp21.1) cause the X-linked recessive form of the disease that affects about 70 percent of all CGD patients. As expected from the genetics, the overwhelming majority of X-linked patients are males. The remaining 30 percent of cases are inherited in an autosomal recessive manner in which males and females are equally affected. These patients have mutations in the genes encoding p40^{phox} (*NCF4* on chromosome 22q13.1; one patient known), p47^{phox} (*NCF1* on chromosome 7q11.23; about 20 percent of cases), p67^{phox} (*NCF2* on chromosome 1q25; about 5 percent of cases), or p22^{phox} (*CYBA* on chromosome 16q24; about 5 percent of cases). Deletions, insertions, splice-site defects, nonsense mutations, missense mutations, and, in rare cases, regulatory mutations have been identified in the five types of CGD at the molecular genetic level. With the exception of p47^{phox}-deficient patients, who are often homozygous for a GT deletion at the beginning of exon 2 in *NCF1*, many CGD patients have mutations unique to their families. The diversity of these mutations and the multiple genes affected provide an explanation for the genetic, biochemical, and clinical heterogeneity of CGD.

In two separate reports in 1957, Landing and Shirkey as well as Good et al. described a new syndrome of recurrent bacterial infections in boys that were associated with pigmented lipid-laden histiocytes in visceral organs, diffuse granulomas, and normal immunoglobulin levels (Berendes et al., 1957; Landing & Shirkey, 1957). The syndrome was originally referred to as "fatal granulomatous disease of childhood" because most patients died at early ages from severe infections that responded poorly to even the most aggressive therapy (Berendes et al., 1957; Bridges et al., 1959). Over the ensuing several decades, the prognosis for children afflicted with this rare disorder has steadily improved because of an increasing understanding of its molecular and clinical features and the

development of more active antibacterials and antifungals. Fatal granulomatous disease is now known by its more upbeat appellation, *chronic granulomatous disease* (CGD). What is remarkable about the early reports on CGD is the extent to which the clinical and genetic observations in a relatively small number of patients have held true; since then over 2,000 additional patients have been identified and, in numerous cases, reported in the literature.

Because the most striking hallmark of the early cases of CGD was unresolved bacterial and fungal infections, investigators were drawn to study the function of granulocytes from these patients. Indeed, patient neutrophils demonstrated markedly abnormal killing of organisms such as *S. aureus* and *Escherichia coli* in in-vitro assays (Quie et al., 1967). This defect was not due to an immunoglobulin or complement deficiency in patient serum, nor to an abnormality in neutrophil chemotaxis, ingestion, or degranulation. Patient neutrophils also contained normal levels of lysosomal proteins and degradative enzymes. The first clue to the underlying molecular defect came in 1959 in a seminal report by Sbarra and Karnovsky. It had been known since 1933 that neutrophils substantially increase their consumption of oxygen concomitant with phagocytosis of microbes (Baldridge & Gerard, 1933), and it had been assumed that this was due to increased energy metabolism. Sbarra and Karnovsky demonstrated, however, that the oxygen was not used for mitochondrial respiration but was instead utilized for the production of potentially microbicidal molecules such as hydrogen peroxide. This set the stage for the report in 1967 that CGD neutrophils did not undergo this respiratory burst when bacteria were ingested (Holmes et al., 1967). A subsequent report in 1973 identified the oxygen radical superoxide (O_2^-) as the initial product formed from the oxygen consumed in the respiratory burst and as the precursor of the other microbicidal oxygen derivatives (Babior et al., 1973). CGD neutrophils were found not to generate superoxide (Curnutte et al., 1974). The absence of the respiratory burst and its various products (such as superoxide and hydrogen peroxide) was then used as the defining characteristic of CGD and remains the cornerstone for its diagnosis today. Interestingly, one of the earliest assays used to measure respiratory burst activity in phagocytes, the nitroblue tetrazolium (NBT) dye reduction test, is still widely used for detecting CGD (Baehner and Nathan, 1968).

The NBT test also proved to be a powerful tool in defining the genetics of CGD. When used to stain neutrophils adherent to a microscope slide, the NBT "slide" test revealed that many of the mothers of affected males had two populations of cells: one that underwent a respiratory burst and stained positive, and another that failed to reduce the dye and therefore resembled the defective cells in the patient. While this finding indicated that CGD could be inherited in an X-linked recessive fashion, an autosomal recessive mode of inheritance was suggested by pedigrees with females suffering from a nearly identical syndrome of recurrent infections and absent respiratory burst, but normal respiratory burst in neutrophils from patients' mothers (Azimi et al., 1968; Quie et al., 1968).

Before this confusing genetic picture could be clarified, it was first necessary to identify the enzyme responsible for the respiratory burst. This proved to be a membrane-bound NADPH oxidase (Curnutte et al., 1975). An important breakthrough occurred in 1978 when Segal et al. found that a low-potential cytochrome *b* was undetectable in the neutrophils from four CGD patients (Segal et al., 1978). A multicenter European study of the prevalence of cytochrome *b* deficiency in a group of 27 CGD patients revealed that the cytochrome was undetectable in all 19 males who had X-linked CGD whereas it was present in normal levels in all 8 patients (7 females and 1 male) who appeared to have autosomal recessive inheritance (Segal et al., 1983). It thus appeared that cytochrome *b* (termed cytochrome b_{-245} or b_{558} to reflect its –245 mV midpoint potential or its 558-nm alpha absorption peak, respectively) was an important component of the NADPH oxidase and that X-linked CGD could be explained by its deficiency. The defect in autosomal recessive CGD remained unknown, and the picture was complicated by the identification of patients with autosomal recessive inheritance of the disease who had undetectable levels of cytochrome b_{558} (Weening et al., 1985b). Thus, at least three distinct forms of CGD appeared to exist—X-linked, cytochrome *b*-negative (X^0); autosomal recessive, cytochrome *b*-positive (A^+); and autosomal recessive, cytochrome *b*-negative (A^0)—as conclusively demonstrated by complementation studies in which monocytes from pairs of these three groups of patients were fused with each other and acquired NADPH oxidase activity (Hamers et al., 1984; Weening et al., 1985b).

One of the other major breakthroughs in unraveling the mystery of the genetic heterogeneity of CGD was the discovery in several laboratories of a cell-free system for activating NADPH oxidase (Bromberg & Pick, 1984; Curnutte, 1985; Heyneman & Vercauteren, 1984; McPhail et al., 1985). Studies with this system revealed that both the plasma membrane and cytosol fractions were required for oxidase activity. In the X-linked and the autosomal recessive forms of cytochrome b_{558} deficiency, it was the membrane fraction that was defective in the cell-free system (Curnutte, 1985; Curnutte et al., 1987), whereas in the autosomal recessive, cytochrome b_{558}-positive patients the cytosol was devoid of activity (Curnutte et al., 1988). The identities of the missing or defective proteins came to light in parallel with these findings through the convergence of several lines of investigation. First, Orkin et al. identified the gene affected in X-linked CGD, without knowledge of its protein product, through restriction fragment length polymorphism (RFLP) studies that localized the gene to Xp21 and the study of two patients with X-linked CGD who had small interstitial deletions within this region of the X chromosome (Baehner et al., 1986; Royer-Pokora et al., 1986). Second, Jesaitis, Parkos, et al. (Parkos et al., 1987) and Segal (1987) found that cytochrome b_{558} is a heterodimer composed of a heavily glycosylated 91-kDa subunit (termed β) and a nonglycosylated 22-kDa component (termed α). The 91-kDa subunit was found to be identical with the product of the X-CGD gene identified by Orkin et al. (termed *CYBB*) (Dinauer et al., 1987; Teahan et al., 1987), whereas the α subunit gene (termed *CYBA*) was localized to chromosome 16q24 and found to be defective in autosomal recessive, cytochrome b_{558}-negative patients (Dinauer et al., 1990;

Parkos et al., 1988). Finally, selected pairs of defective cytosols from patients with autosomal recessive, cytochrome b_{558}-positive CGD were found to complement each other in the cell-free activation system and to restore near-normal activity (Curnutte et al., 1989; Nunoi et al., 1988). Two cytosolic complementation groups were thus defined by this method, and the deficient proteins were identified as two novel myeloid-specific polypeptides—one that was 47 kDa in mass and the other 67 kDa (Leto et al., 1990; Nunoi et al., 1988; Volpp et al., 1988). In a cooperative study, the 47-kDa protein proved undetectable in 22 of 25 CGD patients with defective cytosols, whereas the 67-kDa polypeptide was absent in the remaining 3 patients (Clark et al., 1989). The gene encoding the 47-kDa component (termed *NCF1*) maps to 7q11.23 and the 67-kDa gene (termed *NCF2)* localizes to 1q25, findings consistent with the autosomal recessive mode of inheritance for each of these deficiencies in CGD (Francke et al., 1990).

A CGD-like syndrome caused by a defect in a third cytosolic component ($p40^{phox}$), in the activation mechanism of the NADPH oxidase (Rac2 deficiency), or by a shortage of substrate supply for the oxidase (glucose 6-phosphate dehydrogenase [G6PD] deficiency) has to be considered for differential diagnosis (see below).

CLINICAL AND PATHOLOGICAL MANIFESTATIONS

Given the key role that the products of the respiratory burst plays in host defense, it is not surprising that patients with CGD suffer from a variety of recurrent bacterial and fungal infections. These infections occur most commonly in organs in contact with the outside world—the lungs, gastrointestinal tract, and skin, as well as the lymph nodes that drain these structures. Because of both contiguous and hematogenous spread of infection, a wide range of other organs can be affected, most notably the liver, bones, kidneys, and brain.

In approximately two thirds of patients, the first symptoms of CGD appear during the first year of life in the form of infections, dermatitis (sometimes seen at birth), gastrointestinal complications (obstruction or intermittent bloody diarrhea due to colitis) (Johnston & Newman, 1977), and a failure to thrive. The clinical picture can be quite variable, with some infants suffering from several of these complications, whereas others appear far less ill. In some cases, the presenting symptoms of CGD can be mistaken for pyloric stenosis, food or milk allergy, or iron-deficiency anemia. In general, infants with X-linked CGD tend to present earlier and with more dramatic symptoms than infants with the autosomal recessive forms of the disease, especially $p47^{phox}$ deficiency (Gallin et al., 1991; Jones et al., 2008; Margolis et al., 1990; Martire et al., 2008; Van den Berg et al., 2009; Weening et al., 1985a; Winkelstein et al., 2000). In a small but noteworthy subset of patients, the diagnosis of CGD is not made until the teenage or adult years because of the mildness or lack of clinical symptoms, as discussed below.

The full spectrum of CGD is summarized in Table 52.1. Despite the rarity of CGD, a number of investigators have either reviewed or assembled large series of patients from the United States, Europe, and Japan (Cohen et al., 1981; Forrest et al., 1988; Gallin et al., 1983; Hayakawa et al., 1985; Hitzig and Seger, 1983; Johnston & Newman, 1977; Jones et al., 2008; Martire et al., 2008; Mouy et al., 1989; Tauber et al., 1983; Van den Berg et al., 2009; Winkelstein et al., 2000). The approximately 1,500 patients represented by these studies provide a striking picture of the multiple manifestations of the disease. As shown in Table 52.1, *S. aureus*, *Aspergillus* species, enteric gram-negative bacteria (including *S. marcescens* and various *Salmonella* species), and *B. cepacia* complex (previously termed *P. cepacia*) are the most frequently encountered pathogens. Most CGD pathogens share the property of producing catalase; as such, they degrade the hydrogen peroxide that they themselves generate within the phagolysosome, thereby failing to complement the peroxide-starved CGD phagocytes. It was therefore suggested that catalase-negative organisms, by supplying the CGD phagocytes with microbial hydrogen peroxide, might complement the hydrogen peroxide deficit in CGD phagocytes, thus inducing killing of the microbes themselves (Mandell & Hook, 1969). Catalase production was thus thought to be an important microbial pathogenicity factor in CGD. However, this hypothesis must be viewed in the context that the majority of all pathogens contain catalase (with the important exception of streptococci). This view has been further challenged by the retained virulence of *Aspergillus* and staphylococci rendered genetically deficient for catalase production (Chang et al., 1998; Messina et al., 2002).

Pneumonia is the most common type of infection encountered in CGD in all age groups and is typically caused by *S. aureus*, *Aspergillus* species, *B. cepacia*, and enteric gram-negative bacteria (Fig. 52.1). If the pneumonia is already severe or the patient fails to respond promptly to the empiric regimen, more invasive approaches are warranted to establish the diagnosis, such as needle biopsy, bronchoscopy, or open lung biopsy. Rarer pathogens requiring special types of treatment (for example, *Nocardia*) are usually only identified by these more aggressive approaches. One of the more problematic pulmonary pathogens is *B. cepacia* complex (previously divided into genomvars, now recognized as multiple species, including *B. cepacia*, *B. multivorans*, *B. cenocepacia*, *B. vietnamiensis*, *B. stabilis*, *B. ambifaria*, *B. dolosa*, *B. anthina*, and *B. pyrrocinia*), as well as the closely related organisms *B. gladioli*, *B. mallei*, *B. pseudomallei*, and *B. pickettii.* These bacteria are unusually virulent in CGD patients and have come to be identified as one of the causes of fatal pneumonias in these patients (Speert et al., 1994). Contributing to this mortality is the fact that many strains of *Burkholderia* are not adequately eliminated during empiric treatment of CGD infections, because *Burkholderia* species are generally resistant to aminoglycosides and some also to ceftazidime. More importantly, cultures of *Burkholderia* may grow slowly, resulting in late diagnosis.

Aspergillus and other fungal infections of the lung also pose difficult challenges because they typically require prolonged treatment (3 to 6 months). If possible, it is important to determine the source of the *Aspergillus* in the patient's environment so that the risk of reexposure can be minimized, such

Table 52.1 INFECTIONS, CHRONIC CONDITIONS, AND ORGANISMS ASSOCIATED WITH CGD*

INFECTIONS	PERCENT OF INFECTIONS	CONDITION	PERCENT OF CASES	INFECTING ORGANISMS	PERCENT OF ISOLATES

*The relative frequencies of different types of infection in CGD are estimated from data pooled from several large series of patients in the United States, Europe, and Japan (Cohen et al., 1981; Forrest et al., 1988; Gallin et al., 1983; Hayakawa et al., 1985; Hitzig & Seger, 1983; Johnston & Newman, 1977; Jones et al., 2008; Martire et al., 2008; Mouy et al., 1989; Tauber et al., 1983; Winkelstein et al., 2000; Van den Berg et al., 2009). These series encompass approximately 1,500 CGD patients after accounting for overlap between reports. The list of infecting organisms is also arranged according to data in these reports and is not paired with the entries in the first column.

†These infections are most frequently seen at the time of presentation.

Figure 52.1 Chest X-ray of a male patient with CGD and fatal *Aspergillus* infection.

as exposure to dirt, manure, leaves, mulch, or other decaying organic matter.

Cutaneous abscesses and lymphadenitis represent the next most common types of infection in CGD and are typically caused by *S. aureus*, followed by various gram-negative organisms, including *B. cepacia* complex and *S. marcescens* (Color Plate 52.I). These infections may respond slowly to antimicrobial therapy and often require incision and drainage for resolution. Recurrent impetigo, frequently in the perinasal area and caused by *S. aureus*, usually requires prolonged courses of oral and topical antibiotics to clear. Hepatic (and perihepatic) abscesses are also quite common in CGD and are typically caused by *S. aureus.* Patients usually present with fever, malaise, and weight loss. Liver function tests are often normal. Resolution may require surgical drainage or excision of the lesion as well as several months of parenteral antibiotics. A recent report cites combined steroid and antibiotic therapy for staphylococcal liver abscesses in CGD patients (Leiding et al., 2011). Osteomyelitis is another important infection in CGD and can arise from hematogenous spread of organisms (*S. aureus*, *Salmonella* spp., *S. marcescens*) or contiguous invasion of bone, typically seen with non-*fumigatus Aspergillus* pneumonia, such as *Aspergillus nidulans* spreading to the ribs or vertebral bodies (Segal et al., 1998). Perirectal abscesses are also common in CGD patients and once formed can persist for years despite aggressive antimicrobial therapy and fastidious local care. Other important but less commonly seen infections in CGD are summarized in Table 52.1.

Not all encounters with microorganisms in CGD result in overt pyogenic infections, as stalemates may develop between the pathogen and the patient's leukocytes. In these cases, chronic inflammatory cell reactions consisting of lymphocytes and histiocytes develop, which can then organize to form granulomas, one of the hallmarks of CGD and causing various clinical symptoms of obstruction.

Another important type of chronic inflammation in CGD is a form of inflammatory bowel disease that closely resembles Crohn's disease and affects 10 to 43 percent of patients (Marciano et al., 2004a). While the colon is typically involved, the ileum and other parts of the gastrointestinal tract can be affected. The symptoms can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can even necessitate colectomy (Ament & Ochs, 1973). Other types of chronic inflammation include gingivitis, chorioretinitis or uveitis, glomerulonephritis, and—rarely—destructive white matter lesions in the brain (Table 52.1) (Frifelt et al., 1985; Hadfield et al., 1991; Martyn et al., 1972) and discoid or even systemic lupus erythematosus (Manzi et al., 1991; Sillevis Smitt et al., 1990a). The eye problems are only rarely of clinical importance or progressive of nature (Buggage et al., 2006; Goldblatt et al., 1999; Palestine et al., 1983).

Lymphadenopathy, hepatosplenomegaly, and eczematoid dermatitis are also common features of CGD and are most frequently encountered in infants and children. Children with CGD are typically anemic, with hemoglobin levels in the 8 to 10 g/dL range and with microcytic erythrocyte indices. The anemia is most likely due to the chronic disease state and, not surprisingly, responds poorly to oral iron therapy. However, iron absorption is also impaired in CGD, perhaps reflecting inflammatory bowel disease. Some X-linked CGD patients have McLeod syndrome, a mild hemolytic anemia characterized by acanthocytosis and weak or absent expression of Kell antigens (Marsh & Redman, 1987). McLeod syndrome is caused by interstitial deletions in the X chromosome that affect both the gene for gp91^{phox} (*CYBB*) and the nearby *Xk* gene that encodes a 37-kDa erythrocyte membrane protein necessary for expression of Kell antigens.

Carriers of CGD, whether of the X-linked form or any of the three main autosomal recessive forms, are usually asymptomatic, with three important exceptions. First, roughly half of X-linked carriers have either recurrent stomatitis or moderately severe aphthous ulceration or both. Second, in a small percentage of X-linked carriers, there can be an unusually high degree of inactivation of the normal X chromosome in the myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10 percent of the cells function, then the carrier has an increased risk of infection (usually mild) (Curnutte et al., 1992; Mills et al., 1980). Third, approximately one quarter of X-linked carriers develop discoid lupus erythematosus, characterized by discoid skin lesions on the sun-exposed regions such as the face, shoulders, arms, upper chest, and back. This syndrome typically becomes apparent in the second decade of life, can range from mild (common) to fairly intense, usually responds well to hydroxychloroquine, and does not appear to progress to systemic lupus erythematosus (Brandrup et al., 1981; Manzi et al., 1991; Schaller, 1972;

Sillevis Smitt et al., 1990b; Yeaman et al., 1992). Discoid lupus erythematosus has not been associated with the carrier state in any of the autosomal recessive forms of CGD. The underlying mechanism responsible for discoid lupus in X-linked CGD carriers is not known, although it has been hypothesized that autoantibodies to antigens from incompletely destroyed microbes (derived from the defective subpopulation of neutrophils) may be responsible (Manzi et al., 1991).

COMPOSITION, ACTIVATION, AND FUNCTION OF THE NADPH OXIDASE

COMPOSITION OF THE NADPH OXIDASE

The phagocyte NADPH oxidase consists of a membrane-bound catalytic subunit and a number of activity-regulating components that reside in the cytosol of resting phagocytes but translocate to the membrane upon cell activation (Fig. 52.2). In this way, the activity of this potent enzyme is restricted to the time when and the site where it is needed. The membrane-bound catalytic subunit is the flavohemeprotein gp91^{phox}, which is stabilized in a 1:1 complex with the transmembrane p22^{phox} protein (Table 52.2) (Huang et al., 1995; Wallach & Segal, 1996). The complex together is called flavocytochrome b_{558}. The N-terminal half of gp91^{phox} contains six hydrophobic regions that serve as membrane-spanning domains and three N-linked glycosylation sites (Wallach & Segal, 1997) (Fig. 52.3). This part of gp91^{phox} contains two heme moieties, each located between two histidines in transmembrane domains of the protein (Fig. 52.3) (Biberstine-Kinkade et al., 2001; Cross et al., 1995; Finegold et al., 1996; Yu et al., 1998). This part of gp91^{phox} also appears to be involved in the interaction with p22^{phox}. The C-terminal part of gp91^{phox} is hydrophilic, probably cytosolic, and contains one FAD group. The location of the putative FAD binding domain has been deduced from sequence homology between the C-terminal half of gp91^{phox} and the ferridoxin NADP reductase flavoenzyme family (Leusen et al., 2000; Rotrosen et al., 1992; Segal et al., 1992; Sumimoto et al., 1992). In a similar way, the position of the putative NADPH binding domain has been mapped on gp91^{phox} (Fig. 52.3). Like gp91^{phox}, the N-terminal half of p22^{phox} contains hydrophobic helices that may be transmembrane domains, and the C-terminal half is more hydrophilic.

The cytosolic NADPH oxidase components p47^{phox} and p67^{phox} each contain two src homology region 3 (SH3) motifs, known to interact with proline-rich regions in the same or in other proteins (Table 52.2, Fig. 52.4). Both of these cytosolic components also contain at least one such proline-rich region. The SH3–proline interactions may be involved both in keeping p47^{phox} and p67^{phox} in an inactive conformation in resting cells (by mutual interaction) and in activating the NADPH oxidase enzyme by promoting interactions between the cytosolic components and flavocytochrome b_{558} (De Mendez et al., 1994; Finan et al., 1994; Leto et al., 1994; Leusen et al., 1994a, 1994b, 1995; Sumimoto et al., 1994). The p67^{phox} protein also contains four tetra-tricopeptide (TPR) regions

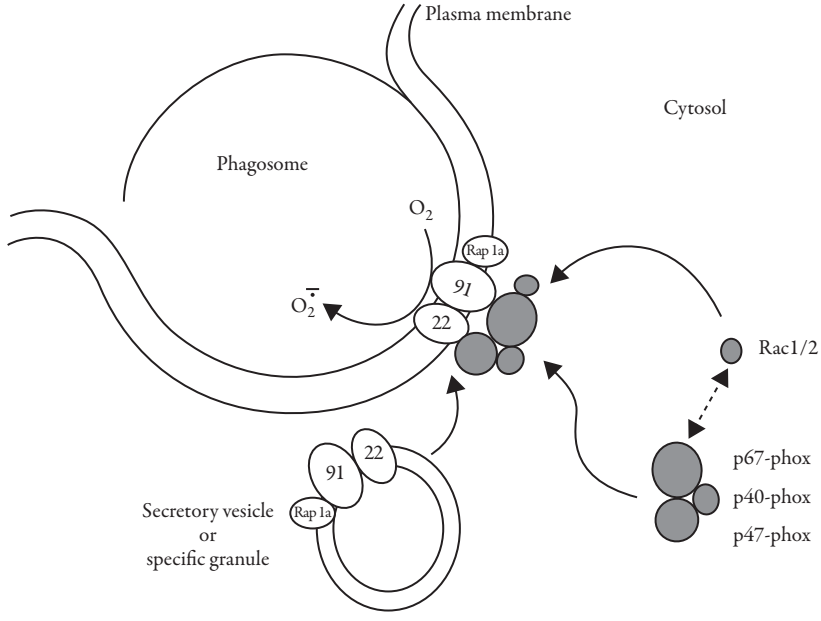

Figure 52.2 Activation of the NADPH oxidase. The membrane-bound NADPH-oxidase components gp91^{phox} and p22^{phox} and the small GTP-binding protein Rap1A are located in resting neutrophils in the membranes of specific granules and secretory vesicles. During cell activation (e.g., after binding of opsonized microorganisms to surface receptors on the neutrophils), these organelles fuse with the plasma membrane, thus leading to upregulation of the expression of these components on the neutrophil surface, especially in plasma membrane areas surrounding phagocytosed material (phagosomes). Concomitantly, the cytosolic NADPH-oxidase components p40^{phox}, p47^{phox}, and p67^{phox} translocate to the cytochrome b_{558} subunits (gp91^{phox} and p22^{phox}) and induce a conformational change in gp91^{phox} that allows NADPH to bind to gp91^{phox} and donate its electrons to the FAD moiety in this subunit. The cytosolic small GTP-binding proteins Rac1 (in macrophages) and Rac2 (in neutrophils) regulate the translocation process by binding to p67^{phox}, to gp91^{phox}, and to the plasma membrane.

in its C terminus, which form binding regions for the small GTPases Rac1 or Rac2; this constitutes another activation mechanism of the phagocyte NADPH oxidase (Koga et al., 1999; Nisimoto et al., 1997). A third cytosolic component, called p40^{phox}, with N-terminal homology to p47^{phox} and one SH3 domain resembling that of p67^{phox}, is possibly involved in stabilization of the p47^{phox}/p67^{phox} complex in resting cells and in facilitating membrane recruitment of this complex during oxidase activation (Table 52.2, Fig. 52.4) (Fuchs et al., 1995; Kuribayashi et al., 2002). Both p47^{phox} and p40^{phox} contain a so-called PX (phox homology) region that can bind to phosphatidyl phosphoinositides in the plasma membrane as yet another interaction to stabilize the active NADPH oxidase complex (Ellson et al., 2001; Kanai et al., 2001). The PX domain in p47^{phox} contains a PXXP motif, a proline-rich region that interacts with both SH3 groups of p47^{phox} in the

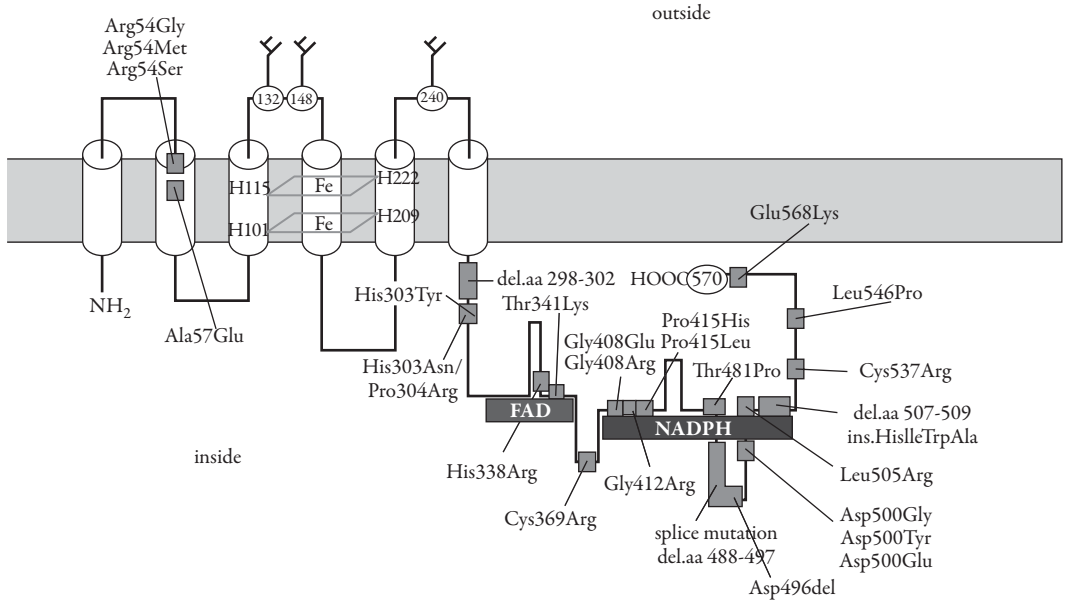

Figure 52.3 Schematic picture of gp91^{phox} and X91^{+} CGD mutations. The hydrophobic regions of gp91^{phox} that serve as membrane-spanning domains are shown as cylinders, while the asparagines that are N-glycosylated are indicated by the codon number and a carbohydrate tree. The heme-binding histidines are located in the third and fifth transmembrane regions. The putative FAD and NADPH binding regions are also indicated, as are the mutations that lead to the X91^{+} phenotype of CGD. The loop of 20 amino acids that covers the cleft of the NADPH binding region in resting cells is indicated in the lower right corner of the picture.

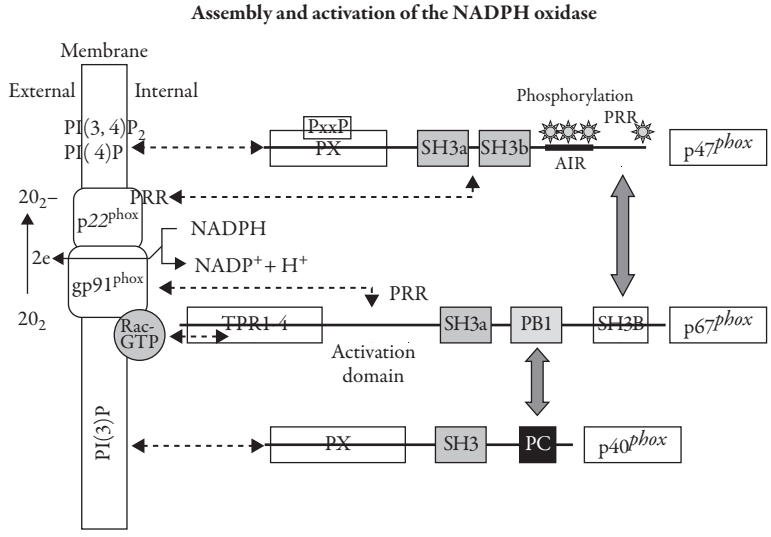

Figure 52.4 Assembly and activation of the NADPH oxidase. In the resting state, the three cytosolic NADPH oxidase subunits p47^{phox}, p67^{phox}, and p40^{phox} form a trimeric complex in the cytosol in which p47^{phox} is folded, kept together by interactions between the PXXP region in its PX domain with the two SH3 regions, and by the C-terminal proline-rich region (PRR) also interacting with the two SH3 regions (Groemping et al., 2003). The PRR in p47^{phox} is supposed to also interact with the SH3 region of p40^{phox} in resting cells, which in turn interacts with the PB1 region of p67^{phox} via a PC motif (*bottom arrow*). Phosphorylation of several serines (*stars*) in the polybasic region of p47^{phox} in activated phagocytes, between the C-terminal SH3 region (SH3b) and the PRR (the auto-inhibitory region [AIR]), causes unfolding of p47^{phox} and thus exposure of the SH3 regions in this protein (Fuchs et al., 1995; Leto et al., 1994). These p47^{phox} SH3 regions are then free to interact with the PRR in p22^{phox}, and the PX region of p47^{phox} is now free to interact with PI(3,4)P_2 and PI(4)P in the plasma membrane around the flavocytochrome b_{558}. Moreover, unfolding of p47^{phox} also leads to release of p40^{phox} from p47^{phox}, leaving the PRR in p47^{phox} free to associate with the carboxy SH3 domain of p67^{phox} in the oxidase complex assembled at the membrane (*top arrow*). P40^{phox} can now bind with its PX region to PI(3)P in the membrane, and p67^{phox} can interact through its TPR regions with Rac-GTP, which is associated through its insert domain with gp91^{phox} and with its lipid tail in the membrane. At the same time, the interaction between p40^{phox} and p67^{phox} (*bottom arrow*) is broken and p67^{phox} associates with its activation domain with gp91^{phox}; this latter interaction is essential for electron flow within the flavocytochrome. All new interactions in activated cells are indicated as broken arrows.

resting state of this protein (Hiroaki et al., 2001) (Fig. 52.4). P40^{phox} also contains in its C terminus an octicosa peptide repeat (OPR), also called PC (Phox Cdc24p) domain, which is involved in binding to a so-called PB1 (Phox and Bem-1) domain in p67^{phox} (Ito et al., 2001; Nakamura et al., 1998; Ponting, 1996). The regions within the cytoplasmic oxidase components that interact with each other or with flavocytochrome b_{558} are partially known from studying natural mutations (Dinauer et al., 1991; Leto et al., 1994; Leusen et al., 1994a, 1994b, 2000; Sumimoto et al., 1994). More detailed information has been gained from analyzing peptides in the two-hybrid system (Fuchs et al., 1995) or in a phage display system (DeLeo et al., 1995a, 1995b), and from peptide walking (Joseph & Pick, 1995; Morozov et al., 1998).

ACTIVATION OF THE NADPH OXIDASE

In the inactive state of the NADPH oxidase in quiescent phagocytes, the flavohemeprotein gp91^{phox} is inaccessible for its substrate NADPH because a stretch of 20 amino acids (residues 484–504) lies over the nucleotide-binding cleft (Fig. 52.5) (Taylor et al., 1993). Interaction of p47^{phox} and p67^{phox} with flavocytochrome b_{558} results in movement of this 20–amino acid loop and hence provides NADPH with access to its binding site in gp91^{phox}. The translocation of the cytosolic NADPH oxidase components to the flavocytochrome is initiated by serine phosphorylation of p47^{phox} (and of p67^{phox} and p40^{phox}) during phagocyte activation (Bolscher et al., 1989; Bouin et al., 1998; Dusi and Rossi, 1993; Forbes et al., 1999; Okamura et al., 1988; Segal et al., 1985) (Fig. 52.4). For more details of this process see the legend to Figure 52.4. One proline-rich region in p22^{phox} involved in binding an SH3 region in p47^{phox} has been identified from the mutation in this proline-rich region in a CGD patient (Leto et al., 1994; Leusen et al., 1994a; Sumimoto et al., 1994). It is not yet known which protein kinases are responsible for the phosphorylation of these oxidase components, nor how these kinases are activated. Possibly, protein kinase C-β plays a role in this respect (El Benna et al., 1996; Korchak et al., 1998; Reeves et al., 1999).

Positioning of the cytosolic oxidase components in the membrane is facilitated by the formation of phosphatidylinositol (PtdIns) species phosphorylated at the inositol-3 position in the membrane by phosphoinositide-3-OH kinase [PI(3)K] during neutrophil activation. The PX domain of p40^{phox} binds to PtdIns(3)P and the PX domain of p47^{phox} binds to PtdIns(3,4)P_2 (Kanai et al., 2001). Charge interactions between gp91^{phox} and the cytosolic components may also play a role in the formation of the oxidase complex, because several substitutions of amino acids in gp91^{phox} for amino acids with a different charge lead to stable expression of mutant gp91^{phox} molecules that no longer support translocation of cytosolic components (Leusen et al., 1994b, 2000). The proper positioning and stabilization of the oxidase complex may also depend on binding of the cytosolic components to cytoskeletal proteins, such as coronin, actin, moesin, and calprotectin, the heterodimer of the calcium-binding proteins S100A8/A9 (Doussière et al., 2002; Grogan et al., 1997; Tamura et al., 2000; Wientjes et al., 2001). In addition, the myeloid-related proteins MRP8 and MRP14 appear to be involved in the conformational change induced in gp91^{phox} during phagocyte activation, in synergy with p47^{phox} and p67^{phox} (Berthier et al., 2003). Finally, cPLA2-generated arachidonic acid is an essential cofactor in NADPH oxidase activation in intact or permeabilized cells, but the mechanism of this phenomenon is unknown (Dana et al., 1998). It must be stressed that the assembled NADPH oxidase complex is not a stable polypeptide complex: there is continuous binding to and release of cytosolic oxidase components from the membrane-bound components, but it is unknown whether electron transfer from NADPH to oxygen requires the actual presence of the cytosolic components in the complex (Van Bruggen et al., 2004).

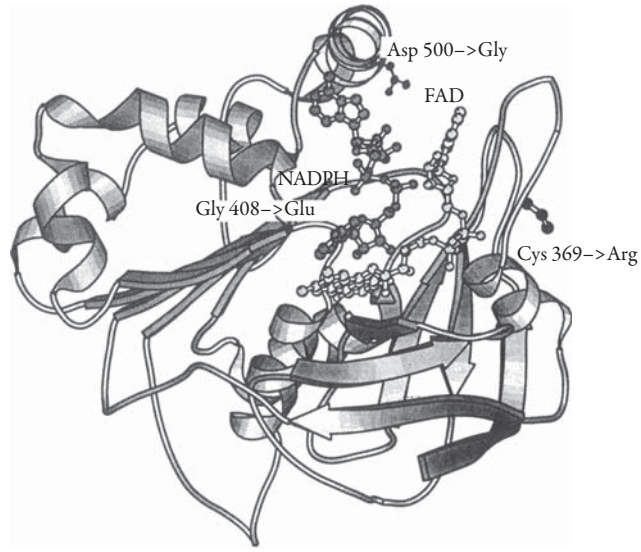

Figure 52.5 Three-dimensional model of the C-terminal, cytosolic part of gp91^{phox}. This figure shows a model of the cytosolic portion of gp91^{phox} based on that for spinach ferridoxin NADP reductase (Karplus et al., 1991), as described by Taylor et al. (1993). The figure was kindly provided by Dr. Nicholas Keep from Prof. Segal's group (London, UK). The protein is shown in the activated, NADPH-bound state. The 20–amino acid coil covering the cleft over the NADPH binding region in the active protein is now drawn aside (on top of the picture). In this coil, the position of Asp500 is indicated. Cys369 is located in another protein loop exposed to the cytosol, but Gly408 is buried in the protein between these two loops. Mutations Asp500Gly, Cys369Arg, and Gly408Glu lead to the X91^{+} CGD phenotype with defective translocation of cytosolic NADPH oxidase components.

Several low-molecular-weight GTP-binding proteins are involved in the NADPH oxidase activation (Table 52.3) (Abo et al., 1991; Knaus et al., 1991). One of these is p21rac, of which two subtypes exist in phagocytes—Rac1 (mainly in macrophages) and Rac2 (mainly in neutrophils) (Dusi et al., 1995). During neutrophil activation, these GTP-binding proteins change from an inactive, GDP-bound state into an active, GTP-bound state, a process that is regulated by guanine-nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs). Two Rac-activating GEFs have been identified in phagocytes: P-Rex1 and Vav1. P-Rex1 is synergistically activated by PtdIns(3, 4, 5)P_3 and the βγ subunits of trimeric G proteins associated with seven-span membrane receptors

(Welch et al., 2002). This indicates that P-Rex1 in neutrophils is under direct control of ligand binding to these receptors, but this was proven only for C5a. Vav1 is activated by tyrosine phosphorylation in its acidic region, a process downstream of receptor-linked tyrosine kinases. Vav1 appears to activate Rac1 and Rac2 in phagocytes in response to formyl-methionyl-leucyl-phenylalanine (fMLP), C5a, IgG complexes, lipopolysaccharide (LPS), or Ca^{2+} ionophore, but not to interleukin-8 (IL-8) or leukotriene B_4 (LTB_4) (Kim et al., 2003; Price et al., 2002; Vilhardt et al., 2002; Zhao et al., 2003). Several GAPs are known in these cells, both in the cytosol and in the membrane (Geiszt et al., 2001). By inactivating Rac, these proteins may be involved in termination of the respiratory burst (Szaszi et al., 1999). The inactive form of Rac is kept in a complex with Rho GDP-dissociation inhibitor (RhoGDI), which shields the geranylgeranyl moiety of Rac (Abo et al., 1991; Kwong et al., 1993; Mizuno et al., 1992). The activated, GTP-bound Rac, liberated from RhoGDI, binds to $p67^{phox}$ and associates with its fatty-acid tail into the phospholipids of the plasma membrane (Diekmann et al., 1994). Probably, Rac also interacts with $gp91^{phox}$ itself, to facilitate electron flux through this protein (Diebold & Bokoch, 2001). Another low-molecular-weight GTP-binding protein called Rap1A is associated with flavocytochrome b_{558} in the membrane (Table 52.3) (Quinn et al., 1992). This association is decreased upon protein kinase A-mediated phosphorylation of Rap1A, which suggests that Rap1A may modulate NADPH oxidase activity in response to agents that elevate cAMP in the cells (Bokoch et al., 1991).

FUNCTION OF THE NADPH OXIDASE

It is clear that the functional defects of CGD phagocytes result from the inability of these cells to generate superoxide, hydrogen peroxide, hypochlorous acid, and other products derived from superoxide. However, the bactericidal potency of superoxide and hydrogen peroxide is low, and cells with myeloperoxidase deficiency, which are unable to generate hypochlorous acid, show almost normal bactericidal activity. By contrast, CGD cells incubated with bacteria together with beads covered with glucose oxidase, which generate hydrogen peroxide in the presence of glucose, show clearly improved killing of the bacteria (Johnston & Baehner, 1970). Similar results have been obtained with liposomes filled with glucose oxidase (Gerber et al., 2001). This would indicate that the reactive oxygen compounds themselves are the prime bactericidal agents. An alternative hypothesis has been formulated by the group of Segal (Reeves et al., 2002). These investigators found that mice deficient in leukocyte elastase and cathepsin G have a similar defect in bacterial killing to that of $gp91^{phox}$ knockout mice. They also found that these proteases are liberated from their carbohydrate matrix in the granules by cations, and that this process takes place in neutrophil phagosomes containing ingested bacteria due to an influx of potassium. This influx is induced together with the influx of protons by the accumulation of superoxide, with its negative charge, generated in the phagosomes. In CGD phagocytes, this process does not take place, resulting in decreased protease activity in these organelles and hence decreased bacterial killing. There is now solid evidence that proton translocation from the cytosol to the phagosome through the voltage-gated H^+ channel Hv1 is the most important ion movement to keep the NADPH oxidase activity going (Ramsey et al., 2006, 2009; Sasaki et al., 2006). In addition, evidence from the group of Ligeti indicates that both direct and indirect bactericidal activity of the reactive oxygen species play an important role in the antimicrobial defense of phagocytes (Rada et al., 2004).

Another hallmark of CGD is the occurrence of diffuse granulomas. Some studies have suggested that this too may be caused by the failure of the leukocyte NADPH oxidase in these patients to generate reactive oxygen species, in particular H_2O_2, and a reduced rate of apoptosis (Hampton et al., 2002; Kobayashi et al., 2004). On the other hand, gene expression profiling has shown that CGD neutrophils have constitutively upregulated expression of genes encoding mediators of inflammation and host defense. In contrast, during phagocytosis-induced apoptosis, CGD neutrophils did not display increased Bax expression, as do normal neutrophils (Kobayashi et al., 2004). Thus, granuloma formation in CGD patients may reflect increased proinflammatory activity supporting survival of CGD neutrophils. This aberrant gene expression profile may thus be a direct or indirect effect of diminished reactive oxygen species (ROS) production or ROS-sensitive gene expression. Also, the diminished production of anti-inflammatory mediators by CGD neutrophils and macrophages during phagocytosis of bacteria or apoptotic cells (Brown et al., 2003) may contribute to the persistence of inflammation in CGD. In addition, apoptotic CGD neutrophils also display diminished surface expression of phosphatidyl serine (PS), which may contribute to their delayed removal by macrophages (Hampton et al., 2002; Yamamoto et al., 2002). This last process was shown to involve insufficient priming of the CGD macrophages by IL-4 (Fernandez-Boyanapalli et al., 2009). The cause of the insufficient PS exposure on apoptotic CGD neutrophils remains to be established. The involvement of Th17 and Treg cells in granuloma formation and chronic inflammation is discussed under Animal Models (see below).

An altered B-cell compartment has been suggested based on the reduced number of circulating $CD27^+$ memory B cells in CGD patients (Bleesing et al., 2006). Although we confirmed this, we have not seen a defective antibody response in patients against (viral) infections or vaccinations (Kuijpers & van den Berg, unpublished data). A relationship between the altered B-cell development and the increased risk of autoimmune phenomena in CGD is as yet unproven.

NONPHAGOCYTE NADPH OXIDASES

Several homologs of $gp91^{phox}$ have been identified in cells other than phagocytes. These homologs have conserved the overall structure of six transmembrane domains with four heme-coordinating histidines in the N-terminal part of the molecule, followed by a cytosolic C-terminus that contains highly conserved binding sites for FAD and NADPH. In a new nomenclature, these proteins are now called Nox (NADPH oxidase) proteins, including $gp91^{phox}$ (Nox2). Nox1 (or Mox1) mRNA is expressed

in colon, uterus, and vascular smooth muscle cells (Suh et al., 1999). Reactive oxygen species produced by this enzyme seem to be generated intracellularly, in contrast to the situation with the phagocyte NADPH oxidase. Overexpression of Nox1 results in increased cell growth, suggesting a role for these oxygen species in signal transduction for cell growth regulation. Another gp91^{phox} homologue, called Nox4 or Renox, has been detected by in situ RNA hybridization and immunohistochemistry in the renal cortex, predominantly in proximal convoluted tubule epithelial cells (Geiszt et al., 2000; Shiose et al., 2001). It has been suggested that Nox4 may participate in the oxygen-sensing mechanism that regulates the production of erythropoietin. Transfection of Nox4 into 3T3 fibroblasts resulted in enhanced superoxide production; however, these modified cells displayed substantially diminished cell growth. Nox3 is highly expressed in the inner ear, especially in the vestibular and cochlear sensory epithelia, and is crucial for the genesis of otoconia, which are tiny calcium carbonate crystals required for sensing gravity. Nox5 is distinguished from the other family members by its longer N terminus, which contains four EF hand Ca^{2+}-binding motifs. It is found in B and T lymphocytes. Some of these alternative NADPH oxidases, in particular Nox1, Nox3, and Nox4, may interact with specific cytosolic partners for activity regulation and localization—that is, with p22^{phox} and with alternative members of the p47 and p67 protein families (Ambasta et al., 2004; Bánfi et al., 2003; Geiszt et al., 2003; Kawahara et al., 2005; Takeya et al., 2003; Ueno et al., 2005).

Finally, two similar homologs have been discovered that are characterized by an N-terminal extension containing a peroxidase homology domain, a calmodulin-like calcium-binding motif, and an additional transmembrane domain (De Deken et al., 2000). RNA for these proteins, called Duox1 and Duox2, is expressed specifically in the thyroid gland, at the apical membrane of the thyrocytes. Duox2, and perhaps also Duox1, is involved in the iodination of the thyroid hormone, because nonsense mutations in the gene for Duox2 have been identified in patients with congenital hypothyroidism (Moreno et al., 2002).

MOLECULAR BASIS

Deficiency of the phagocyte NADPH oxidase, as seen in CGD, can be the result of any of a number of defects.

First, one of the structural components of the enzyme can be deficient, which is the case when mutations occur in the genes encoding gp91^{phox}, p22^{phox}, p40^{phox}, p47^{phox}, or p67^{phox}. Together, mutations in these five genes account for the overwhelming majority of CGD patients, with defects in the X chromosome-encoded gp91^{phox} found in about 70 percent of the cases and in p47^{phox} in about 20 percent. Defects in p40^{phox}, p22^{phox}, or p67^{phox} are rare. Also very rare are defects in the activation process of the NADPH oxidase. In particular, two patients have been described with a mutation in Rac2, leading to CGD-like symptoms in combination with defects in chemotaxis and in degranulation (Accetta et al., 2011; Ambruso et al., 2000; Williams et al., 2000). This finding indicates that Rac2 is involved not only in the activation of superoxide production but also in the activation of other neutrophil functions. Finally, defects may occur in the process that provides the cell with the substrate for the oxidase (i.e., NADPH). This compound is generated in phagocytes for the largest part in the hexose monophosphate pathway, in the successive G6PD and 6-phosphogluconate dehydrogenase (6PGD) reactions. Occasionally, patients are found with a deficiency of G6PD not only in the erythrocytes but also in the leukocytes (Baehner et al., 1972; Gray et al., 1973; Roos et al., 1999; Van Bruggen et al., 2002). These patients suffer from a mild form of CGD.

The *CYBB* gene for gp91^{phox} has a size of 30 kb, with 13 exons (Table 52.2). It is located on the X chromosome, at Xp21.1. Its promoter region has been clarified in some detail. Eight CGD families are known with mutations in the promoter region of *CYBB* that interfere with binding of the transcription factors Elf-1 and PU.1 (Defendi et al., 2009; Newburger et al., 1994; Roos et al., 2010b; Stasia et al., 2003; Suzuki et al., 1998; Voo & Skalnik, 1999; Weening et al., 2000; Woodman et al., 1995). The transcription of *CYBB* and *NCF1* is enhanced by interferon-γ (IFN-γ) (Cassatella et al., 1990; Weening et al., 1996).

The *CYBA* gene for p22^{phox} has a size of 8.5 kb, with six exons (Table 52.2). It is located on chromosome 16, at 16q24. Its promoter region has been partly characterized (Moreno et al., 2003). The *NCF1* gene for p47^{phox} has a size of 15 kb, with 11 exons, and the *NCF2* gene of p67^{phox} measures 40 kb, with 16 exons (Table 52.2). These genes are located on chromosomes 7 and 1, respectively, at 7q 11.23 and 1q25. Finally, the *NCF4* gene for p40^{phox} has a size of 18 kb, with 10 exons, and is located on chromosome 22, at 22q13.1. Detailed information on the promoter regions of these *NCF* genes has been collected (Li et al., 1997, 1999, 2001, 2002). In the NADPH oxidase genes the exon organizations do not coincide with the various functional regions of the proteins they encode.

The *RAC2* gene is located on chromosome 22, at 22q13. It has a size of 18 kb, with at least seven exons (Table 52.3). The promoter region of this gene has not yet been studied in detail. The Rac2 protein has a molecular weight of 22,000 and consists of 192 amino acids. The *G6PD* gene is located on the X chromosome, at Xq28. It has a size of 18 kb, with 13 exons. The G6PD protein has a molecular weight of 58,000 and consists of 531 amino acids. By binding $NADP^+$, the protein forms catalytically active dimers.

LABORATORY FINDINGS

DIAGNOSIS

Patients suspected of suffering from CGD can be diagnosed by the inability of their blood phagocytes to kill catalase-positive bacteria (e.g., *S. aureus*) in vitro or by their inability to generate reactive oxygen species. The respiratory burst can be measured by oxygen consumption (with an oxygen electrode), by superoxide generation (reduction of ferricytochrome *c* or nitroblue tetrazolium), or by hydrogen peroxide production (oxidation of homovanillic acid or Amplex red). Chemiluminescence with luminol or lucigenin is often used as a very sensitive test of NADPH oxidase activity. Flow-cytometric detection of this activity combines the advantage of sensitivity with the possibility of using nonpurified leukocyte suspensions rapidly derived from whole blood. One such assay, with dihydrorhodamine-1,2,3 (DHR) as the fluorescent detector of hydrogen peroxide production, has proven to be highly reliable and sensitive, even on blood that is 24 to 48 hours old. This assay has therefore replaced superoxide measurements and the NBT slide test as the primary screening assay for CGD in many laboratories (Emmendorffer et al., 1994; van Pelt et al., 1996; Vowells et al., 1996).

CGD SUBGROUP IDENTIFICATION

The NADPH oxidase is composed of multiple subunits, five of which may be affected by mutations leading to CGD (see above, Table 52.2). Subgroup characterization has implications for prognosis and family screening and may someday relate to attempts at gene correction. The methods of subgroup characterization are changing rapidly as molecular techniques become more accessible and less expensive. Therefore, the appropriate choice of technique will vary from region to region and over time. Identification of the protein affected may be desirable before mutation analysis is undertaken. CGD subgroup investigation may therefore start with immunoblot analysis of neutrophil fractions or intracellular staining in permeabilized neutrophils with antibodies against the five NADPH oxidase components. If one of the cytosolic components (p40^{phox}, p47^{phox}, or p67^{phox}) is missing, one can be confident that the gene carrying the mutation has been identified. However, if one of the membrane-bound components (gp91^{phox} or p22^{phox}) is missing, the other is always undetectable as well (Parkos et al., 1989; Verhoeven et al., 1989), because the subunits stabilize each other for full maturation and expression (Porter et al., 1994; Yu et al., 1997). In that case, distinction can usually be made by searching for a mosaic pattern of NADPH oxidase activity or gp91^{phox} expression in the neutrophils of female relatives of the patient, because the gene for gp91^{phox} is located on the X chromosome. Convenient assays for this purpose are the NBT slide test, which scores the NADPH oxidase activity per cell on a semiquantitative basis (Meerhof and Roos, 1986), and the DHR flow-cytometric assay (Roesler et al., 1991; Vowells et al., 1996). Alternatively, one can perform

flow cytometry to detect gp91^{phox} on the neutrophil surface with certain anti-gp91^{phox} antibodies (Mizuno et al., 1988). However, it must be kept in mind that up to one third of all X-linked defects may arise from new mutations in germline cells and will therefore not always be present in the somatic cells from the mother. Thus, failure to define the mother as an X-linked carrier does not disprove the X-linked origin of the disease.

If all subunits of the NADPH oxidase are detectable (the cytochrome subunits and the three other recessive components), even though the activity of this enzyme is absent or strongly decreased, the possibility of so-called ($^+$) variants must be considered (Table 52.4). These are caused by mutations in any of the five subunits that leave the protein expression intact but destroy the enzymatic activity of the assembled oxidase complex. In that case, direct sequencing of all five genes may be entertained. Alternatively, a cell-free oxidase assay may be used to distinguish a defect in a cytosolic component (p40^{phox}, p47^{phox}, or p67^{phox}) from a defect in a membrane-bound component (gp91^{phox} or p22^{phox}). For this assay, neutrophil membranes from the patient are mixed with neutrophil cytosol from a healthy donor (or vice versa), incubated with NADPH, and activated with an amphiphilic agent (low concentrations of sodium dodecyl sulfate [SDS] or arachidonic acid). The resulting oxidase activity can be measured by superoxide formation or oxygen consumption and is used to localize the defect to either the cytosol or the membrane fraction (Curnutte et al., 1987). Identification of the mutated gene that causes the defect in NADPH oxidase activity can also be made if transfection of the patient's Epstein-Barr virus (EBV)-transformed B lymphocytes with retroviral vectors that contain the wild-type cDNA restores this activity (Malech et al., 1997).

Patients with variant forms of X-linked CGD are characterized by a partial loss of gp91^{phox} expression and a proportional loss of NADPH oxidase activity (so-called X$^-$ variants) (Table 52.5). For an exact idea of gp91^{phox} expression, it can be useful to measure the heme content of flavocytochrome b_{558} in the neutrophils (Cross & Curnutte, 1995).

Finally, some patients with CGD-like symptoms are known with defects in either G6PD or Rac2. The first type can easily be recognized by measuring the activity of the G6PD enzyme in the red blood cells and confirming the diagnosis by repeating the assay with a leukocyte preparation (Roos et al., 1999; Van Bruggen et al., 2002). Moreover, one will usually find a mosaic of normally and faintly stained cells in the NBT slide test or DHR assay with purified neutrophils of the mother, because the G6PD gene is localized on the X chromosome. Rac2 deficiency can be recognized by the defect in NADPH oxidase activity in combination with defects in chemotaxis toward complement fragment C5a, IL-8, fMLP, LTB_4, and platelet-activating factor (PAF). The NADPH oxidase activity in PMA-activated neutrophils is normal. A defect in the release of proteins from the azurophilic granules but not from the specific granules or secretory vesicles is also apparent (Ambruso et al., 2000; Roos et al., 1993). The Rac2 deficiency can be diagnosed with certainty only by sequencing the *RAC2* gene.

CARRIER DETECTION

Carrier detection of X-CGD is usually performed by searching for a mosaic pattern of oxidase-positive and -negative neutrophils in the NBT slide test, in the DHR flow-cytometric assay, or in a flow-cytometric assay of gp91^{phox} protein expression. However, because of the random process of X-chromosome inactivation, X-CGD carriers may show a near-normal or a near-pathological pattern in these tests. Once the family-specific mutation is known, it is more reliable to perform carrier detection at the DNA level.

Carriers of autosomal (A) CGD subtypes are difficult to detect. The NADPH oxidase activity and the expression of oxidase proteins are normal in phagocytes from obligate carriers (parents of patients). Hence, detection of carriers of autosomal CGD can be performed only at the DNA level. Unfortunately, for p47^{phox}-deficient CGD, this can be difficult (see Mutation Analysis).

MUTATION ANALYSIS

MUTATION ANALYSIS IN X-CGD

The mutations in more than 1,200 families with X-CGD (OMIM #306400) have been characterized (Cross et al., 2000; Heyworth et al., 2001; Hopkins et al., 1992; Rae et al., 1998; Roos et al., 1996a, 1996b). A summary of all mutations can be found in Roos et al. (2010b) and at http://www.uta.fi/imt/bioinfo/CYBBbase/. The results show that CGD is a very heterogeneous disease, not only clinically and cell biologically but also at the molecular level, even within one subgroup. All possible mutations, except gene inversions, have been found in the *CYBB* gene. These different categories will be briefly mentioned, followed by a more detailed description of a few mutations that have given us insight into the structure–function relation of gp91^{phox}.

Deletions and/or insertions in *CYBB* are encountered in about 35 percent of all X-CGD patients; single nucleotide substitutions are seen in the remaining 65 percent. Table 52.5 provides an overview. One hundred eighty-three mutations (27 percent) were found in more than one unrelated family, with hot spots for a c.252G>A mutation at the end of exon 3 (causing outsplicing of exon 3), several C>T mutations (or its complementary G>A) in CpG sequences (caused by deamination of 5-methylcytosine to thymine, thus creating nonsense mutations from the Arg codon CGA into the TGA stop codon), and an A duplication in a stretch of six A's (causing a frameshift). Four hundred ninety-eight families (39 percent) had unique mutations. Twelve polymorphisms in the *CYBB* gene are known (Heyworth et al., 2001; Roos et al., 2010b; Tarazona-Santos et al., 2008).

Deletions range in size from about 6,000,000 to one single nucleotide. When the deletions are very large, not only the *CYBB* gene but neighboring genes are affected as well. Patients with deletions telomeric from *CYBB* suffer from other clinical syndromes in addition to CGD—for example, Duchenne muscular dystrophy, retinitis pigmentosa, and, as mentioned

Promoter mutations	**8**	**0.6**	**X91$^{0\#}$**

*In this nomenclature, the first letter (X) represents the mode of inheritance, while the number (91) indicates the phox component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (^{0}), diminished ($^-$), or normal ($^+$) as measured by immunoblot analysis.

In neutrophils X91^0 but in eosinophils normal expression and function of gp91^{phox}.

Data collected from 1,267 unrelated kindreds with 1,415 patients (Roos et al., 2010b)

above, McLeod syndrome (a mild hemolytic anemia with decreased levels of Kell erythrocyte antigens due to absence of the K^x protein). When deletions are centromeric from *CYBB*, ornithine transcarbamylase deficiency in addition to CGD can occur (Deardoff et al., 2008). In two families, affected brothers were detected who each carried different deletions in their *CYBB* genes (de Boer et al., 1998). Only in one patient has an in-frame partial exon deletion been reported to lead to expression of the truncated (inactive) gp91^{phox} protein (Schapiro et al., 1991).

Insertions in *CYBB* are usually small in size and, like small deletions, may be caused by slipped mispairing at the DNA replication fork. A few larger tandem duplications of 24, 31, and 40 base pairs have been detected, apparently due to unequal crossing over during meiosis or misalignment during DNA repair (Bu-Ghanim et al., 1995; Rabbani et al., 1993; Roos et al., 2010b). Recently, we have found a much larger duplication of 5.7 kb, ranging from a GT repeat in intron 5 to a similar repeat in intron 8, and the mirror deletion of this *CYBB* fragment in another CGD family (Stasia et al., 2012). Several combinations of small deletions and insertions have been found (Ariga et al., 1995; Heyworth et al., 2001; Rae et al., 1998; Roos et al., 2010b); one of them predicted substitution of three amino acids by four others near the C terminus of gp91^{phox} (Azuma et al., 1995). This mutation led to a stable mutant protein and thus to the X91$^+$ CGD phenotype (Table 52.4). Two large fragments of LINE-1 transposable elements have been identified within *CYBB*. The first one is a 1-kb fragment within intron 5, causing a complicated pattern of misspliced mRNA (Meischl et al., 2000). The second is a 2.1-kb fragment within exon 4, causing a frameshift (Brouha et al., 2002). In both families, the insertion was a recent event because it was not found in the somatic-cell DNA from the patients' mothers. The 2.1-kb fragment was identified as part of an active LINE-1 element on chromosome 2 of the patient's mother. We have also found recently an insertion in *CYBB* derived from a retrotransposed, partially spliced and truncated transcript of *TMF1*, a gene present on chromosome 3. This insertion of 5.8 kb caused inclusion of part of exon 2 of the *TMF1* retrogene in reversed orientation between exon 1 and 2 of the *CYBB* transcript, and predicts premature termination of protein synthesis (De Boer et al., unpublished).

Single nucleotide substitutions at exon–intron boundaries lead to aberrations in mRNA splicing, usually causing skipping of an entire exon. However, this phenomenon was proven in only about half of the cases (in the other half, only genomic DNA was investigated). The percentage of splice-site mutations found in CGD is similar to that found in other diseases (Krawczak et al., 1992). Single nucleotide changes in either exons or introns have sometimes created new splice sites, causing partial exon deletions or insertions, respectively, in the mRNA (de Boer et al., 1992a; Noack et al., 1999, 2001a, Roos et al., 2010b).

Missense and nonsense mutations constitute the most frequently encountered cause of many genetic diseases. Nonsense mutations in *CYBB* affect the level of mRNA for gp91^{phox} to a variable degree but have not been seen in CGD to produce stable truncated proteins. Similarly, deletions, insertions, and splice-site mutations in general also lead to the X91^0 phenotype (no gp91^{phox} protein expression, no NADPH oxidase activity). In contrast, missense mutations do not influence the level of mRNA and may give rise to any of three phenotypes. Single amino acid replacements due to missense mutations can lead to intrinsically unstable gp91^{phox} or to gp91^{phox} unable to be stabilized by interaction with p22^{phox} (X91^0 phenotype), to partial deficiencies in this respect (X91$^-$ phenotype: decreased expression, decreased oxidase activity), or to stable but inactive gp91^{phox} (X91$^+$ phenotype) (Table 52.5). In general, missense mutations in regions of gp91^{phox} not involved in binding of its prosthetic groups (hemes, FAD, NADPH) may weaken the stability of the protein but will often leave some enzymatic activity (X91$^-$), whereas mutations in regions that are involved in this binding will destroy the enzymatic activity, even if the protein is still stable (X91$^+$). Indeed, Kuhns et al. (2010) found that missense mutations in the N-terminus (amino acids 1–309) often leave an appreciable amount of NADPH oxidase activity, with mutations in His222 as an exception (this amino acid is one of the four heme-binding sites). In the C-terminus (amino acids 310–570) of gp91^{phox}, missense mutations in general destroy the superoxide-generating capacity despite leaving the protein expression sometimes nearly or completely intact. This fits with the preponderance of X91$^-$ mutations in the N terminus and of X91$^+$ mutations in the C terminus (Table 52.4, Fig. 52.3) and is explained by the FAD- and NADPH-binding sites in the C terminus of gp91^{phox} (Kuhns et al., 2010; Roos et al., 2010b). Small in-frame deletions and a few splice-site mutations with residual normal mRNA splicing have also been found associated with the X91$^-$ phenotype.

The X91$^+$ mutations can be very informative for our understanding of the properties of the different domains in gp91^{phox}.

Table 52.4 presents an overview. Four X91$^+$ patients have amino acid substitutions in the N-terminal half of gp91^{phox} (Fig. 52.3), one of which (Arg54Ser) provided evidence for the non-identity of the two heme groups in gp91^{phox} (Cross et al., 1995). The other X91$^+$ patients have amino acid substitutions in the C-terminal half of gp91^{phox} (Fig. 52.3). In six of these, the translocation of p47^{phox} and p67^{phox} to cytochrome b_{558} upon neutrophil activation was strongly diminished (Bionda et al., 2005; Dusi et al. 1999; Leusen et al., 1994b, 2000). Apparently, not only the loop over the NADPH cleft is of importance as a docking site for the cytosolic oxidase components, but other regions surrounding this area as well (Fig. 52.5). All together, these results provide strong support for the three-dimensional model of the C-terminal half of gp91^{phox} as constructed by Taylor et al. (1993).

Some X91$^-$ mutations have also proven to be informative (for a complete overview see Roos et al., 2010b, and Stasia & Li, 2008). Tsuda et al. (1998) have described a patient with a His101Tyr mutation, causing 90 percent loss of gp91^{phox} protein expression but total loss of heme incorporation. This indicates that His101 of gp91^{phox} may be involved in heme binding, in accordance with the prediction based on the FRE1 protein (Finegold et al., 1996) and with the need of heme incorporation for maturation and stability of the gp91^{phox}/p22^{phox} complex (Yu et al., 1997). Indeed, site-directed mutation of His101, His115, His209, and His222 in gp91^{phox} has subsequently identified these histidines as the heme ligands and critical for biosynthetic maturation of flavocytochrome b_{558} (Biberstine-Kinkade et al., 2001). A CGD mutation of His338Tyr led to about 80 percent decreased heme levels but almost complete loss of FAD incorporation, in accordance with the His-Pro-Phe-Thr 338–341 motif being involved in FAD binding (Yoshida et al., 1998). This is probably also the explanation for the loss of activity in an X91$^+$ CGD patient with a Thr341Lys mutation in gp91^{phox} (Leusen et al., 2000). Two exceptional X91$^-$ mutations were recently claimed to be macrophage specific—that is, to leave almost normal gp91^{phox} expression and superoxide-generating capacity in circulating neutrophils and monocytes, but to impair these parameters in monocyte-derived macrophages and EBV-transformed B cells (Bustamante et al., 2011). The eight patients, from two separate families, suffered from tuberculous or BCG mycobacterial disease. This appears to be a very limited and informative manifestation of gp91^{phox} deficiency, suggesting a special hypomorphic form of CGD.

Finally, five different single nucleotide substitutions have been identified in the 5′ promoter region of *CYBB* (Defendi et al., 2009; Newburger et al., 1994; Stasia et al., 2003; Suzuki et al., 1998; Weening et al., 2000; Woodman et al., 1995). Mutations at −52 and −53 were found to be located in a binding element for the nuclear transcription factor PU.1 and to suppress the binding of PU.1 and the subsequent promoter activity. Remarkably, these mutations abolished NADPH oxidase activity in the neutrophils, monocytes, and transformed B lymphocytes of the patients, but not in their eosinophils (Defendi et al., 2009; Suzuki et al., 1998; Weening et al. 2000). This finding may explain the mild clinical phenotype of most of these patients (Weening et al., 2000). Apparently, eosinophils have an additional *CYBB* activation mechanism, which has been identified as the transcription factor GATA-1 (Yang et al., 2000).

MUTATION ANALYSIS IN AUTOSOMAL CGD

The number of well-characterized mutations in autosomal CGD is much lower than that in X-CGD, owing to the lower incidence of these forms of the disease. Eighty-seven A22 families, about 350 A47 families, 83 A67 families, and 1 A40 family have been investigated. Table 52.6 presents an overview. The results indicate that the genetic basis of A22 and A67 CGD is as heterogeneous as that of X91 CGD, but A47 CGD is much more homogeneous in origin.

In the 87 A22 CGD families (96 patients) with mutations of p22^{phox} (OMIM #233690), 55 different mutations have been found in the 173 identified alleles (for a detailed overview see Roos et al., 2010a, and http://www.uta.fi/imt/bio info/CYBAbase/). In 66 families, the patients carried homozygous deficiencies; in 21 families, the patients were compound heterozygotes. Twelve mutations (22 percent) were found in more than 1 unrelated family, with hot spots

Table 52.6 **MUTATIONS IN *CYBA, NCF1*, AND *NCF2***

	CYBA* (P22^{phox})		***NCF1***† (P47^{phox})		***NCF2***‡ (P67^{phox})	
	NO. OF ALLELES	**FREQUENCY**	**NO. OF ALLELES**	**FREQUENCY**	**NO. OF ALLELES**	**FREQUENCY**
Deletions	42	24.3%	7	11.1%	48	28.1%
Insertions	17	9.8%	1#	1.6%	8	4.7%
Splice-site mutations	29	16.8%	11	17.5%	38	22.2%
Missense mutations	65	37.5%	6	9.5%	41	24.0%
Nonsense mutations	20	11.6%	38	60.3%	36	21.0%

*Mutations in *CYBA*: 87 families with 173 identified alleles in the 96 patients

†Mutations in *NCF1* (other than GT deletion at the start of exon 2): 42 families with 63 identified alleles in the 53 patients

‡Mutations in *NCF2*: 83 families with 171 identified mutations in the 95 patients (one allele carries two mutations)

#Deletion/insertion

of missense mutations at c.70C>A (p.Gly24Arg) in 9 families (14 alleles) and c.268C>T (p.Arg90Trp) in 8 families (14 alleles). Forty-three families (49 percent) had unique mutations. Twelve polymorphisms are known in the $p22^{phox}$ protein (Bedard et al., 2009; Cross et al., 2000; Roos et al., 2010a). A single $A22^{+}$ patient has been found with a Pro156Glu substitution (Dinauer et al., 1991). Pro156 is in a proline-rich region of $p22^{phox}$ that serves as a binding region for an SH3 domain in $p47^{phox}$. Apparently, the Pro156Glu substitution destroys the interaction between these proteins and hence the activation of the NADPH oxidase (Leto et al., 1994; Leusen et al., 1994a; Sumimoto et al., 1994). This substitution is the first recognized mutation that disturbs an SH3–proline interaction and leads to a genetic disease.

The mutations that cause A47 CGD have long puzzled investigators. In more than 300 unrelated patients with $p47^{phox}$ deficiency (OMIM #233700), a dinucleotide deletion has been found at a GTGT tandem repeat corresponding to the first four bases of exon 2 in the *NCF1* gene (Casimir et al., 1991; Iwata et al., 1994; Noack et al., 2001b; Roesler et al., 2000; Roos et al., 1996a, 2010a; Vazquez et al., 2001; Volpp and Lin, 1993). In all but 42 of these families (53 patients or about 15 percent), the GT deletion (ΔGT) appeared to be homozygous (Roos et al., 2007, 2010a). In these 42 exceptions, 20 families had patients who were heterozygotes for the GT deletion and one additional mutation, and 22 families had patients with mutations other than ΔGT on both alleles of *NCF1*. Of these last 22 families, 20 had patients who were homozygotes for a non-ΔGT mutation and 2 families were non-ΔGT compound heterozygotes. Three mutations (13 percent) were found in more than one unrelated family, with a hot spot for the nonsense mutation c.579G>A, which changes the TGG codon for Trp193 into the TGA stop codon. Nineteen of the nonhomozygous ΔGT families (45 percent) had unique mutations. For an overview of these mutations see Roos et al. (2010a) and http://www.uta.fi/imt/bioinfo/NCF1base/. The spectrum of these non-ΔGT mutations is as diverse as that in the other CGD genes (Table 52.6).

Obviously, the ΔGT-bearing allele of *NCF1* is the most common CGD-causing allele in the population, carried by approximately 1 in 500 individuals. The reason for this predominance is that most normal individuals have on each chromosome 7 two $p47^{phox}$ pseudo-genes, which colocalize (one on each side; Antonell et al., 2006) with the functional *NCF1* gene to 7q11.23. These pseudogenes are more than 99 percent homologous to *NCF1* but carry the GT deletion, which renders them inactive because the predicted protein from these pseudogenes contains a premature stop codon. Recombination events between *NCF1* and the pseudogenes lead to the incorporation of ΔGT into *NCF1*, and thus to CGD (Goerlach et al., 1997; Roesler et al., 2000; Vazquez et al., 2001). To date, nine polymorphisms have been recognized in *NCF1* (Cross et al., 2000; Roos et al., 2010a), but the identification of these variations is complicated by the presence of the pseudogenes. Unfortunately, this complicated genetic background of A47 CGD renders reliable carrier testing difficult, because normal individuals appear to be "heterozygous" for the GT deletion by virtue of possessing the pseudogenes. Allele-specific PCR amplification can be used to solve this problem but is not easily applicable (Noack et al., 2001b). A gene-scan method has been developed for determining the relative number of *NCF1* and pseudogenes in genomic DNA. With this test, patients and carriers with the GT deletion can be distinguished from normal individuals and from each other (Dekker et al., 2001). However, it is not yet clear whether a compound protein with the GTGT sequence from *NCF1* followed by the 3′ sequence of the pseudogenes is expressed and has oxidase-promoting activity (Heyworth et al., 2002). We have found indications that the mRNA for such fusion genes is not processed correctly and therefore is unstable (unpublished). In all A47 CGD patients analyzed thus far, the mRNA levels for $p47^{phox}$ were normal, but the amount of $p47^{phox}$ protein in each was undetectable. Thus, only $A47^{0}$ patients have been identified to date.

In the 83 characterized A67 CGD families with abnormal $p67^{phox}$ (OMIM #233710), the 95 patients carry 54 different (and 3 unidentified) mutations among the 171 total alleles affected (one mutation in 8 families is always found in combination with another mutation on the same allele) (Table 52.6) (for a detailed review see Roos et al., 2010a, and http://www.uta.fi/imt/bioinfo/NCF2base/). In 70 families, the patients are homozygous for one mutation; in 13 they are compound heterozygotes. Eighteen mutations (33 percent) were found in more than one unrelated family, with hot spots of G>A splice-site mutation at the start of intron 4 in eight families and a c.304C>T nonsense mutation (p.Arg102X) in six families. Thirty-six families (43 percent) had unique mutations. Twelve polymorphisms in *NCF2* are known (including the 5′ untranslated region), six of which predict amino acid substitutions. In some of the A67 CGD patients, the level of mRNA for $p67^{phox}$ is normal, but in most the $p67^{phox}$ protein is undetectable. However, in four families with three different mutations about half the normal amount of protein was found. Two missense mutations (p.Asp108Val and p.Ala202Val) lead to concomitant decrease in NADPH oxidase activity, presumably due to structural changes in $p67^{phox}$ that preclude efficient oxidase activation (Köker et al., 2009; Yu et al., 2008). In the last family, the mutation predicts an in-frame deletion of Lys58 from the protein and apparently results in the expression of a nonfunctional $p67^{phox}$ that fails to translocate to the plasma membrane because of the inability of this protein to bind Rac (Leusen et al., 1996).

Recently, one patient has been described with $p40^{phox}$ deficiency (Matute et al., 2009). This patient suffered from granulomatous colitis, perianal rash, perioral eczema, sinusitis oral ulcers, and an undefined perioperative infectious episode, but no other symptoms frequently seen in CGD patients. His neutrophils produced normal amounts of superoxide after stimulation with PMA or fMLP, but strongly reduced amounts after phagocytosis of serum-treated zymosan, IgG-coated beads or serum-opsonized *S. aureus*. Killing of opsonized *S. aureus* by the patient's neutrophils was significantly impaired. The $p40^{phox}$ expression by the cells from the patient and his father was about half normal. The patient proved to be a compound heterozygote for two mutations in *NCF4*. On the paternal allele he had a 10-base pair duplication that predicts

a frameshift and a premature stop codon, and on the maternal allele a nucleotide substitution that predicts a missense Arg105Gln mutation in the PX domain. The first mutation destroyed the $p40^{phox}$ protein expression ($A40^0$), whereas the second mutation led to normal expression of a nonfunctional protein ($A40^+$).

MUTATION ANALYSIS IN RAC2 DEFICIENCY

Rac2 deficiency has been described in two patients only (OMIM #602049) (Accetta et al., 2011; Ambruso et al., 2000; Williams et al., 2000), although the cellular deficiencies exactly match those described in another patient with neutrophil defects of unknown etiology (Roos et al., 1993). The first patient with proven Rac2 deficiency suffered from severe bacterial infections and poor wound healing, symptoms that, together with late separation of the umbilical stump, leukocytosis, and absence of pus in infected areas, also observed in the patient, are reminiscent of leukocyte adhesion deficiency (LAD). Indeed, neutrophil studies indicated a defect in chemotaxis toward C5a, fMLP, and IL-8, but in contrast to LAD-I, normal expression of β_2 integrins (CD 18) on the leukocytes (see Chapter 53). Moreover, despite a normal content of enzymes of the azurophil granules, strongly decreased release of these enzymes after neutrophil activation was found, but the release of lactoferrin from the specific granules was normal. Neutrophil polarization and actin polymerization in response to fMLP were also deficient, as were transient adhesion to the L-selectin ligand GlyCAM-1 and stable adhesion to fibronectin. Neutrophils from this patient failed to respond with superoxide production after activation with fMLP or C5a, but responded normally with PMA. Thus, this syndrome combined defects seen in LAD with those observed in CGD and in addition included defects in degranulation and actin-dependent functions, as well as abnormal T-cell development resulting in lymphopenia and absence of T-cell–receptor excision circles on newborn screening (Accetta et al., 2011). Mutation analysis of the Rac2 gene showed a single heterozygous c.169G>A transition in both patients, predicting a substitution of Asp57 for Asn. This Asp57 is in a conserved D-X-X-G motif involved in GTP binding to Ras GTP-ases. Recombinant $Rac2^{D57N}$ bound GDP normally but failed to bind GTP (Williams et al., 2000).

The involvement of Rac2 in multiple neutrophil functions had already been deduced from studies with Rac2 knockout mice (Roberts et al., 1999). However, in these studies it was shown that both Rac2 alleles had to be disrupted for defects to become apparent. The mechanism of the dominant negative effect of $Rac2^{D57N}$ in the patients was clarified by Gu et al. (2001), who found that $Rac2^{D57N}$ binds the guanine nucleotide exchange factor (GEF) TrioN normally, but this binding has no effect on the exchange of GDP for GTP, in contrast to the increased exchange seen with wild-type Rac2. These results suggest that $Rac2^{D57N}$ sequesters GEFs in neutrophils by binding these factors but, because of the impaired binding of GTP, do not release these factors, resulting in decreased turnover rates of Rac2 and possibly other Rho-like GTPases that use these GEFs.

MUTATION ANALYSIS IN G6PD DEFICIENCY

Deficiency of G6PD is one of the most common genetic defects in humans (OMIM #305900), probably because of the protection of G6PD-deficient erythrocytes against proliferation of malaria parasites. The clinical expression of G6PD deficiency varies from mild hemolytic anemia induced by infections or drugs (World Health Organization [WHO] class 3) to chronic nonspherocytic hemolytic anemia with attacks of severe anemia induced by infections and drugs (WHO class 1). The clinical symptoms are often restricted to the erythrocytes, for several reasons. One is that G6PD and the next enzyme in the hexose monophosphate pathway (6PGD) catalyze the only NADPH-generating reactions in cells that lack mitochondria (i.e., erythrocytes). These cells need NADPH for protection against oxidative stress. Other reasons for G6PD deficiency effects in erythrocytes are the long survival time of these cells in the circulation and their lack of protein synthesis. G6PD mutant enzymes often have decreased protein stability, causing a decline in enzyme activity, especially in long-living cells that cannot generate new proteins. A total lack of G6PD activity is probably incompatible with life, because mutations in G6PD concern missense mutations or small in-frame deletions, but not frameshift mutations, gross deletions, or nonsense mutations (with one exception near the C-terminus of the protein) (Beutler et al., 1996).

Occasionally, patients with G6PD deficiency have been described with a decreased neutrophil respiratory burst after activation with opsonized particles, as well as an increased susceptibility of patients to bacterial or fungal infections (Baehner et al., 1972; Cooper et al., 1972; Gray et al., 1973; Mamlok et al., 1987; Roos et al., 1999; Van Bruggen et al., 2002; Vives Corrons et al., 1982). In general, the G6PD activity in these cells needs to be below 5 percent of normal for such impairment to occur (Baehner et al., 1972). This situation may arise when mutations in G6PD severely decrease the enzyme activity even in newly synthesized protein. To date, information about mutations that give rise to these CGD-like symptoms is restricted to a few families. In one of these, we found replacement of Pro172 by Ser, leading to a thermolabile variant G6PD with about 15 percent of normal activity (Roos et al., 1999). In two other families with mild CGD and G6PD deficiency we found a triplet nucleotide deletion that predicted deletion of Leu61. G6PD protein expression and enzyme activity in all blood cells were extremely low (Van Bruggen et al., 2002).

PHENOTYPE–GENOTYPE CORRELATION

In general, the clinical symptoms in A22 and A67 subgroups of CGD appear to be as severe as in $X91^0$ CGD. Clinical comparisons between X-CGD and A47 CGD patients have been made by several investigators, with the general contention that X-CGD patients follow a more severe clinical course than that of A47 CGD patients (Gallin et al., 1991; Jones et al., 2008; Margolis et al., 1990; Martire et al., 2008; Van den Berg

et al., 2009; Weening et al., 1985a; Winkelstein et al., 2000). The milder disease course is probably due to residual superoxide or hydrogen peroxide formation by $p47^{phox}$-deficient neutrophils (Bemiller et al., 1991; Cross et al., 1994; Cross & Curnutte, 1995; Vowells et al., 1996). In a recent paper, Kuhns et al. (2010) show that not the residual $gp91^{phox}$ protein expression but the residual NADPH oxidase activity determines the chance of survival of X-CGD patients. Analysis of the correlation between the clinical course and residual NADPH oxidase activity has not been performed yet.

It might be expected that patients with the $X91^-$ phenotype, with 3 to 30 percent of residual NADPH oxidase activity in their phagocytes, would follow a more benign clinical course than that of patients with the $X91^0$ or $X91^+$ phenotype. This generally appears to be the case, but it is not universally true (Roos et al., 1992). Female carriers of X-CGD mutations may occasionally present with clinical manifestations of the disease similar to those of hemizygous patients. In general, this concerns only carriers with less than 10 percent of normal phagocytes (Roos et al., 1996a; Wolach et al., 2005), but healthy carriers with less than 10 percent of normal phagocytes are also known (Roos et al., 1986).

Functional polymorphisms in the oxygen-independent antimicrobial systems or other host defense elements play an important role in this respect. Foster et al. (1998) found that in a cohort of 129 clinically well-defined CGD patients (104 X-linked, 25 autosomal recessive), an increased risk for abnormal granulomatous or inflammatory processes leading to gastrointestinal or urogenital complications was strongly associated with a polymorphism in the promoter region of myeloperoxidase that increases transcriptional activity, and with the NA2 allele of the Fcγ receptor IIIb, which reacts less efficiently with IgG1-opsonized microorganisms than does the NA1 allotype. Autoimmune and rheumatologic disorders were seen more frequently in CGD patients with variant alleles of mannose-binding lectin and Fcγ receptor IIa.

The question as to how oxidative and nonoxidative mechanisms cooperate in intraphagosomal killing has been addressed by Reeves et al. (2002), who found that charge compensation for superoxide generation is mediated to some extent by potassium influx. These potassium ions are instrumental in liberating proteases from the proteoglycan matrix in the azurophil granules that have fused with the phagosome, but also cause a temporary increase in intraphagosomal pH, needed for optimal functioning of these proteases. While some of these antimicrobial systems may operate independently, the combination of their activities is synergistic in the successful containment of the invading pathogens. Such gene modifiers may explain the variability in the infectious burden in CGD. Also, the prevalence of specific pathogens in certain patients, such as *Nocardia* or atypical mycobacterial strains, may depend on these nonoxidative systems (Dorman et al., 2002; Weening et al., 2000; Winkelstein et al., 2000). In addition, weak nonoxidative defense systems may also allow catalase-negative microorganisms to infect CGD patients. Finally, this variability of nonoxidative defense systems may explain the beneficial effects of rhIFN-γ in vivo in CGD patients (see below), despite its lack of effect on NADPH oxidase activity: many of the nonoxidative systems are activated and modulated by microbial products and a series of temporally expressed cytokines such as IFN-γ.

PRENATAL DIAGNOSIS

Prenatal diagnosis of CGD can be performed by analysis of the NADPH oxidase activity of fetal blood neutrophils (Newburger et al., 1979), but fetal blood sampling cannot be undertaken before 16 to 18 weeks of gestation. Instead, analysis of DNA from amniotic fluid cells or chorionic villi now provides an earlier and more reliable diagnosis for families at risk. In cases where the family-specific mutation is known, this analysis can be performed by PCR amplification and sequencing of the relevant genomic DNA area. Between our laboratories and that at Scripps, we have analyzed more than 80 pregnancies at risk for X-CGD (de Boer et al., 1992b). The same strategy can be used for prenatal diagnosis of other CGD subtypes, although this may be more complicated if the parents carry different mutations. We have performed prenatal diagnosis in two families with a $p67^{phox}$-deficient CGD patient and in four families with $p47^{phox}$-deficient CGD. In the latter four families, the deficiency proved to be due to mutations other than the GT deletion at the start of exon 2 in *NCF1*, which was proven by sequencing of *NCF1*-specific PCR products (de Boer et al., 2002).

If the family-specific mutations are not known, different methods must be applied. Partial or complete gene deletions can be recognized by restriction fragment length polymorphism (RFLP) on Southern blots or by multiplex ligation-dependent probe amplification (MLPA) analysis of genomic DNA, but more subtle abnormalities require the use of allele-specific markers. Sometimes it is possible to identify the family-specific mutation quickly in the genomic DNA of the mother (in the heterozygous state) before analysis of the fetal DNA.

ANIMAL MODELS, COMPARISON WITH HUMAN DISEASE

Natural animal models of CGD are not known. However, Dinauer's group has succeeded in constructing a mouse model of X-linked CGD through *Cybb* gene targeting of murine embryonic stem cells (Pollock et al., 1995). With a similar technique, $p47^{phox}$ and $p40^{phox}$ knockout mice have been constructed (Ellson et al., 2006; Jackson et al., 1995; Reeves et al., 2002). Such models are of great value for testing the safety and efficacy of correction of the genetic defect by gene transfer technologies (see Future Directions, below). In addition, the clinical differences between the various subgroups of CGD and new therapeutic strategies can be studied in detail with these models. By comparison with elastase knockout mice, cathepsin-G knockout mice, and elastase/cathepsin-G double-knockout mice, the importance of the oxidative and nonoxidative microbicidal mechanisms was studied in vivo (Tkalcevic et al., 2000). $P40^{phox}$ knockout

mice have been used to study the exact function of this protein (Ellson et al., 2006). Mice deficient in NADPH oxidase components have also been used to study the involvement of this enzyme system in oxygen sensing, blood pressure regulation, and pathogenesis of atherosclerosis (Archer et al., 1999; Brandes et al., 2002; Fu et al., 2000; Hsich et al., 2000; Kirk et al., 2000; O'Kelly et al., 2000; Wang et al., 2001). Finally, $p22^{phox}$-deficient mice have recently been discovered (Nakano et al., 2008). The mouse strain nmf333, with a balance disorder like *Nox3*-mutated mice, turned out to have a mutation in the *Cyba* gene that destroyed $p22^{phox}$ protein expression and NADPH oxidase activity. However, a role for one or more of the classical phox proteins in human vascular disease or gravity sensing cannot be deduced from the clinical symptoms of CGD patients thus far.

Recently, a role for indoleamine 2,3-dioxygenase (IDO) was suggested to be important in CGD pathology. IDO suppresses T-cell responses (hence promoting tolerance), tumor resistance, chronic infection, autoimmunity, and allergic inflammation. During inflammation, IDO is upregulated in dendritic cells and phagocytes by proinflammatory stimuli—most notably IFN-γ. The IDO enzyme supposedly uses superoxide as a "cofactor" for oxidative cleavage of the indole ring of tryptophan, yielding an intermediate that deformylates to L-kynurenine.

Patients with CGD suffer not only from infectious disease but also from chronic inflammatory conditions, most prominently granuloma formation—even when the pathogen has most likely been already eliminated. The reason for the exaggerated inflammatory response has remained unclear. Recent studies in CGD $p47^{phox}$ knockout mice have demonstrated that a superoxide-dependent step in tryptophan metabolism along the kynurenine pathway is blocked, leading to unrestrained γδ T-cell reactivity, dominant production of IL-17, defective regulatory T-cell ($Foxp3^+$ Treg) activity, and acute lethal inflammation upon pulmonary *Aspergillus* infection. Complete cure and reversal of the hyperinflammatory phenotype upon lung infection were achieved by replacement therapy with a natural kynurenine distal to the blockade in the pathway, combined with the co-administration of rIFN-γ or depletion of IL-17. This treatment restored production of downstream immunoactive metabolites and enabled the emergence of regulatory T cells, such as the $Foxp3^+$ Treg cells (Romani et al., 2008). IDO seems to be blocked posttranslationally in CGD mice, because IFN-γ could still induce IDO expression in $p47^{phox}$ knockout PMN, but these cells were unable to mediate tryptophan conversion to L-kynurenine, 3-hydroxykynurenine, and quinolinate. When this idea was put to the test in CGD patients, remarkable differences with the mouse model came to light. CGD monocytes, dendritic cells, and neutrophils all generated normal amounts of kynurenine when stimulated by rIFN-γ and LPS. Moreover, urinary and serum levels of kynurenine and other tryptophan metabolites were elevated rather than suppressed in CGD patients (De Ravin et al., 2010; Jürgens et al., 2010). Also, in the human system, cytochrome b_5 together with cytochrome P450 and NADPH, rather than superoxide, acts as the IDO-activating system (Maghzal et al., 2008). Thus, it appears that the excessive inflammatory reactions in CGD patients, the formation and maintenance of granulomas, and the susceptibility of these patients to develop autoimmune diseases are independent of IDO activity but may still be dependent on Th17 and/or Treg. Indeed, as was recently shown, ROS production by macrophages is instrumental in the induction of Tregs that suppress the activation and proliferation of effector T cells. This was observed both with CGD monocyte-derived macrophages as well as with $p47^{phox}$-mutated rat macrophages in vitro and in vivo (Kraaij et al., 2010).

TREATMENT OPTIONS

The prognosis for patients with CGD has dramatically improved since the disorder was first described in the 1950s as fatal granulomatous disease. The grim prognosis in these earlier times was borne out in retrospective epidemiological studies. In one such review of 31 patients followed between 1964 and 1989, actuarial analysis showed 50 percent survival through the third decade of life (Finn et al., 1990). In another retrospective study of 48 patients followed between 1969 and 1985 in Paris, the survival rate was 50 percent at 10 years of age, with substantially fewer deaths thereafter (Mouy et al., 1989).

Several large series have been more recently published. Winkelstein et al. reported a retrospective study on 368 CGD patients in the United States (Winkelstein et al., 2000), followed by an Italian registry on 60 patients (Martire et al., 2008), the UK and Ireland CGD registry incorporating 94 patients (Jones et al., 2008), and a study representing larger Europe (not including Italy, Ireland, and the UK) on 429 patients early in 2009 (Van den Berg et al., 2009). In contrast to the mortality rate of 17.5 percent in the U.S. study, the survival curve of the Italian patients indicated a relatively linear death rate between the ages of 1 and 15 years and then a sudden fall in the third decade. The survival rate was 46 percent at 25 years, and this was maintained over the next 10 years. Compared to the earlier reports, CGD patients showed a better outcome, considering that one third of the deaths were due to complications after bone marrow transplantation (Martire et al., 2008). More than 75 percent of the patients received cotrimoxazole and itraconazole prophylaxis, but still half of the deaths were ascribed to *Aspergillus* spp. infections (Martire et al., 2008). In the UK and Ireland almost all CGD patients received antibiotic and antifungal prophylaxis. Despite prophylaxis, estimated survival was still only 55 percent at age 30 years. In the larger European study the median life expectancy was relatively high (37.8 years for X-linked patients, 49.6 years for autosomal recessive patients), even though only 71 percent of the patients received antibiotic maintenance therapy and 53 percent additional antifungal prophylaxis (van den Berg et al., 2009). Kuhns et al. (2010) found that the critical predictor of survival was residual superoxide production. Those with the highest residual superoxide production, regardless of genotype, had survival rates over 80 percent by age 40, while those with the lowest superoxide production had survival rates around 50 percent by about age 30. Interestingly, mortality rates did not diverge between those two extremes of

superoxide production until after age 20, suggesting that mortality may correlate with accumulated end-organ toxicities, such as portal hypertension (Feld et al., 2008; Hussain et al., 2007). Although CGD will always remain a clinical challenge, better figures on survival are to be expected for the future with the newer antifungal drugs now available (see below).

One important factor in the improving prognosis for CGD patients is the emergence of several centers in the world that have concentrated on the study and care of scores of patients with CGD (e.g., the National Institutes of Health [Bethesda, MD], Scripps Clinic/Stanford University [California], and the Academic [Pediatric] Clinics in Amsterdam, London, Munich, Paris, and Zürich). Many insights have been gained from the coordinated treatment of these large groups of patients, and this information has been widely disseminated through the literature and through personal communications.

The cornerstones of treatment of CGD are as follows: (1) prevention of infections through immunizations and avoidance of certain sources of pathogens; (2) use of prophylactic trimethoprim-sulfamethoxazole or dicloxacillin; (3) use of prophylactic antifungal medications such as itraconazole; (4) use of prophylactic recombinant human interferon-γ (rhIFN-γ); (5) early and aggressive use of parenteral antibiotics; and (6) surgical drainage or resection of recalcitrant infections. Of these six components, the most important are prophylactic antimicrobials and early intervention in infections before they have the potential to overwhelm the compromised immune system of the CGD patient.

There are multiple ways in which CGD patients can minimize their risk of infection. They should receive all routine immunizations (including live-virus vaccines) on schedule as well as influenza vaccine yearly. Lacerations and skin abrasions should be promptly washed with soap and water and rinsed with an antiseptic agent such as 2 percent hydrogen peroxide or a Betadine solution. The risk of developing perirectal abscesses can be lessened by careful attention to hygiene, avoidance of constipation, and frequent soaking in warm, soapy baths. The frequency of pulmonary infections can be reduced by refraining from smoking, not using bedside humidifiers, and avoiding sources of *Aspergillus* spores (e.g., hay, straw, mulch, decaying plant material, rotting wood/sawdust, and compost piles). Professional dental cleaning, flossing, and antibacterial mouthwashes can help prevent gingivitis and periodontitis.

Chronic prophylaxis with trimethoprim-sulfamethoxazole (5 mg/kg per day of trimethoprim given orally in one or two doses up to a maximum dose of 160 mg trimethoprim per day) decreases the number of bacterial infections in CGD patients—by more than half in series of 48 and 36 patients, respectively (Margolis et al., 1990; Mouy et al., 1990). In sulfa-allergic patients, dicloxacillin (25–50 mg/kg per day) or trimethoprim alone (100 mg daily) can be used, although there is less documentation of the efficacy of these antibiotics in the prophylactic setting. At one point, there was concern that the sustained use of prophylactic antibiotics could lead to an increased risk of fungal infections. Fortunately, the data do not bear out this concern (Margolis et al., 1990).

The effectiveness of antifungal prophylaxis is far less clear. Itraconazole, a newer orally active triazole antifungal antibiotic, has been reported to be an effective prophylactic agent in one study (Mouy et al., 1994) and had significant activity in a randomized prospective trial (Gallin et al., 2003). However, fungal infections still occurred in patients receiving antifungal prophylaxis even when documented itraconazole blood levels were within the therapeutic range, albeit at markedly reduced rates compared to those not on prophylaxis (Gallin et al., 2003; Jones et al., 2008; Martire et al., 2008). *Aspergillus* spp. stand at the top, warranting an even more aggressive approach to this infection in CGD patients. Most clinical data are from a time when diagnostic tools such as high-resolution CT scans and MRI were not available. Also, many successful antifungals currently in use, such as voriconazole or posaconazole, had at the time not yet been developed. Better diagnosis and treatment should lead to a reduction in *Aspergillus*-related mortality in the future. However, the long-term safety of these newer antifungal drugs has not been fully investigated in the CGD setting.

The efficacy of rIFN-γ as a prophylactic agent in CGD was evaluated in a phase III multicenter, double-blind, randomized, placebo-controlled study involving 128 patients. The results, published in 1991, showed a 70 percent reduction in the risk of developing a serious infection in the rIFN-γ–treated group compared to placebo (Gallin et al., 1991). This benefit is maintained in patients treated for longer periods of time, as reported in two phase IV studies (Bemiller et al., 1995; Weening et al., 1995) and a summary of all published trials with rIFN-γ (Marciano et al., 2004b). In the more recent European cohort studies—being both retrospective and partially prospective—rIFN-γ was used in the treatment of active infection without much evidence of efficacy (Jones et al., 2008). In one study long-term prophylaxis with rIFN-γ did not significantly change the rate of total infections per patient-year compared to controls receiving antimicrobial prophylaxis alone (Martire et al., 2008).

Side effects of rIFN-γ are generally minimal, even with prolonged therapy, and are mainly restricted to mild headaches and low-grade fevers within a few hours after administration. The recommended dose is 0.05 mg/m^2 given subcutaneously three times per week. (For infants weighing <0.5 m^2, the recommended dose is 0.0015 mg/kg given subcutaneously three times per week.) The significant clinical improvements in the phase III patients were not accompanied by improvements in superoxide production, a finding confirmed in subsequent studies (Davis et al., 1995; Mühlebach et al., 1992; Woodman et al., 1992). It now appears that rIFN-γ augments host defense in the vast majority of CGD patients, regardless of genetic subtype, by means other than reversing the respiratory burst defect. The effect of rIFN-γ on changing the enzymatic IDO levels, thereby generating L-kynurenine metabolites in dendritic cells and macrophages of (inbred) CGD knockout mice (Romani et al., 2008), does not seem to be operative in human CGD patients (De Ravin et al., 2010; Jürgens et al., 2010).

One of the most serious errors in the management of CGD patients is the failure to treat potentially serious infections promptly with appropriate parenteral antibiotics and to continue therapy long enough to eradicate them. Once bacterial and fungal infections become well established and gain

the upper hand in a CGD patient, even the best-chosen antibiotics may be relatively ineffective. Therefore, early intervention is of critical importance. It is usually necessary to begin antibiotic therapy empirically before culture results are available; in these cases, the antibiotics should be chosen to provide strong coverage for *S. aureus* and gram-negative bacteria, including *B. cepacia* complex (e.g., a combination of nafcillin and ceftazidime or a carbapenem; aminoglycosides are typically ineffective against *Burkholderia*). If the infection fails to respond within 24 to 48 hours, then more aggressive diagnostic procedures should be instituted to identify the responsible microorganism. Additional empirical changes in antibiotic coverage may be warranted, such as adding high-dose intravenous trimethoprim-sulfamethoxazole to cover ceftazidime-resistant *B. cepacia* and *Nocardia*.

If fungus is identified or strongly suspected, antifungal therapy should be started even before the diagnosis is confirmed. *Aspergillus* infections of the lungs and bones are the most common fungal infections and often require prolonged treatment. The choice of antifungal is still evolving and depends on the center, the availability of different agents, and patient tolerance. In general, the newer triazole antifungals are better tolerated and have better activity than amphotericin derivitives against most molds other than the *Mucorales*. The non-f*umigatus Aspergillus* infections as well as dematiaceous molds in CGD are typically amphotericin resistant. In addition, CGD patients infrequently develop infections due to *Mucorales* species that would require amphotericin (Vinh et al., 2009a). When a lipid formulation of amphotericin B is used, treatment should be continued longer than typically deemed necessary, and based on radiographic, clinical, and culture data and the return of the erythrocyte sedimentation rate to its "normal" baseline for the patient or of the C-reactive protein to normal. Most patients are assumed to require prophylactic treatment. New triazole antifungals for intravenous and oral use, itraconazole, voriconazole, and posaconazole, have already shown great benefit in patients with refractory fungal infections and are the preferred agents in some centers for the empiric treatment of all filamentous mold infections, including in CGD patients. The echinocandin antifungals (caspofungin, micafungin, anidulafungin) can be used for the treatment of refractory *Aspergillus* infections in patients unresponsive to or unable to receive azoles or lipid-formulated amphotericin B. Certain fungal infections may progress under appropriate therapy in CGD, especially with some of the newly characterized fungi that are morphologically similar to *A. fumigatus* but have distinct and aggressive behaviors in CGD patients (Verweij et al., 2008; Vinh et al., 2009b, 2009c). Early treatment with additional intravenous antifungals and surgical resection of infected tissues must be given (Jabado et al., 1998; Segal et al., 1998; Van't Hek et al., 1998; Walsh et al., 2002).

Surgery plays an important role in the management of CGD patients. As noted above, surgical drainage (and sometimes excision) of infected lymph nodes and abscesses involving the liver, skin, rectum, kidney, and brain is often necessary for healing, particularly for the visceral abscesses. In cases of highly aggressive fungal or bacterial infections that fail to respond to the medical and surgical approaches outlined above, granulocyte transfusions may be helpful.

Special caution must be exercised in CGD patients regarding transfusions, whether they be granulocytes, erythrocytes, or platelets. Some CGD patients have McLeod syndrome, as discussed earlier. Since the K^x protein is absent and other Kell antigens are only weakly expressed on the erythrocytes of these patients, they will become quickly sensitized to the Kell antigens that are ubiquitous in the population if they are not transfused with K^x-negative McLeod blood products. Unless the molecular genetic basis of a patient's CGD is known not to involve a deletion of the Xp21.1 region, erythrocyte antigen phenotyping should be done prior to a CGD patient's first blood product transfusion. For patients found to have McLeod syndrome, early consideration should be given to blood storage in case it is needed for surgery or transplantation later on.

Clinically significant or symptomatic complications of granuloma formation are best treated with corticosteroids, as these lesions respond quickly to relatively low doses of these agents (e.g., 0.5–1.0 mg/kg per day of prednisone) (Chin et al., 1987; Danziger et al., 1993). It is usually necessary to treat the granulomas for a few weeks before tapering the steroid dose to prevent a rapid relapse. Corticosteroid therapy (topical or by mouth) may also be required to control the symptoms of CGD inflammatory bowel disease. In general, however, corticosteroid therapy in CGD patients should be avoided whenever possible to minimize the inevitable immunosuppression caused by these agents.

The mechanism of immune pathology in CGD is still opaque. Unrestrained IL-17–producing γδ T-cell activity due to the absence of neutrophil- and macrophage-associated ROS formation and lack of Treg lymphocytes may represent mechanisms in which rhIFN-γ has a role in combination with L-kynurenine derivates. However, the failure to find the human equivalents of the mouse model makes this unlikely. In clinical practice, steroids rescue patients suffering from acute mulch pneumonitis, a syndrome induced by inhalation of large loads of fungal spores, as occurs when gardening or mulching. This syndrome presents with fever, dyspnea, hypoxia, and diffuse infiltrates in the lungs. It is best treated with immediate initiation of corticosteroids (1 mg/kg/d) and antifungals (Siddiqui et al., 2007).

Bone marrow transplantation can cure CGD (see Chapter 60) and has been successfully employed (Fischer et al., 1986; Ho et al., 1996; Kamani et al., 1988). However, the overall results have been mixed, as failure to engraft has been a major problem, at least in the earlier transplants. It appears that newer conditioning regimens employing higher doses of busulfan to achieve adequate myeloid suppression may have overcome this problem (Ho et al., 1996; Seger et al., 2002). A European study reports the outcome of 27 transplanted CGD patients in the period 1985 to 2000. Most of these were children, and most received a myeloablative busulfan-based regimen and had unmodified marrow allografts from HLA-identical sibling donors. After myeloablative conditioning, all patients (23) were fully engrafted with donor cells, whereas after myelosuppressive regimens only 2 of 4 patients were

engrafted (Seger et al., 2002). This latter result recalls a similar observation in the United States (Horwitz et al., 2001). In the European study, severe graft-versus-host disease, exacerbation of infection during aplasia, and an inflammatory flare were seen in the subgroup of nine patients with preexisting infection. Overall survival was 85 percent, with 96 percent cured of CGD. Survival was excellent in patients without infection at the moment of transplantation. Preexisting infections and inflammatory lesions cleared in all engrafted survivors.
